# The 2012 UKACC International Conference on Control (UKACC Control 2012)

Cardiff, UK, 3-5 September 2012

## GREETINGS FROM THE CONFERENCE CHAIRS

On behalf of the general conference committee, we cordially welcome you to attend the 2012 UKACC (United Kingdom Automatic Control Council) International Conference on Control (UKACC Control 2012). We hope you will enjoy your time in Cardiff in the UK and find them stimulating and fruitful.

UKACC Control 2012 is the ninth in this now well established series of prestigious biennial events. It will take place in Cardiff, UK during 3-5 September 2012 and is organised by the Advanced Control and Network Technology Research Unit in the University of Glamorgan. UKACC Control 2012 aims to provide a broad international forum for scientists, engineers, and educators working in the areas of control systems to discuss state-of-the-art science and technologies in the general area of control systems with particular emphasis being placed on applications.

The technologies in automatic control have been playing important roles in our modern civilization and expected to stay as main characters in the future. The conference intends to provide a platform for researchers, engineers, academicians as well as industrial professionals from all over the world to present their research results and development activities in automatic control. The conference will promote the development of automatic control, strengthen the international academic cooperation and communications, and provide an opportunity of exchanging research ideas.

With the tremendous work of the members of the International Program Committee, the final program has a unique set of technical sessions covering latest research and development results in automatic control. It contains a number of high level theoretical papers as well as many interesting application papers. A total of 254 papers were submitted to UKACC Control 2012 from different countries and regions. After being reviewed, 191 papers have been accepted in the final program. There are 3 plenary talks, 36 lecture sessions and 3 poster sessions. The papers were assigned with the purpose of forming coherent sessions.

We have invited an excellent set of plenary speakers. On the first day, after the official opening, there will be a plenary talk on "Control for Performance Optimization" presented by Professor Sebastian Engell in Technische Universität Dortmund, Germany. On the second day, we will have a plenary talk on "Control Systems Engineering: a Business-Driven Approach" jointly given by Professor Peter Fleming in the University of Sheffield, UK and Mr Stephen Hill in Rolls Royce, UK. The third day will start with the plenary talk on "Aircraft Tonal Active Noise Control Techniques and Their Re-use delivered by Mr Ian Stothers in Ultra Electronics Controls, UK.

In addition to the high quality of the academic contributions in the program, UKACC Control 2012 has received various supports from UK industry with sponsorship from commercial organizations and an involvement from the four professional organizations, namely, the Institution of Engineering and Technology (IET), the Institution of Mechanical Engineers (IMechE), the Institute of Measurement and Control (InstMC), and the Institute of Electrical and Electronics Engineers (IEEE). The strong industrial involvement is evident in the program for the three Mini-Symposia.

We would like to take this opportunity to thank the members of the organising committee and the international program committee for their fantastic work. Our sincere thanks also go to many volunteers and reviewers for their diligence and dedication in the preparation of this conference.

***Abstract*—A new formation control methodology modelled by a virtual tendon-driven system using the tensegrity structures is presented. The objective of the work is to regulate the formation of unmanned vehicles within the communications bandwidth and perform point-to-point manoeuvring tasks. The reaction control forces that are experienced by vehicles in the formation are determined by the admissible tendon forces in tensegrity. A control law is designed to stabilize the interspacing between the vehicles in the presence of disturbances by making the combined use of string and spring characteristics. Simulation results demonstrate the effectiveness of the proposed approach in terms of maintaining the formation and avoiding inter-vehicle collisions. Formation shape changing is also performed by varying the relative parameters between the vehicles.**

## I. Introduction

Formation control is a matter of controlling the relative position and orientation of an ensemble of autonomous vehicles while allowing the group to move as a whole in a stable configuration. It is proven that moving a group of vehicles is more beneficial than a single vehicle in the presence of uncertain and adverse environments. This is because vehicles in formation are able to acquire enough and accurate information from the environment, whilst enhancing their power to withstand danger. Hence, the use of groups of multiple autonomous vehicles to perform co-ordinated and co-operative tasks has been attracting a growing amount of attention recently in the area of autonomous robotics and control communities.

It is also well known that formation systems have many advantages such as wide area sensing coverage and system energy conservation due to the reduction of friction in each vehicle. Robustness and efficiency of the system also increases while offering redundancy, reconfiguration ability and structural flexibility for the system. These advantages have led formation control perform a wide variety of functions in land, marine and aerial applications. Specific applications include exploration, search and rescue, microsatellite clusters and transportation of large and heavy objects [1].

Problems to set up in co-operative formation control often involve achieving formation, maintaining formation and dynamic switching between different formation shapes whilst carrying out a task. A number of methodologies have been developed to address the shape dynamics of a group of vehicles in a plane such as implicit polynomial (IP) [2], elliptic Fourier descriptors (EFD) [2], sliding mode controllers [3], extended Kalman filter with an input-state feedback control law [4], Lyapunov function [5], to name a few.

In this paper, formation dynamics of a group of vehicles is synthesised and analysed using a virtual tendon-driven tensegrity system. Tensegrity structures are spatial structural systems with interconnected strings and bars/struts [6], where strings are the tendon members and bars/struts are the compressive members. In literature, tensegrity structures have been mainly used to design mechanical structures and little attention has been paid to their usability to develop formation control algorithms for dynamic systems. In [7], for instance, the authors have demonstrated formation for a group of vehicles using an energy-momentum method in tensegrity models. However, they assumed zero external (disturbance) forces which simplified the problem.

The new control law here is formulated to drive a dynamic group of vehicles into a specified formation with control forces that are represented by admissible tendon forces in tensegrity structures. This control law is designed to prevent strings slacking and yielding and make the structure responsive to the environment disturbance forces. In control terms, this force precludes any two vehicles coming too close to each other (string slacking) in order to avoid collision. The controller also prevents the vehicles moving too far apart from each other (string yielding) in order to keep the vehicles within the communications range. The proposed overall formation system is characterised by three main considerations: vehicles formation geometry which is modelled using the concept of tensegrity, communications topology which is represented by strings and bars of the tensegrity structure, and the interaction control algorithm.

In the remainder of this paper, Section II outlines the benefits of tensegrity properties. Formation shape and its communication topology will be described in Section III whilst tendon controller design and formation system regulation will be explained in Section IV and V respectively. Simulation results are shown in Section VI to demonstrate formation achieving, formation maintaining, formation changing and manoeuvring tasks. Concluding remarks are made in Section VII.

## II. Tensegrity Structures

The artist Kenneth Snelson built the first tensegrity structure [8] and the term tensegrity was coined by Fuller as a

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

contraction of tensional integrity [9]. In nature, bones and tendons of animals and humans are connected in a way that allows for smooth control movements, where the bones provide compressive load-carrying capacity while tendons provide tensions stabilizing the configuration [6]. In structural engineering, controlled tensegrity make buildings responsive to natural environmental disturbances such as earthquakes and winds [6].

In the tensegrity framework, the stability and rigidity of tensegrity structures have been proven using the model of energy function [10]. This has motivated the development of mathematical machinery in the design and analysis of static and dynamic tensegrity systems to achieve shape formation control and other engineering functions. It is possible to form a tensegrity structure by using models of springs, strings and bars which can be combined to provide greater flexibility and control of the whole unit. The extreme shape-changing ability of tensegrity structures has been proven in the approach of a robotic tensegrity worm crawls (which requires stiffness control) while squeezing through crevices requiring large shape changes [11].

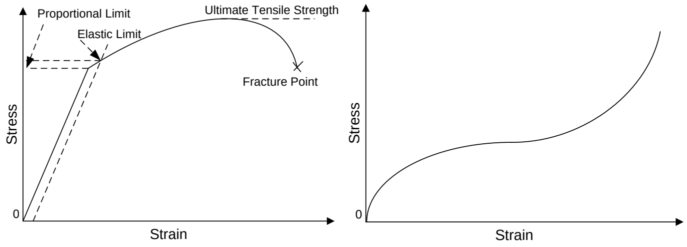
In a dynamic tensegrity-based formation control, one way of controlling the position of each vehicle in the group is by varying the length of the bars. However, for simplicity, the formation controller is designed here based on the relative distance and orientation between the leader and follower vehicles. For example, if the requirement is to expand the formation, the bar lengths could be increased. The same result can also be achieved by varying the interspacing between a designated pair of vehicles by controlling the admissible tendon forces in a tensegrity structure. This tendon controller is designed by assuming a spring with elastic characteristic (non-Hookean) which experiences the properties of both spring and string.

### A. Elastic Spring as Tendon

A linear spring can store energy either by applied compressive force or tensile force on it, however, a string (elastic band) can only store energy in the presence of a tensile force. In a tensegrity system, the tendon/string is always kept in tension, therefore it behaves in a similar manner to the spring. Hooke's Law states that the force that is exerted on a spring is proportional to the extension of the spring. Note that the stress and strain are (uniquely) related to force and extension of the spring, hence, the gradient of a stress - strain graph as shown in Figure 1a is identical to the force versus extension graph. However, a string with elastic characteristics, has a non-linear gradient graph as shown in Figure 1b. This property of the elastic spring is exploited in this paper and is further elaborated in Section IV on formation controller modelling.

## III. Problem Formulation

An example of a 4-vehicle formation connected using the concept of tensegrity is shown in Figure 2. Here, nodes are defined as vehicles and edges are represented by strings/elastic springs(s) and bars(b). The edges correspond to communication topology and control force directions between the vehicles. A chain communication topology is assumed where each vehicle moves according to its neighbour/leader in the formation which may not be its nearest. As shown in Figure 2, $UV_1$ is the leader of $UV_2$ while $UV_2$ act as the leader for $UV_3$ and so on. $\mathbf{f}_{LF}$ represents the force that is exerted on follower ($F$) according to its leader ($L$). The magnitude of this control force is dependant on stress, $\omega$, which is a tensegrity parameter. The edge is a string if $\omega > 0$, and is a bar if $\omega < 0$ [10]. In addition, a centralised control architecture is considered where a virtual leader ($UV_1$) is assigned for leading the whole formation and combined with the chain topology. Hence, the force, $\mathbf{f}_{41}$ and its corresponding communications link in Figure 2 can be ignored.



(a) Spring

(b) Elastomer

Figure 1: The gradient of stress strain curves

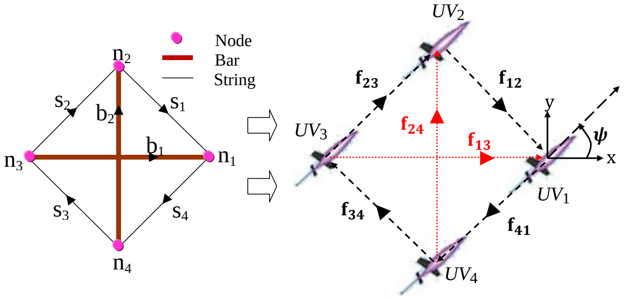


Figure 2: Vehicles communication topology referred to a C2T4 tensegrity system

It has been proven that shape changing task will be simpler to achieve by relaxing the equilibrium of the structure rather than pressing against a fixed equilibrium [6]. The tensegrity control parameter, $\omega$ will affect the edge's tension and cause another new equilibrium interspacing between the nodes. In formation control, the equilibrium interspacing between the vehicles is dependant on $\omega$ and can be represented by a virtual tendon-driven system (spring-mass system) as shown in Figure 3.

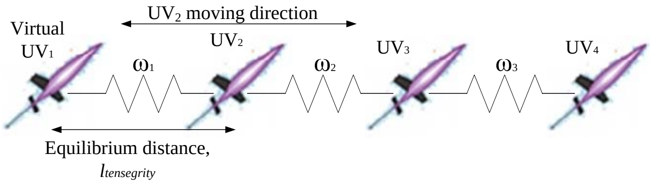

Figure 3: Formation in a virtual tendon system

The force and position of each vehicle in the tendon-driven system can be mathematically defined as

$$m\ddot{\mathbf{q}}+b\dot{\mathbf{q}}+\omega\mathbf{q}+\mathbf{f}(t)=0 \tag{1}$$

where $m$ is the mass of the vehicle, $b$ is the friction coefficient and $\mathbf{q}$ is the position vector of the vehicle defining its local coordinates. $\omega$ is the sum of the two stresses $(\omega_1+\omega_2)$ for vehicle $UV_2$; $(\omega_2+\omega_3)$ for vehicle $UV_3$ and $(\omega_3)$ for vehicle $UV_4$. $\mathbf{f}(t)$ represents the applied force to the tendon system to maintain the interspacing between the vehicles. In order to compensate for uncertain environments, the plant is rewritten as

$$m\ddot{\mathbf{q}}+b\dot{\mathbf{q}}+\omega\mathbf{q}+\mathbf{f}(t)+\mathbf{d}_f=0 \tag{2}$$

where $\mathbf{d}_f$ is an external disturbance force (e.g. wind for aircraft or current for ship). Note that the benefit of this parallel connected formation is that it is easy to keep track of every vehicle in the group. However, a major disadvantage is the error propagation from one pair of vehicles to the other.

## IV. Tendon Controller Modelling

In the formation control framework, there will be $r=n-1$ communication links in a formation containing $n$ vehicles. A separate controller is designed to control each pair of vehicles that are connected by a direct communication link. The signal measured by the controller is the relative distance between leader and follower vehicles and is denoted as $l_{LF}$. The controller output, $\mathbf{f}_{LF}$ is the force function which is modelled by an elastic spring. This tendon force, $\mathbf{f}_{LF}$ that is exerted on the follower vehicle with respect to its leader was designed to have a much larger elastic limit compared to its proportionality limit and is defined mathematically in Equation 3. This equation is essentially a combination of stress-strain relationship of spring and string as illustrated in Figure 1.

$$\mathbf{f}_{LF}=\begin{cases} K\ln\frac{l_{LF}}{l_{tensegrity}}(\mathbf{q}_F-\mathbf{q}_L) & \text{if } 0<l_{LF}\le l_{ultimate} \\ K\exp(-\frac{l_{LF}-l_{tensegrity}}{l_{break}})(\mathbf{q}_F-\mathbf{q}_L) & \text{if } l_{ultimate}<l_{LF}\le l_{break} \\ 0 & \text{if } l_{LF}>l_{break} \end{cases} \tag{3}$$

$$K=K_1\alpha_{LF}\omega_{LF} \tag{4}$$

Where $K_1$ is a gain parameter that is proportional to the disturbance force, $\mathbf{d}_f$ and helps to adapt the controller to external disturbances.

$$K_1\propto\mathbf{d}_f \tag{5}$$

$\omega_{LF}$ represents the stress and $\alpha_{LF}$ is a signed scalar parameter that determines the attracting ($\alpha_{LF}>0$) or repelling ($\alpha_{LF}<0$) force that is exerted on the follower vehicle. This is further elaborated in Section IV A.

The parameter, $l_{tensegrity}$ is the desired distance between a given pair of vehicles. $l_{ultimate}$ is the maximum distance between the controlled pair of vehicles, where ultimate tensile strength (attracting or positive force) that is applied to the follower vehicle increases. After this point, this attracting force starts to reduce. This is done in order to reduce the rebound force that will occur on the follower if the disturbance is suddenly removed.

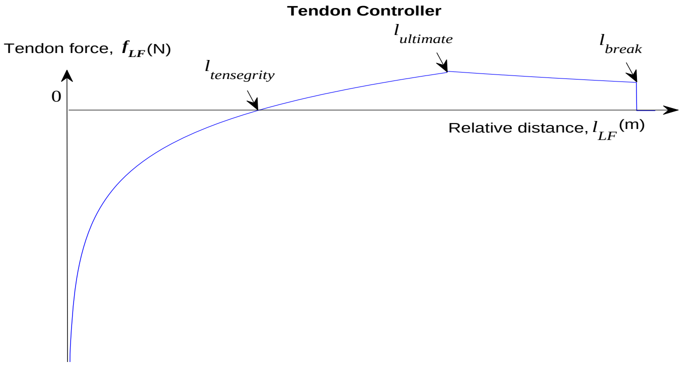

Figure 4: Design of control force with response to displacement

$l_{break}$ is the maximum length of the string; the string is fractured at this point if the disturbance force continues to be added to the string. In formation control terms, $l_{break}$ is the maximum communication length between the vehicles. The control force, $\mathbf{f}_{LF}$, is equal to zero at this point to give up a straying vehicle rather than trying to apply more force on it to pull it back to the formation. This vehicle might collide with the other vehicles in the formation when the disturbance force is suddenly removed due to the large restoring force.

Figure 5 is drawn to show the block diagram representation of the overall tensegrity-based nonlinear tendon-driven control for a pair of vehicles. To ensure zero steady-state tracking error, an integral term is added to the closed loop system.

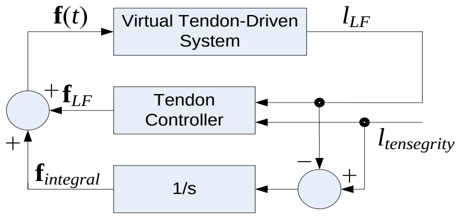

Figure 5: Block diagram of tendon-driven system with integral action

### A. Analysis of Tendon Force

Tension along the spacing edge between any two vehicles is changed according to the edge's extension and can be divided into two categories: attracting force (positive force) and repelling force (negative force). By considering the two vehicles within the $l_{ultimate}$ communication range, the tendon force can be mathematically defined as in Equation 6 with the parameter $K_1$ set to unity for simplicity.

$$\mathbf{f}_{LF}=\alpha_{LF}\omega_{LF}[\ln l_{LF}-\ln l_{tensegrity}](\mathbf{q}_F-\mathbf{q}_L) \tag{6}$$

The equilibrium of the tendon-driven system can be found by equating the sum of all the forces that are acting on vehicles in the system to zero i.e.

$$\sum_{r=1}^{n-1}\alpha_{L_rF_r}\omega_{L_rF_r}[\ln l_{L_rF_r}-\ln l_{tensegrity_r}](\mathbf{q}_{F_r}-\mathbf{q}_{L_r})=0 \tag{7}$$

The subscript $r$ refers to a particular communication link that connected a pair of vehicles and $n$ is the total number of vehicles in the formation. Let the position vector $\mathbf{q}^e = (x^e, y^e)$ represents the equilibrium tensegrity structure. Hence, the equilibrium stress constant of a pair of vehicles can be defined as

$$\widetilde{\omega}_{LF}(x^e, y^e) = \alpha_{LF}\,\omega_{LF}[\ln l_{LF} - \ln l_{tensegrity}] \tag{8}$$

The edge here is modelled as a string, hence, $\omega_{LF} > 0$. Also, by assuming the tendon-driven system in equilibrium, $\widetilde{\omega}_{LF}(x^e, y^e) = \omega_{LF}$, therefore equation 8 can be simplified as

$$1 = \alpha_{LF}[\ln l_{LF} - \ln l_{tensegrity}] \tag{9}$$

Equation 9 proves that the tendon-driven system experiences an attracting force ($\alpha_{LF} > 0$) when the relative distance ($l_{LF}$) between the vehicles is larger than its equilibrium distance ($l_{tensegrity}$); and repelling force ($\alpha_{LF} < 0$) when the relative distance ($l_{LF}$) between the vehicles is smaller than its equilibrium distance ($l_{tensegrity}$).

## V. Regulation of Formation Subsystem

The objective in this section is to regulate the interspacing distance between a pair of leader and follower vehicles. The equilibrium distance, $l_{tensegrity}$ and the maximum communication range, $l_{break}$ are the key control parameters which are assumed to be 16m and 32m, respectively for simulations purposes. The two vehicles formation was simulated in a tendon-driven system using the proposed tendon controller and compared with a linear PI controller. All the parameters in tendon-driven system shown in Equation 2 are considered to be unity. And the parameters of PI controller were optimized using the Ziegler-Nichols (ZN) tuning method in order to give a fast and smooth response. The values estimated for $K_P$ and $K_I$ were 0.4091 and 0.1002, respectively.

Figure 6 shows that the tendon control system with a desired step response of 16m was achieved in a settling time of 50.04s with an overshoot of 1.35%, while the linear controller has a slower settling time of 60.77s and experienced a higher overshoot of 3.56%. The dip at the beginning of step response is due to the higher repelling force that was produced by the linear controller as shown in Figure 7. This repelling force was encountered because the initial spacing between the vehicles was kept very small. However, the tendon controller was able to eliminate this effect and provided a smooth and quick response to the system with a lower repelling force.

Next external disturbance forces, $\mathbf{d}_f$ of magnitude 30N and 110N were added to the subsystem to demonstrate controller performance. These impulse disturbances were triggered at 150s for a period of 150s to force change $l_{LF}$. Both positive and negative disturbances are considered demonstrating the dilation and squeezing of inter-vehicle spacing respectively.

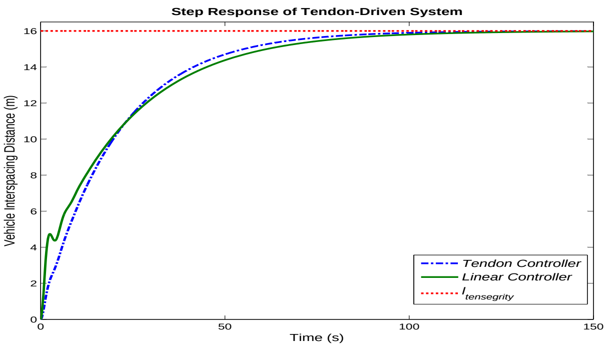

Figure 6: Closed-loop unit step response for formation subsystem

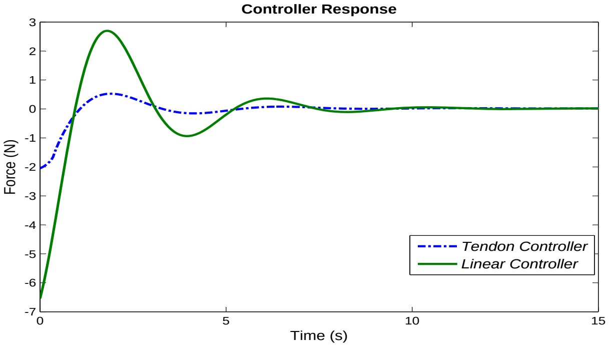

Figure 7: Subsystem controller response

Simulation results in Figure 8 depicts that an increasing positive disturbance force caused the follower and leader vehicles to further repel from each other. It can be observed that as long as the follower vehicle moves within the prescribed communications range, the formation can be maintained (Figure 8(a)). The follower vehicle will lose communication with its leader when the separation between the vehicles is more than $l_{break}$, 32m. This will cause the removal of control force in order to give up the straying follower (Figure 8(b)). However, the PI controller produced a large attracting control force to the follower vehicle when it moved out of the communication to pull it back to its equilibrium position. This had caused a collision between the two vehicles when the disturbance force is suddenly removed. This collision happened due to the rebound force being larger than the vehicle's repelling force.

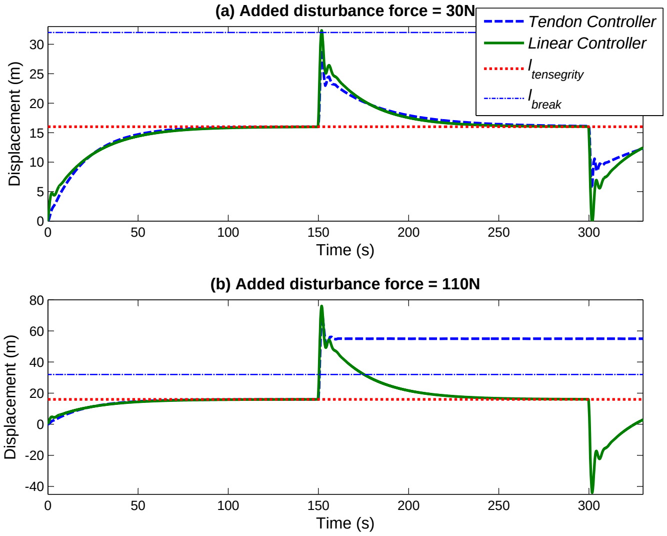

Figure 8: Step responses under positive disturbance force

Table I provides a quantitative comparison between step responses under the positive and negative disturbance forces. In contrast to the positive disturbance force, an increasing negative disturbance force caused the distance between the two vehicles become smaller. Note that the relative distance in tendon control system is never equal to or less than zero due to the force that is exerted on the follower vehicle tends to be infinitely large (see Equation 3). This helps to prevent the collision between the vehicles. However, the linear controller was unable to prevent the collision, shown by negative bold displacement in Table I.

TABLE I: Tendon and linear controller comparison

| Disturbance force $\mathbf{d}_f$, (N) | maximum and minimum vehicles interspacing (m) | | | |
|---|---|---|---|---|
| | $\mathbf{d}_f$ added at 150s | | $\mathbf{d}_f$ removed at 300s | |
| | Tendon controller | Linear controller | Tendon controller | Linear controller |
| 30 | 29.06 | 32.36 | 5.57 | 0.07 |
| 100 | **55.04** | 76.05 | **55.03** | **-43.91** |
| -30 | 5.37 | 0.08 | 28.95 | 32.36 |
| -100 | 1.04 | **-44.07** | **32.08** | 75.97 |

∗ The vehicles undesired spacings are highlighted in bold. Negative values show the vehicles's collision and the communication lost is represented by bold positive value.

## VI. Formation Maintenance and Manoeuvring

In this section, the overall formation system is described as a combination of tendon-driven systems outlined previously. The formation manoeuvring will be described and demonstrated through simulations.

### A. Formation control and dynamic shape changes

In order to adapt to the changes in the environment such as obstacles, the formation control method should be flexible so that shape changes can be conveniently carried out. Here, formation control is achieved by maintaining the distances between nominated pairs of vehicles using the concept of tendon-driven system. Note that each vehicle in the formation is assumed to be autonomous and that it makes decisions based on the relative distance and bearing among individuals. For example, $UV_2$ makes its decision to move according to the distance ($d_1$) and relative orientation ($\theta_{ro1}$) with respect to its leader, $UV_1$ as shown in Figure 9. The topology of closed-loop formation system composed of $r$ communication links is depicted in Figure 10.

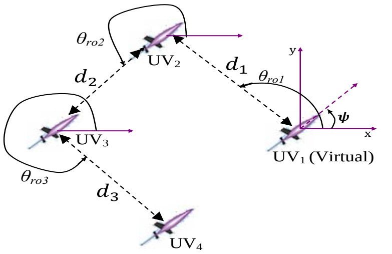

Figure 9: Relative parameters in formation

The synchronisation of two vehicles requires the consideration of the following equations:

$$\begin{aligned} x_{n+1} &= d_n \cos(\theta_{ron} + \psi) + x_n \\ y_{n+1} &= d_n \sin(\theta_{ron} + \psi) + y_n \end{aligned} \quad (10)$$

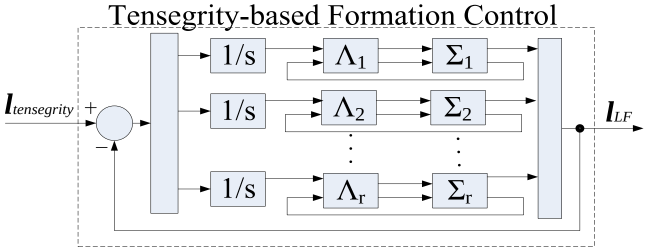

Figure 10: Block diagram of tensegrity-based formation closed-loop system. Tendon-driven systems and tendon controllers are denoted by Σ and Λ, respectively.

where ($x_{n+1}$, $y_{n+1}$) is the updated relative position of $UV_{n+1}$ and ($x_n$, $y_n$) is the current position of its leader, $UV_n$ in the global reference frame of coordinates. For formation shape change, vehicle's relative orientation ($\theta_{ron}$) and the equilibrium spacing ($d_n$=$l_{tensegrity}$) along the edges are set as reference parameters. By controlling these variables, the shape changing task can be achieved.

### B. Autopilot design

In order to design the controller, it is assumed that all the vehicles in the formation have the same dynamics which can be represented by a linear first order Nomoto model given by Equation 11.

$$T\ddot{\psi} + \dot{\psi} = K_n \delta \quad (11)$$

whose transfer function is:

$$\frac{\psi}{\delta}(s) = \frac{K_n}{s(1+Ts)} \quad (12)$$

Where $K_n$ is the gain and $T$ is the system time constant that can be uniquely determined from the input rudder angle ($\delta$) and the output heading angle ($\psi$). From [12], the values of $K_n$ and $T$ are chosen to be 0.049 and 17.78 for simulation purposes.

An autopilot must have the function of maintaining the trajectory of the vehicle by following the desired heading ($\psi$(t)). It must also have the function of performing the change of heading without excessive oscillations and in the minimum possible time. In order to accomplish this, a suitable PD heading controller was developed which was tuned heuristically using trial and error.

The completed formation control setup is shown in Figure 11, where **q** is the position vector of the unmanned vehicle. The task was to move the leader with heading angle, $\psi$ and velocity, $v$ from one way-point to the next.

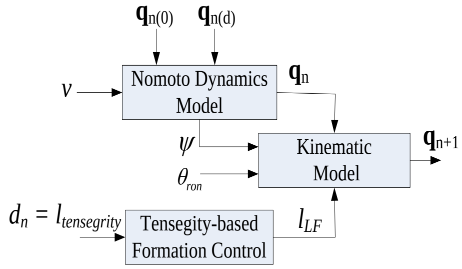

Figure 11: Block diagram of the formation control model

### C. Simulation results

The tensegrity-based formation control design method was simulated using a group of four UVs in a diamond shape formation, as in Figure 9, where $UV_1$ is the virtual vehicle. The objectives were to regulate the inter-UV distances within the prescribed communications range and to perform the formation changing and manoeuvring tasks. Commanded and actual trajectories of the formation along the $x-$ and $y-$axis are shown in Figure 12. The formation was required to move from initial way-point (WP0) to the final waypoint (WP4), through WP1, WP2 and WP3 by following the line of sight (LOS) between successive waypoints. Note that there is no crossover or collisions between any of the vehicle's paths. However, a longer route was taken during turning manoeuvres due to constant velocity assumption in order to maintain the shape of the formation.

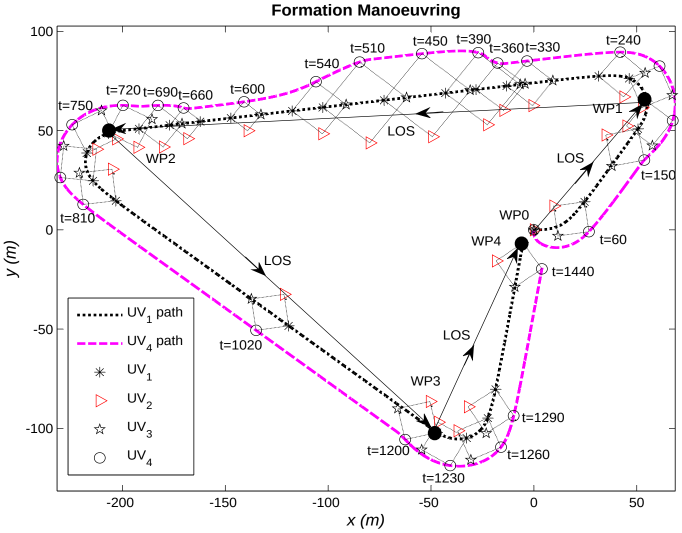

Figure 12: Simulations of formation changing and manoeuvring

The formation's size was changed twice at 350s and 500s for a period of 150s. In order to avoid any sudden changes to the formation and have to avoid inter-vehicle collisions, the reference input ($l_{tensegrity}$) in Figure 10 is taken to be a ramp signal with 0.5 slope. From the controller responses shown in Figure 13, it can be seen that the vehicles experience negative/repelling force when the shape dilation (parameter of $d_n$ or $l_{tensegrity}$ was changed from 16m to 30m) is performed. The subsequent positive force is expected as in Figure 7. Note that a time frame of 30s is needed for this shape dilation task. A positive/attracting force was applied at time 500s to contract the quadrilaterals shape from edge length of 30m to 10m. A longer time (40s) is required for this task due to the nonlinear controller characteristics. The formation was returned to its original shape ($d_r = 16$m) at 650s with a negative force.

## VII. Conclusions

A nonlinear control law that is modelled by the tendon-driven system using the concept of tensegrity structures is presented. It has been demonstrated that this control method can regulate the shape of formation in the presence of disturbances. The proposed approach is also scalable to any number of autonomous vehicles in the formation and is only limited by the communication bandwidth. It is also shown that the shape of the formation is conserved during manoeuvring. The shape changing algorithm can also be modified to include obstacle avoidance. Further research is required to develop more advanced mathematical machinery that can be used to analyse the stability of shape formation based on the tensegrity structures. The management of vehicle failures will also be considered in the future research.

# Polymer Extrusion Process Monitoring Using Nonlinear Dynamic Model-based PCA

Xueqin Liu, Kang Li, Marion McAfee, Jing Deng

*Abstract*— **Polymer extrusion is one of the final forming stages in the production of many polymeric products in a variety of applications. It is also an intermediate processing step in injection moulded, blown film, thermo-formed, and blow moulded products. However, polymer extrusion is a complex process which is difficult to set up, monitor, and control. As a consequence, high levels of off- specification products and long down-times are the problems facing the plastics industry. This paper proposes a new method for fault detection of the polymer extrusion processes, where the nonlinear finite impulse response (NFIR) model and principal component analysis (PCA) are integrated to form a nonlinear dynamic model-based PCA monitoring scheme. Here the NFIR model is used to capture the nonlinearity and dynamics of the extrusion process. The residuals resulting from the difference between the model predicted outputs and process outputs are then analyzed by PCA to detect process faults. The experimental results confirm the efficacy of the proposed model-based PCA approach for fault detection of polymer extrusion processes.**

**Keywords**
Principal component analysis; nonlinear dynamic model; polymer extrusion process.

## I. Introduction

Extrusion has been used widely as a major method of processing polymer materials for a few decades. However, polymer extrusion is a complex process which is difficult to set up, monitor, and control. As a consequence, high levels of off- specification products and long down-times are the problems facing the plastics industry. Thus the close monitoring of the system performance to provide early detection of significant process changes or disturbances, is recognized by the industry to be of increasing strategic importance. Various fault detection methods have been developed based on the first principles, the identified causal models [1] or the multivariate statistical process control including principal component analysis (PCA) [2] and independent component analysis [3].

It was reported that PCA had been successfully applied to a continuous polymer film production line [4], [5]. However, the conventional PCA is a linear method, it may not be able to describe the nonlinear and dynamic characteristics of the extrusion processes properly as they are complex in nature and nonlinear relationship exists between the process variables. To cope with this problem, extended versions of PCA for describing system nonlinear or dynamic behavior have been developed. For nonlinear process monitoring, nonlinear extensions of PCA have been investigated which include principal curves [6], [7], multi-layer auto-associative neural networks (ANNs) [8], [9], and the kernel function approach [10], [11]. For dynamic process monitoring, linear dynamic PCA (DPCA) was first proposed by augmenting matrix with time-lagged variables [12]. More recently, subspace identification for a state space model was proposed [13] which mainly deals with the linear dynamic system. Again, an attempt has been made to apply the time-lagged data extension with Kernel PCA for handling nonlinearity and dynamics. However, this combination could be computationally expensive due to the augmented data matrix [14]. Recently, Rotem *et. al* [15] presented a model-based PCA approach, where the system nonlinear and dynamic behavior are described by first-principle models. Unfortunately, it is often difficult to obtain such models to describe the complex thermodynamic behavior in the polymer extrusion process. To overcome this problem, this paper proposes a new method for monitoring of the nonlinear dynamic polymer extrusion processes, where the nonlinear finite impulse response (NFIR) model based on the Fast Recursive Algorithm (FRA) and the PCA are integrated to form a nonlinear dynamic model-based PCA monitoring scheme. Different from the DPCA, which makes use of all the potential time-lagged variables, the FRA determines and selects the most important and relevant nonlinear dynamic terms from the potential ones to construct the NFIR model. Here the NFIR model, which is a nonlinear extension of FIR [16], is employed to capture the nonlinear and dynamic behavior of the extrusion process. The residuals resulting from the difference between the model predicted outputs and process outputs are analyzed by PCA to detect process faults. The effectiveness of the proposed model-based PCA approach was demonstrated by the monitoring results for data recorded from a polymer extrusion process.

The paper is organized as follows. The PCA and the dynamic PCA methods are briefly described in Section II. This is followed by the proposed nonlinear dynamic model-based PCA for process monitoring in Section III. The experimental polymer extrusion process and data generation are described in Section IV. Section V then presents the monitoring results of an application study to a polymer extrusion process. A concluding summary is given in Section VI.

## II. PCA And Dynamic PCA

This section provides the description of the PCA and the dynamic PCA for process monitoring.

Suppose a data matrix $\mathbf{X} \in \mathbb{R}^{N\times m}$ consists of $N$ samples and $m$ variables, the PCA decomposition allows the construction of two statistics for a sample vector $\mathbf{x} \in \mathbb{R}^m$, a Hotelling's $\mathrm{T}^2$ statistic and a Q statistic:

$$T^2 = \mathbf{x^T P}\Lambda^{-1}\mathbf{P}^T\mathbf{x} = \mathbf{t^T}\Lambda^{-1}\mathbf{t}, Q = \mathbf{x}^T\left[\mathbf{I}-\mathbf{PP}^T\right]\mathbf{x} \quad (1)$$

for which confidence limits can be calculated based on [2], $\Lambda$ is a diagonal matrix consisting of $r$ eigenvalue of covariance matrix of scaled $\mathbf{X}$. $\mathbf{t} = \mathbf{x^T P}$ is a score vector, and $\mathbf{P} \in \mathbb{R}^{m\times r}$ ($r \leq m$ is the number of retained PCs) is a loading matrix.

Dynamic PCA proposed by [12] arranges the process variables to form an autogressive (AR) structure:

$$\underline{\mathbf{X}} = [\mathbf{X}_0, \mathbf{X}_{-1}, \cdots \mathbf{X}_{-d}] \in \mathbb{R}^{(N-d)\times(d+1)m} \quad (2)$$

where $\underline{\mathbf{X}}$ is an augmented set of variables, representing an AR model structure of order $d$ and the subscript $0, 1, d$ refer to the backshifts. The PCA is then applied to $\underline{\mathbf{X}}$ and the corresponding $T^2$ and $Q$ statistics can be constructed. The above method could be computationally expensive due to the augmented variables. Moreover, the dynamic PCA model is obtained under the assumption that the recorded variables are linear, therefore, it may not be suitable to model the nonlinear dynamics efficiently. To tackle this problem, a new model-based PCA method is proposed to account for both the nonlinear and dynamic behaviors of the extrusion process. If the model is accurate, the residual between the measured values and the model predicted values will be relatively insensitive to the variations caused by the nonlinearity or dynamics of the normal operating conditions [15], [16]. Consequently, PCA is more sensitive to process variation caused by the process faults, such as the disturbance of the material variations. In the following section, a new model-based PCA monitoring scheme will be introduced in more detail.

## III. Nonlinear Dynamic Model-based PCA for Process Monitoring

The proposed model-based PCA involves a nonlinear dynamic modelling approach to identify a non-linear finite impulse response model to capture the underlying relationship between the process input and output variables. The residuals resulting from the difference between the model predicted outputs and process outputs are analyzed by PCA to detect process faults.

### *A. Nonlinear Dynamic Model Based On Fast Recursive Algorithm*

Assuming a general nonlinear dynamic MISO system can be formulated as

$$y(t) = f(u_1(t-1),\cdots,u_1(t-d_{u_1}),\cdots,u_p(t-1),\cdots,u_p(t-d_{u_p}) \quad (3)$$

where $y$ and $u_i$ ($i = 1,\cdots,p,\ p \leq m$) are the system output and input variables respectively. $p$ is the number of input variables. $d_{u_i}$ is the time delay for the process inputs $u_i$. By using a polynomial function, Eq. (3) can be approximated by a linear-in-the-parameter model:

$$\mathbf{y} = \sum_{i=1}^{M} \theta_i \phi_i(\mathbf{u}) + \mathbf{e} \quad (4)$$

where $\phi_i(.)$, $(i = 1,\cdots,M)$ are all candidate model terms, $\mathbf{u} = [\mathbf{u}_1,\cdots,\mathbf{u}_p]^T$, $u_i^T = [u_i(t-1),\cdots,u_i(t-d_{u_i})]$ is the model input vector, and $\mathbf{e}$ is the model residual.

If $N$ data samples $\{y,\mathbf{u}\}^N$ are used for model training, then Eq. (4) can be written in the form

$$\mathbf{y} = \Phi\Theta + \mathbf{e} \quad (5)$$

where $\Phi = [\phi_1,\ldots,\phi_M] \in \mathbb{R}^{(N-d)\times M}$ is the regression matrix, $\phi_i = [\phi_i(u(d-d_{u_i}+1)),\cdots,\phi_i(u(N-d_{u_i}))]^T$; $\mathbf{y} = [y(d+1),\ldots,y(N)]^T \in \mathbb{R}^{N-d}$, $d$ is the maximum delay among $d_{u_i}$. $\Theta = [\theta_1,\cdots,\theta_M] \in \mathbb{R}^M$, and $\mathbf{e} = [e(d+1),\cdots,e(N)]^T \in \mathbb{R}^{N-d}$.

In Eq.(5), $\Theta$ can be estimated using least-squares by minimizing the loss function

$$J(\Theta) = \mathbf{e}^T\mathbf{e} \quad (6)$$

The corresponding solution is given by $\widehat{\Theta} = (\Phi^T\Phi)^{-1}\Phi^T\mathbf{y}$.

Due to the noise and correlation between regressors, the matrix $(\Phi^T\Phi)^{-1}\Phi^T$ is always ill-conditioned, which may lead to inaccurate calculation of the model coefficients. Therefore, a subset selection technique such as the Fast Recursive Algrithm [17] is applied in order to determine the most important and relevant terms of all potential ones with respect to the available data [18].

**Fast Recursive Algorithm**

The FRA employs a residual matrix $\mathbf{R}_k$ defined as:

$$\mathbf{R}_k \triangleq I - \Phi_k(\Phi_k^T\Phi_k)^{-1}\Phi_k^T \qquad \mathbf{R}_0 \triangleq I \quad (7)$$

where $\Phi_k = [\phi_1,\cdots,\phi_k]$, and $k = 1,\cdots,M$. According to [17] and [19], $\mathbf{R}_k$ can be updated recursively:

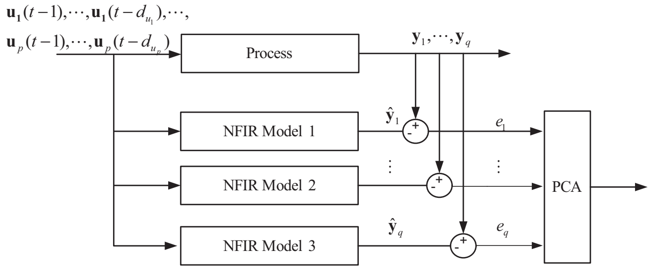
$$\mathbf{R}_{k+1} = \mathbf{R}_k - \frac{\mathbf{R}_k\phi_{k+1}\phi_{k+1}^T\mathbf{R}_k^T}{\phi_{k+1}^T\mathbf{R}_k\phi_{k+1}},\ k = 0,1,\cdots,M-1 \quad (8)$$

Now, the cost function in (6) can be rewritten as: $J(\Theta,\Phi_k) = tr(\mathbf{y}^T\mathbf{R}_k\mathbf{y})$.

In a forward stepwise stage, the nonlinear model terms are selected one at a time. Thus, suppose at the $k$th step, one more term $\phi_j$, $k+1 \leqslant j \leqslant M$ from the candidate term pool is to be selected. The net contribution of $\phi_j$ to the cost function can be calculated as

$$\Delta J_{k+1}(\Theta,\Phi_k,\phi_j) = \frac{\parallel (\mathbf{y}^{(k)})^T\phi_j^{(k)} \parallel^2}{\parallel \phi_j^{(k)} \parallel^2} \quad (9)$$

where $\phi_j^{(k)} \triangleq \mathbf{R}_k\phi_j$, $\mathbf{y}^{(k)} \triangleq \mathbf{R}_k\mathbf{y}$.



$\mathbf{u}_1(t-1),\cdots,\mathbf{u}_1(t-d_{u_1}),\cdots,$
$\mathbf{u}_p(t-1),\cdots,\mathbf{u}_p(t-d_{u_p})$

PCA

Fig. 1: Nonlinear dynamic model-based PCA

By defining an auxiliary matrix $\mathbf{A} \in \mathbb{R}^{k \times M}$ and $\mathbf{a}_u \in \mathbb{R}^{M \times q}$ with elements

$$a_{i,j} \triangleq \begin{cases} 0, & 1 \leq j < i \\ (\phi_i^{(i-1)})^T \phi_j^{(i-1)}, & i \leq j \leq M \end{cases} \tag{10}$$

$$\mathbf{a}_{i,u} \triangleq \begin{cases} (\phi_i^{(i-1)})^T \mathbf{y}^{(k)}, & 1 \leq i \leq k \\ (\phi_i^{(k)})^T \mathbf{y}^{(k)}, & k < i \leq M \end{cases} \tag{11}$$

the cost function can be updated recursively:

$$\Delta J_{k+1}(\Theta, \Phi_k, \phi_j) = \frac{\| \mathbf{a}_{j,u} \|^2}{a_{j,j}} \tag{12}$$

The model term that provides the largest contribution to (12) is then selected, and this procedure continues until some criterion (e.g., Akaike's information criterion [20]) is met or until a pre-set maximum number of model terms are selected. After a satisfactory model with $M$ terms has been constructed, the model coefficients are then computed recursively from

$$\hat{\theta}_j = \left( \mathbf{a}_{j,u}^T - \sum_{i=j+1}^{M} \hat{\theta}_i a_{j,i} \right) / a_{j,j}, \quad j = k, k-1, \cdots, 1. \tag{13}$$

### B. Nonlinear Dynamic Model-Based PCA Monitoring Scheme

Having discussed the nonlinear dynamic modelling approach based on the FRA, the model-based PCA monitoring scheme, as shown in Fig. 1, will be introduced in detail, where the nonlinear models are employed to predict process outputs. The residuals between the system outputs and predicted outputs are used to construct the PCA model. The following summarizes the construction procedure of the proposed model-based PCA and its application to the process monitoring:

1) Process dynamic data including the input and output variables are recorded for nonlinear dynamic modelling;
2) The nonlinear modelling approach based on the FRA is applied to obtain the NFIR models to describe the nonlinear dynamic relationship between the system input and output variables;
3) The residual resulting from the difference between the model outputs and process outputs is calculated as $\mathbf{e}_i = \mathbf{y}_i - \hat{\mathbf{y}}_i$ ($i = 1, \cdots, q$, $q$ is the number of output variables).
4) The residual matrix $\mathbf{E} = [\mathbf{e}_1, \cdots, \mathbf{e}_q]$ is constructed and scaled;
5) Compute the PCA model for the scaled residual matrix $\mathbf{E}$;
6) Construct the $T^2$ and the $Q$ statistics, and calculate the confidence limit as discussed in [21].
7) For a centered new data sample $\mathbf{z}$ during the on-line monitoring procedure, the scaled residual $\mathbf{e}_z$ between the actual process output and the model predicted ouput is calculated;
8) Calculate the constructed $T^2$ and $Q$ statistics by:

$$T^2 = \mathbf{e}_z^T \mathbf{P} \Lambda \mathbf{P}^T \mathbf{e}_z \qquad Q = \mathbf{e}_z^T \left[ \mathbf{I} - \mathbf{P}\mathbf{P}^T \right] \mathbf{e}_z, \tag{14}$$

9) Check whether $T^2$ or $Q$ exceeds the corresponding control limit; if so, the hypothesis that the soft sensor is violated is accepted, otherwise the soft sensor is reliable.

It is clear that the effectiveness of the proposed model-based PCA method relies on the sensitivity of the system model to the different types of process faults. For instance, if process fault only affects the process output, then it is important that the model-based PCA should be insensitive to the process outputs. Therefore, if the NARX (nonlinear autoregressive with exogenous input) structure is employed, which relies on the past values of the process outputs, then the generated residuals couldn't reflect the influence of the process fault on the the process output. Consequently its monitoring ability can be compromised. However, with the NFIR structure, which only makes use of the past values of the process inputs, the predicted outputs are not affected by the process faults. As a result, the model residuals are capable of reflecting the deviation of process outputs from those obtained without process faults. Based on the above discussion, the NFIR model is preferred over the NARX model to be incorporated by PCA.

## IV. Experimental Polymer Extrusion Process

There are two types of extrusion processes in the polymer industry: continuous and discontinuous. According to the number of screws used in the extruder, there are single-screw, twin-screw and multi-screw extruders. Of these single screw continuous extruders are the most commonly used in polymer industry. The conventional single screw extrusion process has a standard setup including a barrel which is heated by a number of electrical heaters, a rotating screw, and an extrusion die for the final product [22]. Typical temperature and pressure sensors are installed along the barrel and the die to provide continuous data for the process. For process operation, the polymer materials are fed into the barrel through the hopper by gravity, and then they are conveyed and melted along the flights of the screw and finally pushed out through the die to achieve a desired form.

Different types of faults may occur in a polymer extrusion process, such as (i) incoming material variations in terms of size, physical properties and compositions; (ii) process upsets; (iii) equipment faults; (iv) the operator errors.

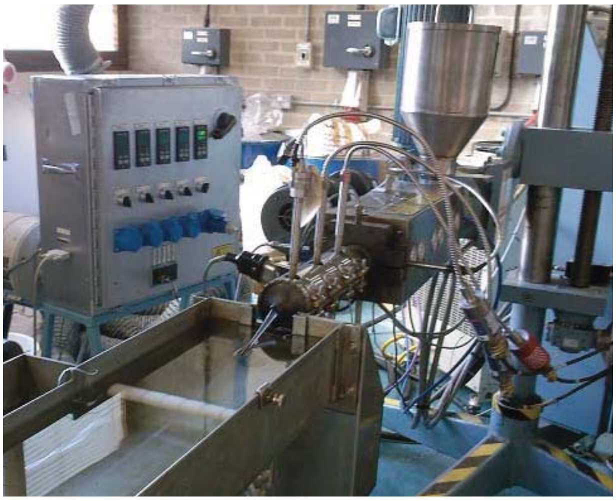

Fig. 2: The laboratory extruder with a in-line-rheometer die

TABLE I: Description Of The Recorded Process Variables

| Number | Description | Variable | Unit | Note |
|---|---|---|---|---|
| 1 | Screw speed | $N$ | rpm | Input |
| 2 | Barrel zone 1 temperature | $T_1$ | $^o$C | |
| 3 | Barrel zone 2 temperature | $T_2$ | $^o$C | |
| 4 | Barrel zone 3 temperature | $T_3$ | $^o$C | |
| 5 | Barrel pressure | $P_b$ | MPa | Output |
| 6 | Die pressure 2 | $P_2$ | MPa | |
| 7 | Viscosity | $\eta$ | Pas | |

Figure 2 depicts the experimental single screw extruder (Killion KTS-100) used in this paper. An in-line-rheometer die is especially instrumented in the experiment for the calculation of the melt viscosity. The analyzed variables are given in Table I. For obtaining some information-rich data sets of process inputs, the screw speed, $N$, and the temperature settings at the three heating zones, $T_1$, $T_2$, $T_3$, were excited using a Pseudo-Random Signal applied in a 'random walk' algorithm respectively. That is the signal excited by a Gaussian sequence and the period of input change was also defined by a Gaussian sequence where the mean and standard deviation were defined on the basis of measured pressure and viscosity response time to step changes in the inputs. Thus a wide operating range was covered in the sequences while consecutive input changes were within practical operating limits [23].

Two low-density polyethylene (LDPE) materials were used in this work, one is LD159AC (LDPE(A)) and the other is DOW352E (LDPE(B)). All signals were acquired at 1Hz using a 16-bit DAQ card through a SC-2345 connector box. At first, 6000 process data samples of LDPE(A) were collected under the above conditions and used as fault free reference samples. These samples were divided into two data sets where the first 2000 samples was used for model identification using the FRA, and the remained 4000 samples for test purpose. A third data set of 4000 samples was collected under the same conditions as above with a different material LDPE(B), which is used as a faulty data set. The generated screw speed, barrel pressure and the viscosity signals under normal conditions are illustrated in Fig. 3.

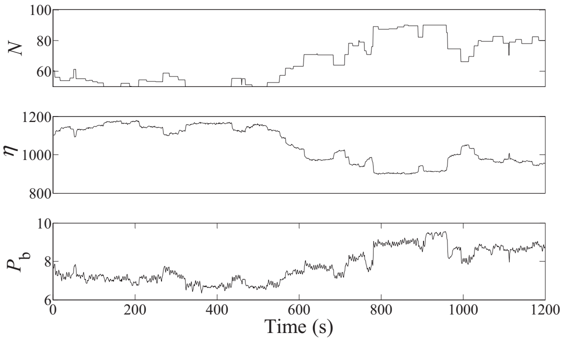

Fig. 3: Generated signals under normal conditions

## V. Application of Model-Based PCA to Polymer Extrusion Process

The description of the polymer extrusion line used in this application study was explained in Section IV. This section discusses the proposed monitoring approach involved in the NFIR model identification for process outputs using the FRA, followed by the PCA applied to the generated residuals.

To build the system model, the screw speed $N$, and the barrel set temperatures $T_1, T_2, T_3$, are employed as the process inputs to predict the three outputs, including the barrel pressure $P_b$, the die pressure $P_2$, and the viscosity $\eta$. As mentioned above, the different model structure employed by model-based PCA has distinct sensitivity to the process faults. To illustrate this point, both NARX and NFIR models are used to predict the process outputs. The three process outputs are generated using the FRA based on the LDPE(A) fault free data with a time series of system variables as below. The NFIR model is given as:

$$\begin{aligned} \mathbf{P}_b(t) &= -2.7 + 10^{-4}\mathbf{N}(t-1)\eta(t-1) \qquad (15)\\ \mathbf{P}_2(t) &= 2.2 + 10^{-4}\mathbf{N}(t-1)\eta(t-1)\\ \eta(t) &= 202.5 - 0.06\mathbf{T_3}(t-1) - 0.05\mathbf{N}(t-1)\mathbf{T}_3(t-5)\\ &\quad +0.03\mathbf{N}(t-1)\mathbf{T}_3(t-8) \end{aligned}$$

The NARX model has the form of

$$\begin{aligned} \mathbf{P}_b(t) &= -0.2 + 0.6\mathbf{P}_b(t-1) + 3\times10^{-5}\mathbf{N}(t-1)\eta(t-1) \quad (16)\\ \mathbf{P}_2(t) &= 0.3 + 0.4\mathbf{P}_b(t-1) + 3\times10^{-5}\mathbf{N}(t-1)\eta(t-1)\\ \eta(t) &= 364.8 + 10^{-4}\eta(t-1) - 0.01\eta(t-1)^2\\ &\quad +0.04\mathbf{N}(t-1)\mathbf{T}_3(t-24) \end{aligned}$$

The error residuals of the above NFIR model has zero mean and variance of 0.04, which can be approximated by a normal distribution. Its performance on the unseen validation data of LDPE(A) including the measured barrel pressure, the melt pressure in the die, and the viscosity is shown in Fig. 4. It shows that the predicted values of the unseen data based on the NFIR model match the measured values very well. For comparison, the NARX model performance on the same data is also illustrated in Fig 4.

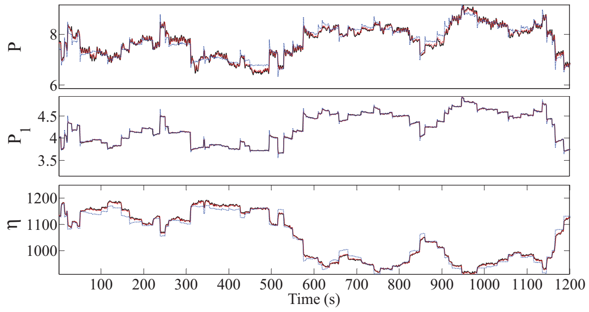

Fig. 4: Modeling result of the NFIR and the NARX on unseen LDPE(A) data under normal conditions. Solid black line: actual output; red dashed line: NARX model output; blue dashed line: NFIR model output.

## A. Process Monitoring

An attempt to monitor an extrusion process using PCA directly will lead to unavoidable difficulties because of the nonlinear and dynamic nature of the process [7], [24], [25]. In this subsection, the monitoring results of applying the proposed model-based PCA on the residual matrix is investigated. A PCA model was produced using the residual matrix **E**, which is composed of the errors between the model predicted outputs and the measured outputs. The proposed NFIR-PCA approach for process monitoring is further compared to both conventional linear DPCA and the NARX-PCA in this section.

The number of principal components, $r$, was determined according to its variance contribution. Thus, two principal components which could capture 79.1% of the variance of the of the total variance of the 3 error variables were chosen for the NFIR-PCA model. Compared to NARX-PCA, two linear principal components captured 86.2% of the total variance. By contrast, one principal component was required for the linear DPCA model and 96.4% of the total variance was explained. After establishing the PCA model, on-line monitoring of the extrusion process requires the $T^2$ statistic to monitor system variations in the PCA model space, and a second $Q$ statistic to monitor system variations in the PCA residual space. The 99% confidence limits for the $T^2$ and $Q$ statistics are determined respectively as discussed in [21].

For the recorded 2000 reference samples, Table II summarizes the Type I error, or false alarm rate, for the $T^2$ and the $Q$ statistics of the linear DPCA, the NARX-PCA and the NFIR-PCA methods for a confidence of 99%. These results imply that the Type I errors for the $T^2$ statistic of linear DPCA is far lower than expected, which is later shown to result in its insensitivity of detecting process fault. This can be attributed to that the principal component in linear DPCA is unable to describe the nonlinear behavior in the extrusion process and that the assumption of the monitored variables follow a Gaussian distribution no longer holds.

TABLE II: Number of Type I errors For Reference Data From Linear DPCA, NFIR-PCA And NARX-PCA With 99% Control Limits

| Method | #PC(s) | Variance Contribution | $T^2$ | $Q$ |
|---|---|---|---|---|
| Linear DPCA | 1 | 96.4% | 0 % | 2.2% |
| NARX-PCA | 2 | 86.2% | 1.9% | 0.9% |
| NFIR-PCA | 2 | 79.1% | 2.0% | 0.7% |

Monitoring results of the proposed method for the testing data set 1) the unseen LDPE(A) fault free data; 2) the unseen LDPE(B) faulty data are shown in Fig. 5. The straight lines represent the 99% control limits. Fig. 5c shows all the unseen LDPE(A) data (the first 4000 samples) is under the control limit, which implies the NFIR model is capable to capture the nonlinear and dynamic behavior. Moreover, for the second fault data set, both $T^2$ and $Q$ statistics of NFIR-PCA in Fig. 5c show the data samples are beyond the control limit (50 samples after the new material introduced) implying the NFIR model is no longer validated for different material. In contrast, the $T^2$ of linear DPCA and the $Q$ of the NARX-PCA are not sensitive to this disturbance. The application study therefore indicated that using linear principal components and incorrect distribution function to describe nonlinear dynamic behavior may render the monitoring statistics insensitive or increase the false alarms. It also demonstrated that the monitoring ability of the NARX-model structure, which relies on the past values of the process outputs, is compromised when the process outputs are affected by process faults.

# VI. Conclusions

This paper has studied the incorporation of NFIR model into the multivariate statistical process control framework, motivated by the fact that monitoring processes with linear dynamic model may lead to insensitive statistics or false alarms. The application of the NFIR model to remove the nonlinear and dynamic information from the monitored variables, together with the use of PCA to monitor the resulting residuals can thus help to circumvent the above problems. The benefit of applying the NFIR model instead of the NARX is that the NFIR model requires no feedback of the process output, and hence its model residual is able to reflect the process faults more closely.

A further contribution of this paper has been to apply the Fast Recursive Algorithm for model identification. In comparison with the traditional subset selection method, such as the orthogonal least square algorithm (OLS), the FRA is able to select the most important and relevant model terms more efficiently without compromising model accuracy [17], [19], [26]. Unlike DPCA, which makes use of all the potential time-lagged data variables, the FRA selects only the most important ones for the NFIR model. The effectiveness of the proposed model-based PCA approach

***Abstract*—In this paper, the optimal bandwidth allocation scheduling problem for two-layer networked learning control systems (NLCSs) is studied. In NLCS, multiple networked feedback control loops share a common communication channel and they compete to bid for available bandwidth. A non-cooperative game fairness model is first formulated, which takes into consideration of a number of factors, such as transmission data rate, control sampling strategy and scheduling pattern. Then, a novel two-layer hierarchical market competition algorithm (THMCA) is proposed. Two hierarchical population individuals are defined in the algorithm, namely the holding companies and the subsidiary companies which altogether form conglomerates. Market competitions among these conglomerates lead to the convergence to a monopoly at the end, resulting in an optimal solution of the above problem. The algorithm is shown to have a high convergence rate and the comparison simulation results on a NLCS with up to 100 subsystems have demonstrated the effectiveness of the proposed method.**

## I. Introduction

A networked control system (NCS) [1] is defined as a feedback control system where the control loops are closed via a communication network. Due to its various advantages such as low cost installation, ease of maintenance and great flexibility, NCSs have been widely applied in manufacturing, aircraft and power systems etc. Most researches have focused on the traditional single-layer NCSs in the last decade. However, there exist many complex plants that are composed of a great number of subsystems and the traditional single-layer NCS architecture may not be applicable. Recently, a two-layer Networked Learning Control System (NLCS) architecture has been proposed [2]. In this architecture, the bottom layer is for real-time control, and local controllers communicate with the sensors and actuators attached to the plant through shared networks. The upper layer is used for complex learning and scheduling tasks.

In a real-time NLCS, limited network bandwidth along end-to-end paths [3] inevitably cause network-induced delays [4] or packet dropout which further deteriorates the system performance even causes instability. Therefore, an optimized scheduling for bandwidth allocation among all network links plays a key role in improving the quality of network service (QoS) and the performance of control system (PoC). This can be achieved generally through the following two steps. Firstly, bandwidth scheduling is designed to allocate the available bandwidth to control units to meet communication demand. A non-cooperative game (NG) [5] theory based rational competition mechanism can be employed, which emphasizes individual rational defined by Nash equilibrium (NE) and can simultaneously satisfy individual and collective requirements. Secondly, the exact solution to the bandwidth scheduling problem can be obtained by a complete enumeration.

This is however prohibitive due to its excessive computational time for real-time applications. To tackle this problem, several intelligent optimization methods can be adopted, for example genetic algorithm (GA) [6], particle swarm optimization (PSO) [7], clone evolutionary algorithm [8], bacterial foraging (BF) [9] and shuffled frog leaping algorithm (SFLA) [10] etc. Evolutionary algorithms (EAs), such as GA and PSO, are stochastic based search methods. GA is one of the early proposed evolutionary algorithms which has found many successful applications. However, it is computationally expensive, and the convergence cannot be guaranteed. Bacterial foraging (BF) algorithm is a feature selection method based on a heuristic search strategy with fast computing speed. But a large storage capacity is required to complete the computation. Shuffled frog leaping algorithm (SFLA) is a meta-heuristic optimization method which is based on observing, imitating, and modeling of the behavior of a group of frogs searching for the location where maximum amount of food is available. The SFLA combines the benefits of both the genetic-based memetic algorithm and the social behavior-based PSO algorithm. However SFLA suffers from the curse of dimensionality problem.

In this paper, a new integer-coded two-layer hierarchical market competition algorithm (THMCA) is proposed to efficiently solve the bandwidth scheduling problem in the NLCS applications. The rest of the paper is organized as follows. Section 2 introduces NLCS and the non-cooperative game scheduling scheme. A new two-layer hierarchical market competition algorithm (THMCA) is proposed in Section 3. Section 4 presents the comparative simulation results. Finally, a brief conclusion is given in Section 5.

## II. Bandwidth non-cooperative game model for a networked learning control system

### A. System Architecture

The two-layer networked learning control system architecture [2] is shown in Fig.1, where Ci, Si and Ai represent the i-th controller, sensor and actuator respectively. Local controllers are connected to the sensors and actuators, attached to the complex plant via the bottom layer communication network, typically some fieldbus dedicated to real-time control. Local controllers also communicate with the computer system, which functions as a learning and scheduling agent through the upper layer communication network. This network can be local area network (LAN), wide area network (WAN), or possibly the internet. Control and learning signals at two levels share the available network bandwidth with other consumers. This general architecture can be adopted in many industrial applications with distributed plants and units, such as the power systems.

### B. Bandwidth non-cooperative game model

Suppose the set of subsystems is denoted as $L = \{\ell_i | 1 \leq i \leq n\}$, where $n$ is the total number of subsystems in a NLCS. The network can only provide limited available bandwidth. Each subsystem aims to improve its own bandwidth utilization instead of the overall network performance. Therefore, all the subsystems in a NLCS form a non-cooperative game (NG). The NG model is a triple, namely $G(L, S, u_i)$, where $S$ is the set of strategies including transmission data rate, allotted bandwidth and sampling period for each subsystem, that is, $S = \{s_i | s_i = (b_i, \delta_i, t_i), i \in L\}$, $b_i \in [\delta_i^{min}, U_d]$ is the pre-allocated data rate to the subsystem $l_i$, and $t_i$ is the sampling period. Data rate set available for all subsystems in NLCS is given as $D = \{\delta_i | 1 \leq i \leq n\}$, $\delta_i \in [\delta_i^{min}, \delta_i^{max}]$. The minimum data rate $\delta_i^{min}$ is to guarantee the most basic work. Maximum bandwidth of the network is $U_d$ and $\delta_i^{max} \leq U_d$. $u_i$ is the utility function of subsystem $l_i$ which maps $S$ to real numbers $u : S \to R$. If and only if $u_i(s_i^*) > u_i(s_i)$, the quality of $s_i^*$ is better than $s_i$ for subsystem $l_i$.

The available data rate $\delta_i$ satisfies the probability distribution $d_i(\delta_i)$ defined as follows [11].

$$d_i(\delta_i) = \begin{cases} 0 & \delta_i < \delta_i^{min} \\ (\Delta/\Delta_i)^c & \delta_i^{min} \leq \delta_i \leq \delta_i^{max} \\ 1 & \delta_i > \delta_i^{max} \end{cases} \tag{1}$$

where $\Delta = \delta_i - \delta_i^{min}$, $\Delta_i = \delta_i^{max} - \delta_i^{min}$ and $c \geq 1$ works as an empirical constant which can be adjusted for a specific subsystem.

Given the above definition, the mean value of occupied bandwidth for a subsystem is thus given as

$$Ed_i(\delta_i) = (c\delta_i^{max} + \delta_i^{min})/(c+1) \tag{2}$$

The utility function is defined as follows:

$$u_i(s_i) = \begin{cases} \frac{[\|e_i\|^2 - (\delta_i - Ed_i)^2 - \gamma_i t_i](\frac{b_i}{Ed_i} e)^\mu}{e^{\mu \frac{b_i}{Ed_i}} \|e_i\|^3} \\ if\ 0 \leq b_i < Ed_i \\ [1 - (\frac{b_i - Ed_i}{Ed_i - \delta_i^{max}})^\nu] \frac{\|e_i\|^2 - (\delta_i - Ed_i)^2 - \gamma_i t_i}{\|e_i\|^3} \\ if\ Ed_i \leq b_i \leq \delta_i^{max} \end{cases} \tag{3}$$

Here, the rights law is used, including compounding data rate $\delta_i$ and sample period $t_i$, and $\gamma_i$ is the weight coefficient for trade-off. $\|e_i\|$ is the maximum expectation deviation between optional data rate and the distribution of each subsystem, that is $\|e_i\| = \max(|\delta_i^{min} - Ed_i|, |\delta_i^{max} - Ed_i|)$. $\mu, \nu$ are the empirical constants for specific subsystems to adjust the change rate of utility functions.

## III. Two-layer hierarchical market competition algorithm (THMCA)

The two-layer hierarchical market competition algorithm (THMCA) is inspired by competitions among enterprises in economic activities. The THMCA begins with an initial population called perfect competition companies. Some of the best companies that have the best objective fitness function values are selected to be the holding companies. The rest become the subsidiary companies which are then divided among the holding companies based on their power. The power of a holding company is positively proportional to its fitness value. The holding companies and their subsidiary companies form different conglomerates. Then subsidiary companies move toward their relevant holding companies and the position of the holding companies will be updated if necessary. In the next step, the market competition among the conglomerates begins, and the weak conglomerates are eliminated. This is called monopolistic competition procedure. Then the oligopoly procedure begins. The market competition will gradually lead to an increase in the power of strong conglomerates (oligopolies) and a decrease in the power of weaker ones. Finally the weak conglomerates which could not to improve their performance will collapse. These competitions among the conglomerates will cause all the companies to converge to a state called monopoly where only one conglomerate exits in the market and all the other companies become subsidiary companies of this holding company.

To begin with, an initial population called perfect competition companies is created. In a $D$-dimensional problem, the position of the $i$-th company is defined as $Company_i = [x_{i,1}, x_{i,2}, \cdots, x_{i,D}]$, $i = 1, 2, \cdots, N_c$, where $N_c$ is total number of competition companies.

The fitness function of the $i$-th company is defined as:

$$fit_i(Company_i) = fit_i(x_{i,1}, x_{i,2}, \cdots, x_{i,D}) \tag{4}$$

Then, the cost function of the $i$-th company can be defined as:

$$f_i = \frac{1}{fit_i(x_{i,1}, x_{i,2}, \cdots, x_{i,D})} \tag{5}$$

$N^{holding}$ of the most powerful competition companies are selected as the holding companies, which form different conglomerates. The remaining $N^{sub}$ are the subsidiary companies of these holding companies. At the next step, the subsidiary companies must be divided among the holding companies based on their power. The initial number of subsidiary companies of a conglomerate is directly proportional to its power. Theoretically, the normalized cost of the $n$-th holding company can be defined as:

$$F_n^{holding} = \max_i\{f_i^{holding}\} - f_n^{holding} \tag{6}$$

where $f_n^{holding}$ is the cost of the $n$-th holding company.

The normalized power of each holding company is defined as:

$$P_n^{holding} = \|F_n^{holding} / \sum_{n=1}^{N^{holding}} F_n^{holding}\| \tag{7}$$

Then the initial number of subsidiary companies of a conglomerate becomes

$$N_n^{sub} = round\{P_n^{holding} \times N^{sub}, 0\} \tag{8}$$

where $N_n^{sub}$ is the initial number of subsidiary companies of the $n$-th conglomerate. For each holding company, $N_n^{sub}$ of the subsidiary companies are randomly selected and allocated. These subsidiary companies along with their holding company form the conglomerate.

Then the subsidiary companies start to move toward their relevant holding companies. The positions of the subsidiary companies of the $n$-th conglomerate are updated as follows:

$$SUB_{n,i} = sub_{n,i} + \frac{rand() \times \omega(holding_n - sub_{n,i})}{\cos\theta} \tag{9}$$

where $sub_{n,i}$ is the position of the $i$-th subsidiary company of the $n$-th holding company, $rand()$ is a random number between 0 and 1, $\omega$ is a weight factor, and $holding_n$ is the position of the $n$-th holding company. To search different points around the holding company, a random amount of deviation is added to the direction of movement. The movement of a subsidiary company toward its relevant holding company at its new direction $\theta$ is a random angle between $-\varepsilon$ and $\varepsilon$, where $\varepsilon > 0$ is the parameter that adjusts the deviation from the original direction.

However, a subsidiary company in a conglomerate may reach a position with higher fitness (or lower cost) than its holding company. In such case, the positions of the holding company will be replaced by the higher one. The rest will move toward the new position of the holding company.

The total power of a conglomerate depends on both the power of the holding company and the power of its subsidiary companies. But the holding company has larger weights. This total power is defined by the weighted cost of two hierarchical companies:

$$power_n^{cong} = \frac{1}{p_n^{cong}} = \frac{1}{f_n^{holding} + \tau\overline{f_{n,i}^{sub}}} \tag{10}$$

where $p_n^{cong}$ is the total cost of the $n$-th conglomerate and $0 < \tau < 1$. Cost $\overline{f_{n,i}^{sub}}$ is the geometry mean of $i$-th subsidiary company in $n$-th conglomerate. In fact, $\tau$ represents the role of the subsidiary companies in determining the total power of a conglomerate.

The market competition among conglomerates begins and all the conglomerates try to take possession of the subsidiary companies of other conglomerates. This competition is modeled by picking some of the weakest subsidiary companies of the weakest conglomerates and making a competition among all conglomerates to possess these subsidiary companies. Each of the conglomerates will have a likelihood of taking possession of these subsidiary companies based on its total power; therefore, powerful conglomerates have greater chance to possess subsidiary companies. The possession probability of each conglomerate must be found. The normalized total cost of each conglomerate is calculated as:

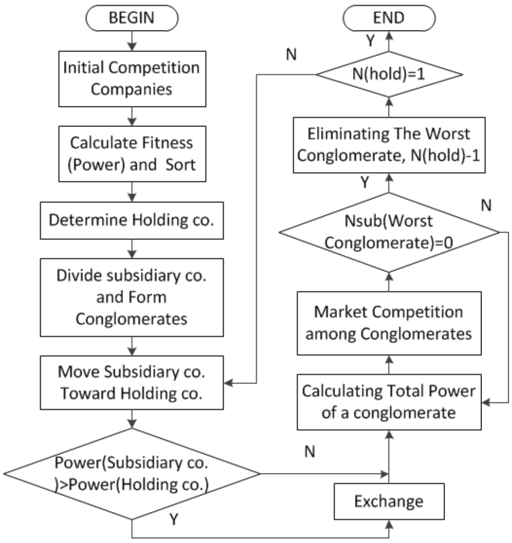
$$P_n^{cong} = \max_i\{p_i^{cong}\} - p_n^{cong} \tag{11}$$

where $P_n^{cong}$ is the normalized total cost of the $n$-th conglomerate.

The possession probability of each conglomerate is given by

$$pp_n^{cong} = \|P_n^{cong} / \sum_{n=1}^{N^{holding}} P_n^{cong}\| \tag{12}$$

where $pp_n^{cong}$ is the possession probability of the $n$-th conglomerate. A vector is formed to divide the relevant subsidiary companies among the conglomerates:



BEGIN
Initial Competition Companies
Calculate Fitness (Power) and Sort
Determine Holding co.
Divide subsidiary co. and Form Conglomerates
Move Subsidiary co. Toward Holding co.
Power(Subsidiary co. )>Power(Holding co.)

Y
END

Fig. 2. Flowchart of two-layer hierarchical market competition algorithm

$$\mathbf{PP}^{cong} = [pp_1^{cong}, pp_2^{cong}, \cdots, pp_{N^{holding}}^{cong}] \tag{13}$$

Then a random vector with the same size is generated:

$$\mathbf{RAND} = [rand_1, rand_2, \cdots, rand_{N^{holding}}] \tag{14}$$

where $rand_1, rand_2, \cdots, rand_{N^{holding}}$ are randomly generated numbers between 0 and 1.

Finally, vector $\mathbf{Dif}$ is formed by subtracting $\mathbf{RAND}$ from $\mathbf{PP}^{cong}$:

$$\begin{aligned} \mathbf{Dif} &= \mathbf{PP}^{cong} - \mathbf{RAND} \\ &= \begin{pmatrix} PP_1^{cong} - rand_1, \\ PP_2^{cong} - rand_2, \\ \cdots \\ PP_{N^{holding}}^{cong} - rand_{N^{holding}} \end{pmatrix}^{\mathrm{T}} \end{aligned} \tag{15}$$

The mentioned subsidiary companies will be given to an conglomerate which has the maximum relevant index in $\mathbf{Dif}$ vector.

The powerless conglomerates will collapse in the market competition. Different criteria can be defined for collapse mechanism. In this paper, a conglomerate is assumed to be collapsed when it loses all of its subsidiary companies.

After the market competitions, all the conglomerates will collapse except the most powerful one and all companies under their possession become subsidiary companies of this conglomerate. All the subsidiary companies also have the same positions and the same fitness. In such case, the algorithm stops. The flowchart of the procedure is illustrated in Fig.2.

In the integer coded THMCA, the company position consists of a sequence of integer numbers, representing the sequence of the bandwidth allocation cycle duration of each subsystem during the scheduling horizon. A positive integer represents an increased bandwidth allocation, while a negative integer represents the bandwidth decrease of the subsystem.

TABLE I
RANGE OF THE OUTPUT DATA RATES OF SUBSYSTEMS FOR TWO DISTRIBUTIONS

| Data Rate | DND | | SD | |
|---|---|---|---|---|
| Subsystems | $\delta_i^{min}$ | $\delta_i^{max}$ | $\delta_i^{min}$ | $\delta_i^{max}$ |
| $l_1$ | 20.58 | 75.51 | 32 | 51 |
| $l_2$ | 41.63 | 88.68 | 56 | 85 |
| $l_3$ | 53.45 | 97.20 | 19 | 31 |
| $l_4$ | 64.02 | 106.71 | 98 | 120 |
| $l_5$ | 76.84 | 111.69 | 28 | 42 |
| $l_6$ | 77.68 | 115.60 | 102 | 135 |
| $l_7$ | 65.97 | 108.10 | 49 | 76 |
| $l_8$ | 56.32 | 99.59 | 84 | 116 |
| $l_9$ | 46.24 | 90.73 | 156 | 196 |
| $l_{10}$ | 32.30 | 80.18 | 246 | 380 |

## IV. SIMULATION STUDIES

To verify the effectiveness of the proposed bandwidth scheduling method, numerical simulations were carried out using MATLAB on an Intel(R) Core(TM)-i5-3.10-GHZ desktop personal computer (PC) with Windows 7 Enterprise.

The proposed THMCA was tested on NLCSs with $Num$ = 10, 20, 50 and 100 subsystems. The required data for ten subsystems is given in table I, which shows the distributions of sending data rates for the first ten subsystems. Two different distributions, namely the Discrete Normal Distribution (DND) and Stochastic Distribution (SD) are generated to cover general cases. The simulation test system first has 10 subsystems. Initially, the network bandwidth is $U_d = 1000Kbps$. For NLCS with 20 subsystems, the data of the ten subsystems was duplicated and the total bandwidth available was multiplied by two. For the problem with more subsystems, the data was scaled appropriately.

The optimal THMCA parameters for ten subsystems which were chosen after several runs are given as $N^{holding} = 10$, $N^{sub} = 200$, $\tau = 0.2$, $\omega = 2$. For NLCS with more subsystems, the same parameters were utilized, except for $N^{holding}$ and $N^{sub}$ which increase correspondingly. Another parameter to be selected is $\theta \in (45°, 90°)$, which adjusts the deviation from the original direction. These values were found suitable to produce good solutions in terms of the processing time and the quality of the solutions. The fitness function is set to be the utility function of NG, that is, $fit_i = u_i$.

For the comparison purpose among the THMCA and other optimization methods, all the simulation experiments used the same basic parameter settings.

The convergence of the algorithm for ten subsystems in NLCS with 50, 100, 150, 200, 250 and 300 initial competition companies with discrete nomal distribution data rate is shown in Fig.3. It is clear that the initial number of 200 competition companies is notably the best on both convergence (mean solution time) and the bandwidth consumption.

From the results of 10 simulation runs, it is found that the optimal solution can be obtained after 8-th to 10-th market competition interactions. Fig.4 shows the convergence of the

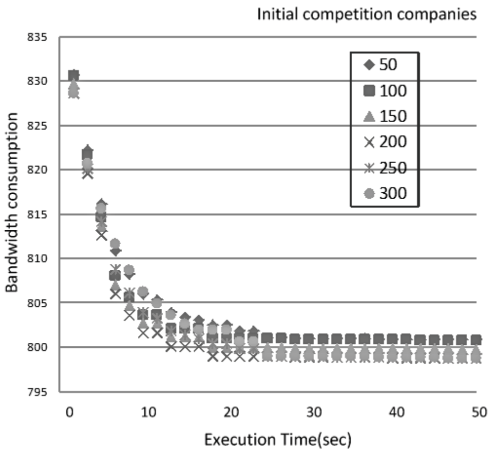

Fig. 3. Convergence characteristics of market competition algorithm with different initial competition companies in 10-subsystem NLCS

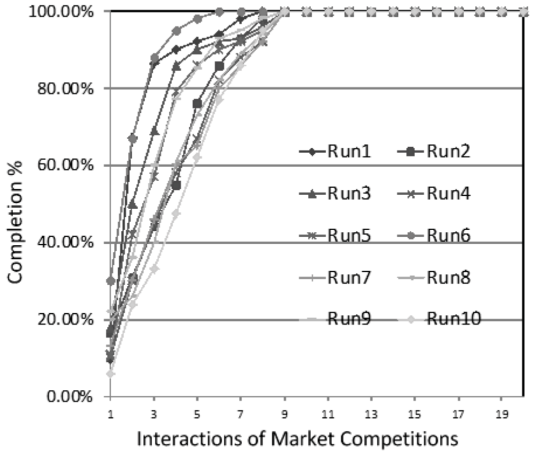

Fig. 4. 10-runs convergence of market competition algorithm in 10-subsystem NLCS

iteration for the 10-subsystem test system with stochastic distribution data rate. This indeed verifies the high convergence rate of the algorithm.

When the overall fitness value is stabilized, the nash equilibrium point is reached. For discrete normal distribution, this is: $\{b_1, b_2, \cdots, b_{10}\} = \{55.90,\ 68.12,\ 77.56,\ 93.37,\ 101.34,\ 105.82,\ 94.70,\ 84.18,\ 60.79,\ 56.84\}$. For stochastic distribution, this is $\{38,\ 78,\ 27{,}110,\ 36,\ 117,\ 62,\ 101,\ 107,\ 318\}$.

Figure 5 and 6 illustrate the proportion of statistical output data rates with lower limit, the reserved data rate and output data limit of the two distributions. It is evident that the game model based method is able to produce a fair network resource allocation in NLCS under different constraints. The overall performance of the system remained stable by effectively restricting large network resource utilization.

Figure 7 shows the ratio between the scheduled sampling period of subsystems and the original sampling period $t_i^*/t_i$, where the lower ratio means a better optimization scheme. The optimization results of the sampling period after the adjustment within the requirements of the two data rates distributions is also shown. Further, when the discrete normal distribution data rates was used, larger probability distribution leads to better optimization results, indicating that this method is adequate for meeting the requirements of most data rates.

The best bandwidth results obtained by THMCA are compared with those obtained by the shuffled frog leaping algorithm (SFLA) [11], BF [9], GA [6], hybrid quantum clone evolutionary algorithm (HQCE) [8], and quantum inspired

TABLE II
COMPARISON OF TOTAL BANDWIDTH CONSUMPTION(KBPS) WITH DIFFERENT NUMBER OF SUBSYSTEMS

| $Num$ | GA | HQCE | Q-PSO | BF | SLFA | THMCA |
|---|---|---|---|---|---|---|
| 10 | 825 | 817 | 807 | 823 | 803 | 798 |
| 20 | 1643 | 1630 | 1611 | 1641 | 1601 | 1591 |
| 50 | 4105 | 4074 | 4026 | 4099 | 4002 | 3976 |
| 100 | 8209 | 8149 | 8053 | 8196 | 8005 | 7952 |

TABLE III
COMPARISON OF AVERAGE EXECUTION TIME(SEC) WITH DIFFERENT NUMBER OF SUBSYSTEMS

| $Num$ | GA | HQCE | Q-PSO | BF | SLFA | THMCA |
|---|---|---|---|---|---|---|
| 10 | 30 | 24 | 22 | 28 | 21 | 17 |
| 20 | 82 | 65 | 61 | 75 | 58 | 46 |
| 50 | 214 | 169 | 158 | 196 | 147 | 119 |
| 100 | 1504 | 1189 | 1112 | 1376 | 1076 | 836 |

PSO (Q-PSO) [7] for NLCS with up to 100 subsystems in table II.

The execution time is also an important factor. Table III lists the execution time with different size of subsystem obtained by THMCA, SFLA, BF, GA, HQCE, and Q-PSO. It is obvious that the execution time of THMCA increases linearly with the size of the bandwidth scheduling problem. The overall execution time obtained by THMCA is less than that of other methods.

## V. CONCLUSIONS

Resource allocation in a networked learning control system is a constrained nonlinear optimization problem. A fair non-cooperation game model has been proposed in this paper. Then, the resource allocation problem is transformed into a problem of settling the equilibrium point of the game model. A new optimization algorithm namely two-layer hierarchical market competition algorithm (THMCA) has been proposed to solve the problem effectively. The proposed method has been tested and compared with a few alternatives. Simulation results show that the computational time and bandwidth consumptions of THMCA are less than other algorithms such as SFLA, GA, BF, quantum-inspired PSO, and hybrid quantum clone evolutionary algorithm. However, the performance of the THMCA also depends on certain parameters selected. Future research includes developing more efficient algorithms and addressing uncertainties in the proposed non-cooperation game model.

***Abstract*—This paper proposes a new nonlinear optimization algorithm for the construction of radial basis function (RBF) networks in modelling nonlinear systems. The main objective is to speed up the learning convergence of the conventional conjugate gradient method. All the hidden layer parameters of RBF networks are simultaneously optimized by the conjugate gradient method while the output weights are adjusted accordingly using the orthogonal least squares (OLS) method. The derivatives used in the conjugate gradient algorithm are efficiently computed using a recursive sum squared error criterion. Numerical examples show that the new method converges faster than the previously proposed continuous forward algorithm (CFA).**

## I. Introduction

The Radial Basis Function (RBF) networks are well known for strict interpolation for approximating scattered data in multi-dimensions [1]. It has been proved that a RBF network can approximate any multi-variate continuous function if a sufficient number of RBF nodes are provided [2]. The RBF networks have been successfully applied in nonlinear system identification [3], signal processing [4] and fault diagnosis [5]. A standard RBF network consists of a nonlinear hidden layer and a linear output layer. The training of such RBF networks involves the optimization of hidden layer parameters (centers and widths) and linear output weights, with the aim of minimizing the cost function like sum squared error (SSE) or Akaike information criterion (AIC) [6].

A variety of methods for training RBF networks have been proposed. Unsupervised clustering methods and the supervised least squares based subset selection methods are widely used. Though these methods, like $k$-means clustering [7], orthogonal least squares (OLS) [8] and the fast recursive algorithm (FRA) [9], are fast and powerful techniques, they may not build a compact model. To address this problem, methods combining the OLS with evolutionary algorithms [10], [11] have been proposed. However, they are often computationally expensive and suffer from slow convergence due to their random search nature [12].

Alternative solutions are gradient based methods, like conjugate gradient and Newton algorithms [13]. However, they treat all the hidden layer parameters and output weights separately without the consideration of the correlation between these two sets of parameters, therefore, they may converge slowly or not at all if the initial guess is far from the minimum. To speed up the convergence and simplify the computational complexity, the continuous forward algorithm (CFA) [14] has been proposed recently. This method employs the conjugate gradient algorithm to optimize the hidden layer parameters while the optimal output weights are transformed into a set of dependant parameters based on the least squares method, thus without explicit optimizing the output weights. The CFA can be considered as a stepwise algorithm as it optimizes one hidden node at a time. Its advantage is that the model parameters and model size can be determined simultaneously and the computational complexity is not high for each iteration of optimization. The disadvantage is that the learning convergency can be slow and the parameters are not necessarily optimal as the previously obtained parameters are fixed and become the constraints when optimizing the new hidden layer nodes. In other words, it does not optimize all the hidden layer parameters simultaneously.

In this paper, a conjugate gradient method combined with OLS approach is introduced to construct RBF networks, in which all the hidden layer parameters are optimized simultaneously by the conjugate gradient method while the output weights are adjusted accordingly using the OLS method in the continuous space, leading to an improved model performance with fast learning convergence. This is achieved effectively using a recursive sum squared error (SSE) and all the derivatives are updated recursively at each iteration. A numerical example confirms that the new method could converge faster than the CFA.

## II. Problem formulation and preliminaries

A RBF network for modelling a nonlinear system can be formulated as [14]

$$y(t) = \sum_{i=1}^{m} \mathbf{p}_i(\mathbf{x}(t), d_i, \mathbf{s}_i)\theta_i + \xi(t) \tag{1}$$

where $\{\mathbf{x}(t), y(t)\}$ are the system input and output variables at time instant $t$. $\mathbf{x}(t)$ is of assumed known dimension of $q$, $t = 1, 2, \ldots, N$, $N$ being the size of the training data set. $\mathbf{p}_i(\mathbf{x}(t), d_i, \mathbf{s}_i)$ denotes the RBF network function of the $i$th hidden node with the width $d_i \in \Re^1$ and centers $\mathbf{s}_i \in \Re^q$, here $i = 1, 2, \ldots, m$, $m$ being the number of RBF nodes. $\theta_i$ is the weight parameter. $\xi(t)$ is a model residual sequence. For a RBF network, all adjustable parameters are the hidden layer parameters and output weights. More specifically, all the hidden layer parameters can be expressed as

$$\mathbf{V} = \begin{bmatrix} \mathbf{v}_1 \\ \mathbf{v}_2 \\ \vdots \\ \mathbf{v}_m \end{bmatrix} = \begin{bmatrix} d_1 & s_{11} & s_{12} & \ldots & s_{1q} \\ d_2 & s_{21} & s_{22} & \ldots & s_{2q} \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ d_m & s_{m1} & s_{m2} & \ldots & s_{mq} \end{bmatrix} \tag{2}$$

where the vector $\mathbf{v}_i$ includes the $i_{th}$ hidden layer node parameters. $d_i$ and the set $\{s_{i1}, ..s_{iq}\}$ are the width and centers of the $i_{th}$ hidden layer node, respectively. For simplicity, $\mathbf{v}_i = [d_1, s_{i1}, \ldots, v_{iq}]$ can be denoted as $\mathbf{v}_i = [v_{i1}, \ldots, v_{ir}]$ where $r = q + 1$.

Equation (1) can be expressed in the matrix form as

$$\mathbf{y} = \mathbf{P\Theta} + \Xi \tag{3}$$

where $\mathbf{y} = [y(1), \ldots, y(N)]^T$ is the output vector, $\mathbf{\Theta} = [\theta_1, \ldots, \theta_m]^T$ is the unknown parameter vector, $\Xi = [\xi(1), \ldots, \xi(N)]^T$ is the residual vector, and $\mathbf{P} = [\mathbf{p}_1, \ldots, \mathbf{p}_m]$ is a $N$-by-$m$ matrix with $\mathbf{p}_j = [p_j(\mathbf{x}(1), \mathbf{v}_j), \ldots, p_j(\mathbf{x}(N), \mathbf{v}_j)]^T$. The RBF network modeling aims to minimize the sum squared error (SSE)

$$\Xi^T\Xi = (\mathbf{y} - \mathbf{P\Theta})^T(\mathbf{y} - \mathbf{P\Theta}) \tag{4}$$

by optimizing $d_i$'s, $\mathbf{s}_i$'s and $\theta_i$'s.

If all the hidden layer parameters are determined, the output weights can then be obtained by least squares methods. The orthogonal least squares (OLS) is the most popular algorithm for determining both the linear parameters and model structure. It computes the output weights using the orthogonal decomposition given by [15]

$$\mathbf{P} = \mathbf{WA} \tag{5}$$

where $\mathbf{A}$ is a $m$-by-$m$ triangular matrix,

$$\mathbf{A} = \begin{bmatrix} 1 & \alpha_{12} & \ldots & \alpha_{1m} \\ 0 & 1 & \ldots & \alpha_{2m} \\ \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{6}$$

and $\mathbf{W} = [\mathbf{w}_1, ..., \mathbf{w}_m]$ is a $N$-by-$m$ matrix with orthogonal columns $\mathbf{w}_i$,

$$\mathbf{W} = \begin{bmatrix} w_{11} & w_{12} & \ldots & w_{1m} \\ w_{21} & w_{22} & \ldots & w_{2m} \\ \vdots & \vdots & \vdots & \vdots \\ w_{N1} & w_{N2} & \ldots & w_{Nm} \end{bmatrix} \tag{7}$$

which satisfies

$$\mathbf{W}^T\mathbf{W} = diag\{\mathbf{w}_1^T\mathbf{w}_1, \ldots, \mathbf{w}_m^T\mathbf{w}_m\}. \tag{8}$$

The orthogonal decomposition involved in OLS can be carried out by the classic Gram-Schimdt (CGS) method. This computes one column of $\mathbf{A}$ at a time and factorizes $\mathbf{P}$ as follows:

$$\left.\begin{array}{l} \mathbf{w}_1 = \mathbf{p}_1 \\ \left.\begin{array}{l} \alpha_{ik} = \dfrac{< \mathbf{w}_i, \mathbf{p}_k >}{< \mathbf{w}_i, \mathbf{w}_i >},\ 1 \leq i < k \\ \mathbf{w}_k = \mathbf{p}_k - \displaystyle\sum_{i=1}^{k-1} \alpha_{ik}\mathbf{w}_i \end{array}\right\} k = 2, \ldots, m \end{array}\right\} \tag{9}$$

The model (3) can thus be expressed as

$$\mathbf{y} = (\mathbf{PA}^{-1})(\mathbf{A\Theta}) + \Xi = \mathbf{Wg} + \Xi \tag{10}$$

where $\mathbf{g} = [g_1, g_2, \ldots, g_m]^T = \mathbf{A\Theta}$ is the orthogonal weight vector. The original model weight vector $\mathbf{g}$ can then be calculated by [8]

$$\mathbf{g} = (\mathbf{W^TW})^{-1}\mathbf{W}^T\mathbf{y} - (\mathbf{W^TW})^{-1}\mathbf{W}^T\Xi. \tag{11}$$

and the sum squares of $\mathbf{y}$ is given by

$$\mathbf{y}^T\mathbf{y} = \mathbf{g}^T\mathbf{W}^T\mathbf{Wg} + \Xi^T\Xi + \mathbf{g}^T\mathbf{W}^T\Xi + \Xi^T\mathbf{Wg} \tag{12}$$

If $\Xi$ is a zero mean white sequence and is uncorrelated with $\mathbf{P}$ and all stochastic processes of interest are ergodic, then $\mathbf{W}^T\Xi = 0$ [8]. Hence (11) and (12) can be further simplified to

$$\mathbf{g} = (\mathbf{W^TW})^{-1}\mathbf{W}^T\mathbf{y}, \tag{13}$$

and

$$\mathbf{y}^T\mathbf{y} = \mathbf{g}^T\mathbf{W}^T\mathbf{Wg} + \Xi^T\Xi, \tag{14}$$

respectively. Finally, the weight $\theta_i$ can be computed using backward elimination

$$\left.\begin{array}{l} \theta_m = g_m \\ \theta_i = g_i - \displaystyle\sum_{k=i+1}^{m} \alpha_{ik}\theta_k, i = m-1, \ldots, 1 \end{array}\right\} \tag{15}$$

Substituting $\mathbf{g}$ in (10) and (14) using (13), we get

$$\Xi = \mathbf{y} - \mathbf{W}(\mathbf{W^TW})^{-1}\mathbf{W}^T\mathbf{y}. \tag{16}$$

and

$$\Xi^T\Xi = \mathbf{y}^T\mathbf{y} - \mathbf{y}^T\mathbf{W}(\mathbf{W^TW})^{-1}\mathbf{W}^T\mathbf{y}. \tag{17}$$

Using the property in (8), the (17) is converted into a recursive form given by

$$\begin{aligned} \Xi^T\Xi &= \mathbf{y}^T\mathbf{y} - \mathbf{y}^T\{\sum_{j=1}^{m} \frac{\mathbf{w}_j\mathbf{w}_j^T}{\mathbf{w}_j^T\mathbf{w}_j}\}\mathbf{y} \\ &= \mathbf{y}^T\mathbf{y} - \mathbf{y}^T\mathbf{Ry} \end{aligned} \tag{18}$$

where $\mathbf{R} = \sum_{j=1}^{m} \frac{\mathbf{w}_j\mathbf{w}_j^T}{\mathbf{w}_j^T\mathbf{w}_j}$ is a recursive matrix.

## III. THE PROPOSED METHOD

To address the problem of slow convergence in the conventional conjugate gradient method, the CFA [14] considers the coupling relationship between $\mathbf{V}$ and $\mathbf{\Theta}$. It converts $\mathbf{\Theta}$ and the estimation error sequence $\mathbf{\Xi}$ into $(\mathbf{P}^T\mathbf{P})^{-1}\mathbf{P}^T\mathbf{y}$ and $\mathbf{y}-\mathbf{P}(\mathbf{P}^T\mathbf{P})^{-1}\mathbf{P}^T\mathbf{y}$ using least-squares method respectively, and then computes the derivatives of the estimated error sequence with respect to $\mathbf{V}$. After the updated $\mathbf{V}$ are determined using derivative information, the output weights $\mathbf{\Theta}$ are recalculated by the least squares methods. However, It optimizes each vector parameter $\mathbf{v}_i, i = 1, ..., M$ at a time while other parameters $\mathbf{v}_j, j = 1, ..., M, j \neq i$ being fixed and become the constraints, hence the resultant model may be not optimal, though the computational complexity is significantly reduced in each iteration..

The proposed algorithm not only considers the coupling relationship between $\mathbf{V}$ and $\mathbf{\Theta}$ and but also computes all the hidden layer parameters $\mathbf{V}$ simultaneously. The proposed algorithm first optimizes all the hidden layer parameters in (2) using conjugate gradient algorithm and then adjusts the output weights $\mathbf{\Theta}$ by the OLS method.

The conjugate gradient involves computing the first derivative of the SSE with respective to the hidden layer parameters $\mathbf{V}$, which is given by [16]

$$\nabla(\mathbf{\Xi}^T\mathbf{\Xi}) = 2\left(\frac{\partial\mathbf{\Xi}}{\partial\mathbf{V}}\right)^T\mathbf{\Xi} \tag{19}$$

where the first order derivative of the error sequence $\frac{\partial\mathbf{\Xi}}{\partial\mathbf{V}}$ is also called the Jacobian matrix, given by

$$\left.\begin{aligned} \mathbf{J} &= \frac{\partial\mathbf{\Xi}}{\partial\mathbf{V}} = -\left[\frac{\partial\mathbf{R}}{\partial\mathbf{v}_1}\mathbf{y}, ..., \frac{\partial\mathbf{R}}{\partial\mathbf{v}_m}\mathbf{y}\right] \\ \frac{\partial\mathbf{R}}{\partial\mathbf{v}_k} &= \left[\frac{\partial\mathbf{R}}{\partial v_{k1}}, ..., \frac{\partial\mathbf{R}}{\partial v_{kr}}\right], k = 1, ..., m \\ \frac{\partial\mathbf{R}}{\partial v_{ki}} &= \sum_{j=1}^{m}\frac{\partial\left\{\frac{\mathbf{w}_j\mathbf{w}_j^T}{\mathbf{w}_j^T\mathbf{w}_j}\right\}}{\partial v_{ki}}, i = 1, ..., r \end{aligned}\right\} \tag{20}$$

where $\mathbf{v}_k = \{\mathbf{v}_{k1}, ..., \mathbf{v}_{kr}\}$.

The key step for the conjugate gradient algorithm is the computation of the Jacobian matrix. For each element in the Jacobian matrix shown in (20), the derivative of $\mathbf{w}_k$ with respect to $v_{ki}, k = 1, ..., m, i = 1, ..., r$ needs to be computed. The mapping between $\mathbf{w}_k$ and $v_{ki}$ can be obtained from the relations among $v_{ki}$, $\mathbf{p}_k$ and $\mathbf{w}_k$. Each RBF term $\mathbf{p}_k$ is determined by a vector $\mathbf{v}_k = [v_{k1}, ..., v_{kr}]$. Further, (9) indicates $\mathbf{w}_k$ is dependant on $\mathbf{p}_1, ..., \mathbf{p}_k$ and independent of $\mathbf{p}_{k+1}, ..., \mathbf{p}_m$, hence,

$$\frac{\partial\mathbf{w}_k}{\partial v_{ij}} = \begin{cases} 0, & k < i, j = 1, ..., r \\ \dfrac{\partial\mathbf{w}_k}{\partial v_{ij}}, & k \geq i, j = 1, ..., r \end{cases} \tag{21}$$

and thus, the element in (20) is simplified as

$$\frac{\partial\mathbf{R}}{\partial v_{ki}} = \sum_{j=1}^{m}\frac{\partial\left\{\frac{\mathbf{w}_j\mathbf{w}_j^T}{\mathbf{w}_j^T\mathbf{w}_j}\right\}}{\partial v_{ki}} = \sum_{j=k}^{m}\frac{\partial\left\{\frac{\mathbf{w}_j\mathbf{w}_j^T}{\mathbf{w}_j^T\mathbf{w}_j}\right\}}{\partial v_{ki}}, i = 1, .., r \tag{22}$$

while $k = m$, (22) becomes

$$\frac{\partial\mathbf{R}}{\partial v_{mi}} = \frac{\partial\left\{\frac{\mathbf{w}_m\mathbf{w}_m^T}{\mathbf{w}_m^T\mathbf{w}_m}\right\}}{\partial v_{mi}}, i = 1, .., r \tag{23}$$

Compare (22) and (23), and it is clear that to compute the derivative with respect to the last term parameters $\mathbf{v}_m = [v_{m1}, ..., v_{mi}]$ only $\frac{\partial\mathbf{w}_m}{\partial\mathbf{w}_{mi}}, i = 1, ..., r$, is needed while for other derivatives, say $\mathbf{v}_k = [v_{k1}, ..., v_{ki}]$, only $\frac{\partial\mathbf{w}_k}{\partial\mathbf{v}_{ki}}, ..., \frac{\partial\mathbf{w}_m}{\partial\mathbf{w}_{ki}}, i = 1, ..., r$, need to be computed. To simplify the computational complexity for derivatives, each term except the last one is moved to the last position and its derivatives is then computed as proposed in [12]. If any term position is changed, the orthogonal decomposition procedure needs to be repeated. Suppose $\mathbf{p}_k, k = 1, ..., m-1$, is to be moved to the last position. This leads to shifting the columns $\mathbf{p}_{k+1}, ..., \mathbf{p}_m$, left by one place. This is given by

$$\{\mathbf{p}_1, ..., \mathbf{p}_k, ..., \mathbf{p}_m\} \to \{\mathbf{p}_1, ..., \mathbf{p}_{k-1}, \mathbf{p}_{k+1}, ...\mathbf{p}_m, \mathbf{p}_k\} \tag{24}$$

and consequently their corresponding orthogonal basis is changed. If $k = 1$, then all the orthogonal terms $[\mathbf{w}_1^{'}, ..., \mathbf{w}_m^{'}]$ need to be computed using (9). If $k > 1$, the terms $[\mathbf{w}_1, ..., \mathbf{w}_{k-1}]$ are left unchanged and only $[\mathbf{w}_k^{'}, ..., \mathbf{w}_m^{'}]$ need to alter. In details, shift the position by

$$\left.\begin{aligned} \mathbf{p}_j^{'} &= \mathbf{p}_{j+1}, \ k \leq j < m \\ \mathbf{p}_m^{'} &= \mathbf{p}_k \end{aligned}\right\} \tag{25}$$

and then re-decompose $\mathbf{p}_k^{'}, ..., \mathbf{p}_m^{'}$ by

$$\left.\begin{aligned} \alpha_{nj}^{'} &= \frac{<\mathbf{w}_n, \mathbf{p}_k^{'}>}{<\mathbf{w}_n, \mathbf{w}_n>}, \ 1 \leq n < k \\ \alpha_{nj}^{'} &= \frac{<\mathbf{w}_n^{'}, \mathbf{p}_k^{'}>}{<\mathbf{w}_n^{'}, \mathbf{w}_n^{'}>}, \ k \leq n < j \\ \mathbf{w}_j^{'} &= \mathbf{p}_j^{'} - \sum_{n=1}^{k-1}\alpha_{nj}^{'}\mathbf{w}_n - \sum_{n=k}^{j-1}\alpha_{nj}^{'}\mathbf{w}_n^{'} \end{aligned}\right\} j = k, ..., m. \tag{26}$$

The derivative with respect to the last term $\mathbf{p}_m$ in Jacobian matrix is calculated by

$$\left.\begin{aligned} \frac{\partial\mathbf{p}_m}{\partial v_{mi}} &= \left[\frac{\partial p_m(x(1))}{\partial v_{mi}}, ..., \frac{\partial p_m(x(N))}{\partial v_{mi}}\right] \\ \frac{\partial\mathbf{w}_m}{\partial v_{mi}} &= \frac{\partial\mathbf{p}_m}{\partial v_{mi}} - \sum_{j=1}^{j=m-1}\frac{\mathbf{w}_j^T\frac{\partial\mathbf{p}_m}{\partial v_{mi}}}{\mathbf{w}_j^T\mathbf{w}_j}\mathbf{w}_j \\ J_{mi} &= -\frac{\partial\mathbf{R}}{\partial v_{mi}}\mathbf{y} \\ &= -\frac{\frac{\partial\mathbf{w}_m}{\partial v_{mi}}(\mathbf{w}_m^T\mathbf{y}) + \mathbf{w}_m(\frac{\partial\mathbf{w}_m^T}{\partial v_{mi}}\mathbf{y})}{\mathbf{w}_m^T\mathbf{w}_m} \\ &\quad + 2\frac{\mathbf{w}_m(\mathbf{w}_m^T\mathbf{y})(\frac{\partial\mathbf{w}_m^T}{\partial v_{mi}}\mathbf{w}_m)}{(\mathbf{w}_m^T\mathbf{w}_m)^2} \end{aligned}\right\} i = 1, ..., r \tag{27}$$

Other terms $\mathbf{p}_k, k = 1, ..., m-1$, moved to the last position also use the formula (27) where $\frac{\partial \mathbf{p}_m^{'}}{\partial \mathbf{v}_{mi}^{'}}$ equals $\frac{\partial \mathbf{p}_k}{\partial \mathbf{v}_{ki}}$. To compute $\frac{\partial \mathbf{p}_k}{\partial \mathbf{v}_{ki}}$, the basis function $\mathbf{p}_k = [p_k(\mathbf{x}(1), \mathbf{v}_k), \dots, p_k(\mathbf{x}(N), \mathbf{v}_k)]$ should be given. In this paper, the Gaussian function is considered

$$p_k(\mathbf{x}(t), \mathbf{v}_k) = p_k(\mathbf{x}(t), d_k, \mathbf{s}_k) = \text{exp}(-\eta) \qquad (28)$$

where $\eta = \sum_{i=1}^{i=q} (\frac{x_i - s_{ki}}{d_k})^2$, $t = 1, \dots, N$ and $k = 1, \dots, m$. The first-order partial derivatives with respect to widths and centers are

$$\frac{\partial p_k}{\partial d_k} = \frac{2}{d_k} \eta \text{exp}(-\eta) \qquad (29)$$

and

$$\frac{\partial p_k}{\partial s_{ki}} = \frac{2}{d_k^2} (x_i - s_{ki}) \text{exp}(-\eta) \qquad (30)$$

respectively.

The procedure of the new method is summarized as follows:

*Step 1*: Initialize all the hidden layer parameters $\mathbf{V}$ randomly or using OLS based subset selection method [15], [17]. It should be pointed out that to choose appropriate values could speed up the model convergence.

*Step 2*: Compute Jacobian and Hessian matrices using (25)-(27).

*Step 3*: Update the $\mathbf{V} = \mathbf{V} + \Delta \mathbf{V}$ and construct the basis functions terms $\mathbf{P}$ in the form of (28) using the new parameters $\mathbf{V}$, and then compute the SSE using (9) and (18).

*Step 4*: Repeat step 3 until the SSE is reduced to some error target or the iteration number reaches a given number. After the hidden layer parameters $\mathbf{V}$ are determined, the output weights are calculated by back elimination (15).

## IV. A NUMERICAL EXAMPLE

To verify the efficacy of the new method, a numerical examples is used to test its convergence rate. The comparison with CFA will be also discussed. All the tests were carried out using MATLAB R2010a on a desktop Intel E8400 PC with Windows XP system.

The following nonlinear system model [3]

$$\begin{aligned} y(t) = & -0.6377y(t-1) + 0.07298y(t-2) \\ & + 0.03597u(t-1) + 0.06622u(t-2) \\ & + 0.06568u(t-1)y(t-1) + 0.02357u^2(t-1) \\ & + 0.05939 \end{aligned} \qquad (31)$$

Here $t$ denotes the time series and $u$ and $y$ represent the system input and output, respectively. A data sequence of length 500 was generated for training, with input $u$ being uniformly distributed within $[-1, 1]$.

For comparison, the CFA was also used to model the nonlinear system. For a fair comparison, these two methods used the same initialization procedure. The iteration stops when the SSE reduction rate is less than 0.01. Fig. 1, Fig. 2 and Fig. 3 illustrate the training curves for the CFA and new methods with model size of 5, 6 and 7 separately. These results are averages over 100 different trials. It is shown that the new method converges faster than the CFA.

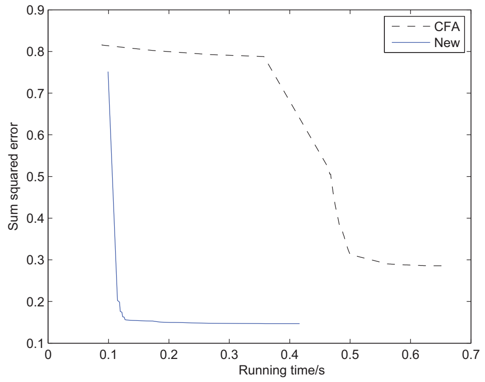

Fig. 2. Variation in training SSE for CFA and the new method with size 6

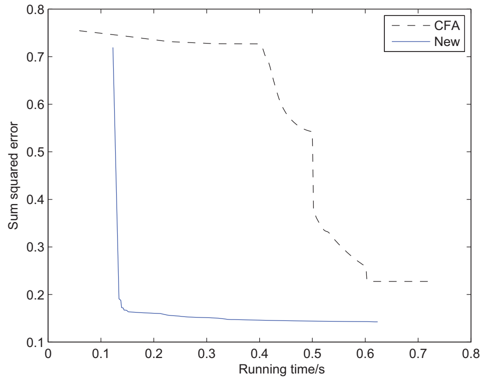

Fig. 3. Variation in training SSE for CFA and the new method with size 7

## V. CONCLUSION

An improved conjugate gradient algorithm for constructing RBF models has been proposed. Unlike previously proposed CFA method which optimizes one hidden node parameters at a time, the new method optimizes all the RBF parameters simultaneously, leading to a faster convergence rate. A numerical example has confirmed the effectiveness of the proposed method.

***Abstract*—The injection stretch-blow Moulding (ISBM) process is typically used to manufacture PET containers for the beverage and consumer goods industry. The process is somehow complex and users often have to heavily rely on trial and error methods to setup and control it. In this paper, a novel identification method based on a radial basis function (RBF) network model and heuristic optimization methods, such as particle swarm optimization (PSO), deferential evolution (DE), and extreme learning machine (ELM) is proposed for the modelling and control of bottle section weights. The main advantage of the proposed method is that the non-linear parameters are optimized in a continuous space while the hidden nodes are selected one by one in a discrete space using a two-stage selection algorithm. The computational complexity is significantly reduced due to a recursive updating mechanism. Experimental results on simulation data from ABAQUS are presented to confirm the superiority of the proposed method.**

## I. Introduction

Over last few decades, the use of plastics has experienced healthy growth due to its many high performances including lightweight with high tensile/impact/tear strengths, high temperature/chemical resistance, high clarity/modulus/plasticity and low cost [1]. The injection stretch-blow moulding (ISBM) process is a kind of blow-moulding process in making thin-walled polyethylene terephthalate (PET) bottles for the carbonated soft drink and mineral water industries. In such a process, polymer granules is first extruded and injected into a hollow tube to produce structurally amorphous preforms. The resultant preforms are then loaded and conveyed in an infrared oven for reheat. Finally, the heated preforms are simultaneously stretched by a rod and blown with high pressure air to produce to the finished article shape. This stretch blowing and subsequent cooling takes around one second. Due to the fast production rate, the ability to mould complex part and some other attractive features, ISBM process has become one of the most popular methods adopted in the polymer industry.

The quality of made bottles is usually indicated by the bottle wall thickness distribution, top load, burst, and the section weights. All these variables are correlated to the process parameter settings, including preform temperature distribution, blowing air pressure and the delay between rode stretching and air blowing [2]. Unfortunately, the current ISBM process is still an open-loop system where optimal process settings are found by trial and error [3]. This is not only time consuming but also leads to wasting of materials, and the process is sensitive to both internal and external interruptions. Therefore, the design of feedback control for ISBM process is extremely urgent. The bottle wall thickness and its section weights are clearly the best options for feedback signals, but they are either difficult to measure in real-time or the cost is too high. Alternatively, the 'soft-sensor' method to infer these parameters based on the mathematical process model becomes an affordable and cost-effective approach.

In non-linear system identification, the radial basis function networks are recognized as an universal approximation model that has been widely applied in data mining, pattern recognition, signal processing, and system modelling and control [4]. The RBF network has a simple topological structure, and it is easy to be trained compared to the multilayer perceptron (MLP) neural network alternative. The construction of RBF network model mainly involves two steps, the optimization of basis function parameters and the estimation of output layer weights. The latter can be easily achieved by least-square estimation while the former is difficult to implement as it involves non-linear optimization. The conventional way to handle those non-linear parameter are either by exhaustive search or gradient-based methods, which can be computationally expensive, and the global best solution cannot be guaranteed [5].

Heuristic approaches, such as simulated annealing (SA) [6], evolutionary algorithm (EA) [7], Tabu search (TS) [8], particle swarm optimization (PSO) [9], differential evolution (DE) [10], ant colony optimization (ACO) [11] and harmony search (HS) [12] have offered the alternatives for such an optimization problem. Unlike conventional calculus-based methods, heuristic approaches randomly generate some new solutions from which the best one is selected. The employment of heuristic methods in the RBF network construction can be implemented at either the global or the local level. In the former case all the non-linear and linear parameters are optimized simultaneously while in the latter case only the non-linear parameters of a single hidden node are regarded as one solution, and the RBF model is built step by step through subset selection algorithm [13]. Simultaneous optimization

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

of the whole RBF network can archive the global optimal solution. However, it can be computationally expensive, and a large number of iterations are required in the optimization process. By contrast, subset selection involves fewer parameters to be optimized at each step, thus it is more efficient. The recently proposed two-stage subset selection algorithm has also shown its ability in reaching the near global optimal solution while retaining the computational efficiency of the forward alternative [14, 15].

In this paper, heuristic optimization methods, such as the Particle Swarm Optimization, Differential Evolution and the recently developed Extreme Learning Machine [16, 17] are effectively integrated with our two-stage selection (TSS) algorithm, leading to a flexible and efficient construction scheme for RBF neural modelling. Non-linear parameters in the hidden layer will be continuously optimized at each step while the output layer weights are estimated by the least-squares. The main advantages over the conventional subset selection methods are that both the centre vector and width vector in a RBF function are optimized separately for each hidden node. Thus the model size can be significantly reduced, leading to improved generalisation performance. The experimental results on the simulation data illustrate the compactness and performances of the obtained model. It also shows that the PSO and DE have similar capabilities in non-linear parameter optimization while the extreme learning machine provides an efficient alternative with significantly reduced computational effort.

The rest of this paper is organized as follows. Section II and III give an overview of the ISBM process and the heuristic methods employed. The new two-stage selection algorithm is then introduced in Section IV with the experimental results given in V. Finally, VI concludes the paper and provides with suggested future work.

## II. The ISBM process

Practically, it is difficult to generate enough data for system identification. Thus a commercial finite element (FE) package known as ABAQUS is used to simulate the ISBM process. Several conditions need to be pre-set before the simulation process. These include the geometry of the preform, stretch rod and mould, material model, pre-blow process conditions (mass flow rate, pre-blow air pressure, preform temperature) and final-blow process conditions (final-blow air pressure and cooling time).

The pre-blow process conditions have a major influence on the final thickness and mechanical properties distributions in the ISBM process. At this stage, the simulations are only focused on modelling wall thickness distribution at different pre-blow process conditions. The preform reheating stage and cooling stage are beyond the scope of this study. Four parameters of the process were identified to be important, namely mass flow rate, pressure, temperature, and timing. The mass flow rate indicates the velocity of air blowing to the pre-form while the pressure affects the total amount of air consumed. The pre-form temperature was assumed uniform and equivalent to the setting value in the simulation, and the timing reflects the delay between stretching and blowing. Each of the four parameters were given different settings as shown in table I, and totally 144 possible combinations were obtained. Meanwhile the bottle wall volume is divided into three parts: shoulder, side-wall and base. These volume distribution indicators can generally represent the weight distribution. The frictional force between mould and bottle was infinite during the simulation.

TABLE I
DOE settings of each parameter in ISBM simulation

| Mass flow rate(g/s) | Pressure(MPa) | Temperature(°C) | Timing(ms) |
|---|---|---|---|
| 5 | 0.6 | 95 | 0 |
| 17 | 0.8 | 100 | 50 |
| 29 | 1 | 105 | 100 |
| 40 |  | 110 |  |

## III. Review of RBF network model and heuristic optimization methods

### A. Radial Basis function network model

A general RBF neural model can be expressed as

$$y(t) = \sum_{k=1}^{n} \theta_k \varphi_k(\mathbf{x}(t); \mathbf{c}_k; \mathbf{\Sigma}_k) + \varepsilon(t) \tag{1}$$

where $y(t)$ is the actual output at sample time $t$, $\mathbf{x}(t) \in \Re^p$ is the input vector, $\varphi_k(\mathbf{x}(t); \mathbf{c}_k; \mathbf{\Sigma}_k)$ denotes the nonlinear activation function, $\mathbf{c}_i = [c_{i1}, c_{i2}, \cdots, c_{ip}]^T$ is the centre vector, and $\mathbf{\Sigma}_i$ is the associated norm matrix. Finally, $\theta_k$ represents the output layer weight for each RBF node, and $\varepsilon(t)$ is the network error at sample time $t$. By using a set of $N$ data samples $\{\mathbf{x}(t), y(t)\}_{t=1}^{N}$ for model training, (1) can then be re-written in a matrix form as

$$\mathbf{y} = \mathbf{\Phi}\boldsymbol{\theta} + \mathbf{e} \tag{2}$$

If the regression matrix $\mathbf{\Phi}$ is of full column rank, the Least-Squares estimate of the regression coefficients in (2) is given by

$$\hat{\boldsymbol{\theta}} = (\mathbf{\Phi}^T\mathbf{\Phi})^{-1}\mathbf{\Phi}^T\mathbf{y} \tag{3}$$

where $\mathbf{\Phi}^T\mathbf{\Phi}$ is sometimes called the information matrix. The associated minimal cost function is

$$J_n(\hat{\boldsymbol{\theta}}_n) = \mathbf{y}^T(\mathbf{I} - \mathbf{\Phi}_n)(\mathbf{\Phi}_n^T\mathbf{\Phi}_n)^{-1}\mathbf{\Phi}_n^T\mathbf{y} \tag{4}$$

### B. Particle Swarm Optimization

PSO involves a number of particles which move through the problem search space seeking an optimal or satisfactory solution. The position of each particle is adjusted according to its velocity and the difference between its current position, the best one it has found so far, and the best position to date found by its neighbours.

Suppose $\mathbf{x}_i$ denotes the $i^{th}$ particle in the swarm, $\mathbf{v}_i$ represents its velocity, $\mathbf{p}_i$ is its best position to date, while

$\mathbf{p}_g$ denotes the best position from the entire swarm. In inertia-weighted PSO, $\mathbf{v}_{(i+1)}$ and $\mathbf{x}_{(i+1)}$ are updated as:

$$\mathbf{v}_{(i+1)} \leftarrow w_0\mathbf{v}_i + c_1r_1(\mathbf{p}_i - \mathbf{x}_i) + c_2r_2(\mathbf{p}_g - \mathbf{x}_i) \quad (5)$$
$$\mathbf{x}_{(i+1)} \leftarrow \mathbf{x}_i + \mathbf{v}_i \quad (6)$$

where $w_0$ is the inertia weight used to scale the previous velocity term, $c_1$ and $c_2$ are acceleration coefficients, and $r_1$ and $r_2$ are two uniform random number generated between 0 and 1. The acceleration coefficients $c_1$ and $c_2$ can be fixed or varied during the iterative procedure. In order to ensure that each updated particle is still inside the search space, it is also necessary to define a value range, and check both the position and velocity for each particle at the end of an iteration.

### C. Deferential Evolution

As a population based optimization technique, DE [10] also starts with some initial points which are randomly generated in the search space, and then pushes the populations toward the global optimum point through repeated operations of mutation, crossover and selection. New populations are obtained by adding the weighted difference of two vectors to a third one, where the vectors are mutually different random points from the last generation.

Suppose $\mathbf{x}_i^{(l)}$ $(i = 1, 2, \cdots, p)$ is the solution vector in generation $l$, the operations in the classic DE method can be summarised as follows:

- **Mutation**: A mutant vector is generated by:
$$\mathbf{v}_i^{(l+1)} = \mathbf{x}_{r1}^{(l)} + F(\mathbf{x}_{r2}^{(l)} - \mathbf{x}_{r3}^{(l)}) \quad (7)$$
where $r1$, $r2$, $r3$ are random indices from $[1, 2, \cdots, p]$ and $F \in [0, 2]$ is a real constant which controls the amplification of the added differential variation. Larger values for $F$ lead to higher diversity in new populations, while lower values cause faster convergence.
- **Crossover**: This operation is implemented to increase the diversity of the population. A trial vector is defined as
$$\mathbf{u}_i^{(l+1)} = [u_{i1}^{(l+1)}, u_{i2}^{(l+1)}, \cdots, u_{ip}^{(l+1)}]^T \quad (8)$$
with elements given by
$$u_{ij}^{(l+1)} = \begin{cases} v_{ij}^{(l+1)} & rand_i(0,1) \leq C_r \ or \ i = b_r \\ x_{ij}^{(l)} & otherwise \end{cases} \quad (9)$$
where $p$ is the vector dimension, $C_r \in [0, 1]$ is the predefined crossover constant, $rand_i(0, 1)$ uniformly generates a scaler from $[0, 1]$ at the $i^{th}$ evaluation, and $b_r$ is a random index chosen from $[1, 2, \cdots, p]$ so that $\mathbf{u}_i^{(l+1)}$ contains at least one parameter from $\mathbf{v}_i^{(l+1)}$.
- **Selection**: The last step is to compare all the trial vectors $\mathbf{u}_i^{(l+1)}$ with the target ones $\mathbf{x}_i^{(l)}$ using a criterion, such as their contribution to a loss function, and then decide which one becomes a member of the next generation.

The above procedure continues until a pre-set number of iterations is reached or the desired accuracy is obtained.

### D. Extreme Learning Machine

The Extreme Learning Machine (ELM) was first introduced for the training of Single-hidden Layer Feedforward neural Network (SLFN). It builds the SLFN model by randomly assigning non-linear parameters for each hidden node instead of iterative training. The target is then simply a linear combination of the hidden nodes, and the output layer weights can be easily estimated by Least-Squares. As a result, the learning speed in ELM can be several orders of magnitude faster than traditional learning. Using incremental methods, it has been proven that the ELM can be regarded as a universal approximator [18].

The SLFN has a similar structure to a RBF network. For a multi-input, multi-output (MIMO) system, it can be expressed as

$$\mathbf{y}(t) = \sum_{k=1}^{n} \boldsymbol{\theta}_k \varphi_k(\mathbf{w}_k \cdot \mathbf{x}(t) + b_k) \quad (10)$$

where $\mathbf{x}(t) = [x_1(t), x_2(t), \cdots, x_p(t)]$ and $\mathbf{y}(t) = [y_1(t), y_2(t), \cdots, y_m(t)]$ is the system input and output vector; $\mathbf{w}_k = [w_{k1}, w_{k2}, \cdots, w_{kp}]$ is the weight vector between the $p$ inputs and the $k^{th}$ hidden node; $b_k$ is the threshold of the $k^{th}$ hidden node; $(\cdot)$ denotes the inner product, and $\varphi$ is the activation function. Finally $\boldsymbol{\theta}_k = [\theta_{k1}, \theta_{k2}, \cdots, \theta_{km}]$ is the output layer weight vector between the $k^{th}$ hidden node and $m$ outputs.

In ELM, the non-linear parameters $\mathbf{w}_k$ and $b_k$ in (10) are assigned randomly, and it has been proven that the the required number of hidden nodes $n \leq N$ if the activation function $\varphi$ is infinitely differentiable [16].

According to the above theorem, the ELM is also valid for the RBF network in (1). The construction process can be summarised in two steps:

1) Randomly assign the hidden nodes parameters, including the number of hidden nodes $n$, and non-linear parameters $\mathbf{c}_i$ and $\boldsymbol{\sigma}_i$ for $i = 1, 2, \cdots, n$;
2) Form the regression matrix $\boldsymbol{\Phi}$, and estimate the output layer weights using (3);

The main issue in using ELM is that the sparsity of the constructed model cannot be guaranteed due to its stochastic characteristics. Fortunately, subset selection methods can be easily integrated to solve this problem, and better generalization performance can be achieved.

## IV. Two-stage selection based on Heuristic optimization

The two-stage selection algorithm includes a forward model construction stage and a backward model refinement stage. At its first stage, one RBF centre is selected and added to the model at each step. The significance of each centre is measured by its contribution to the cost function. This process continues until some pre-defined modelling criteria are met (such as Akaike's information criterion or a pre-defined number of hidden nodes is reached), the algorithm then moves to the second stage where the importance of previously selected centres are reviewed, and any insignificant ones are replaced. The computational efficiency involved in such process is achieved by defining a residual matrix $\mathbf{R}_k$ which can be updated recursively. Moreover, PSO and DE are used to find the best centre at each step while ELM is used to form the centre pool before the selection process.

### A. First stage - forward selection

Refer to (4), a recursive matrix $\mathbf{M}_k$ and a residual matrix $\mathbf{R}_k$ are defined to simplify the computation.

$$\mathbf{M}_k \triangleq \mathbf{P}_k^T \mathbf{P}_k \qquad k = 1, \cdots, n \tag{11}$$

$$\mathbf{R}_k \triangleq I - \mathbf{P}_k \mathbf{M}_k^{-1} \mathbf{P}_k^T \qquad \mathbf{R}_0 \triangleq I \tag{12}$$

where $\mathbf{P}_k^T \in \Re^{N \times k}$ contains the first $k$ columns of the regression matrix $\mathbf{\Phi}$ in (2).

By substituting (12) into (4), the cost function becomes

$$J(\mathbf{P}_k) = \mathbf{y}^T \mathbf{R}_k \mathbf{y} \tag{13}$$

At this forward stage, the RBF centres are optimized one at a time, and given by the best solution from the entire population of the heuristic methods after several iterations. Suppose at the $k^{th}$ step, one more centre $\mathbf{p}_{k+1}$ is to be added. The net contribution of $\mathbf{p}_{k+1}$ to the cost function can then be calculated as [14]:

$$\Delta J_{k+1}(\mathbf{P}_k, \mathbf{p}_{k+1}) = \frac{(\mathbf{y}^T \mathbf{p}_{k+1}^{(k)})^2}{\mathbf{p}_{k+1}^T \mathbf{p}_{k+1}^{(k)}} \tag{14}$$

where $\mathbf{p}_{k+1}^{(k)} \triangleq \mathbf{R}_k \mathbf{p}_{k+1}$. According to [14], an auxiliary matrix $\mathbf{A} \in \Re^{n \times n}$ and a vector $\mathbf{b} \in \Re^{n \times 1}$ need to be defined to reduce the computational complexity. Their elements are given by:

$$a_{i,j} \triangleq (\mathbf{p}_i^{(i-1)})^T \mathbf{p}_j, \quad 1 \le i \le j \tag{15}$$

$$b_j \triangleq (\mathbf{p}_j^{(j-1)})^T \mathbf{y}, \quad 1 \le j \le n \tag{16}$$

where $(\mathbf{p}_j^{(0)} = \mathbf{p}_j)$. The efficiency of the this forward stage then follows from updating these terms recursively as:

$$a_{i,j} = \mathbf{p}_i^T \mathbf{p}_j - \sum_{l=1}^{i-1} a_{l,i} a_{l,j} / a_{l,l} \tag{17}$$

$$b_j = \mathbf{p}_j^T \mathbf{y} - \sum_{l=1}^{j-1} (a_{l,j} b_l) / a_{l,l} \tag{18}$$

By substituting (15) and (16) into (14), the net contribution of a new RBF centre $\mathbf{p}_{k+1}$ to the cost function can then be expressed as:

$$\Delta J_{k+1}(\mathbf{p}_{k+1}) = \frac{b_{k+1}^2}{a_{k+1,k+1}} \tag{19}$$

In heuristic methods, (19) provides the formula to evaluate each solution in the population. For instance, the selection of local best and global best particles in PSO or the selection between trial vector and target vector in DE.

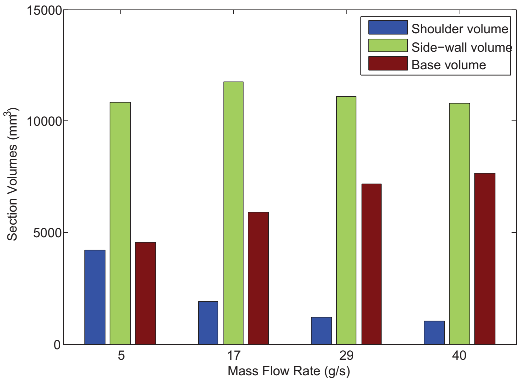

Fig. 1. Effect of mass flow rate on the section volumes (The other three parameters were kept constant, and set as Pressure = 10bar, Temperature = 100°C, Timing = 50ms

### B. Second stage - backward network refinement

The model from the first stage is not optimal due to the correlations between selected terms, that is the prior selected centres introduced a constraint on the latter selections. This second stage is therefore adopted to eliminate such constraint and replace any insignificant centres by new one generated from the population. Clearly, the last selected centre in the forward construction has always been maximally optimized for the whole network, the backward refinement can be divided into two main steps: Firstly, a selected centre $\mathbf{p}_k$, $k = 1, \cdots, n-1$ is shifted to the $n^{th}$ position as if it were the last selected one; then the optimization is implemented to find an alternative centre at the $n^{th}$ position based on the re-ordered $n-1$ centres. If the shifted one is less significant than the new centre from the population it will be replaced, leading to a reduced training error and potential improvement in the generalisation capability. This review is repeated until a pre-defined number of check loops is reached. The detailed algorithm and its computational analysis can be found in [13].

## V. Experimental results

According to table I, a total number of 144 experiments need to be carried out to generate the required data. However, running these experiments and measuring the section weights are practically difficult. Therefore, a manufacturing simulation software, known as ABAQUS/standard version 6.10 [2], was adopted as a substitute of the real process. Each simulation lasted around 20 minutes, and when all finished, four experiments were regarded as failure with their associated results being removed from the final data set. For the remaining 140 data points, 100 were used for RBF model training, and another 40 were reserved for model validation. The effect of mass flow rate is illustrated in Fig. 1 while other three parameters were kept constant.

The two-stage selection algorithm integrated with PSO, DE, and ELM was then applied on the training data. For heuristic optimization methods, their algorithm parameter settings are shown in table II. From the implementation, it is found that

TABLE II
PARAMETER SETTINGS FOR THE HEURISTIC APPROACHES (THE INITIAL CENTRE VECTORS WERE RANDOMLY SELECTED FROM THE TRAINING DATA)

| Method | Parameter | Value | Description |
|---|---|---|---|
| PSO | $\mathbf{x}_i$ | $[c_i; \sigma_i]$ | $i^{th}$ particle in the swarm |
| | $\sigma_i$ | $\in [0.1, 4]$ | Range of the width of $i^{th}$ RBF centre |
| | $S$ | 20 | Number of particles |
| | $G$ | 30 | Number of updating cycles |
| | $w_0$ | 0.8 | Inertia weight in velocity updating |
| DE | $\mathbf{x}_i$ | $[c_i; \sigma_i]$ | $i^{th}$ solution vector in the population |
| | $\sigma_i$ | $\in [0.1, 4]$ | Width of $i^{th}$ RBF centre randomly generated from the specified range; if $\sigma_i < 0$ in the mutation step, $\lvert\sigma_i\rvert$ is used |
| | $S$ | 10 | Population size |
| | $G$ | 20 | Maximum number of generations |
| | $F$ | 0.8 | Weight of vector difference |
| | $C_r$ | 0.6 | Crossover constant |
| ELM | $\sigma_i$ | $\in [0.1, 4]$ | Width of $i^{th}$ RBF centre randomly generated from the specific range; |

TABLE III
COMPARISON OF BOTTLE SHOULDER VOLUME MODELLING PERFORMANCES (RMSE)

| Algorithm | Model size | Training error | Test error |
|---|---|---|---|
| PSO+FRA | 4 | 0.2395 | 0.2770 |
| PSO+TSS | 4 | 0.1687 | 0.1998 |
| DE+TSS | 4 | 0.1780 | **0.1869** |
| ELM+TSS | 4 | 0.2531 | 0.2784 |
| | | | |
| PSO+FRA | 5 | 0.2333 | 0.2319 |
| PSO+TSS | 5 | 0.1441 | 0.1575 |
| DE+TSS | 5 | 0.1448 | **0.1216** |
| ELM+TSS | 5 | 0.2354 | 0.2408 |
| | | | |
| PSO+FRA | 6 | 0.1791 | 0.1972 |
| PSO+TSS | 6 | 0.1297 | **0.1272** |
| DE+TSS | 6 | 0.1089 | 0.1293 |
| ELM+TSS | 6 | 0.1896 | 0.2261 |

the increase of swarm size normally affects the performance more than the increase of updating cycles in PSO, while in differential evolution, these two control parameters have the similar effects.

The resultant RBF models are usually evaluated by the Root Mean Squared Error (RMSE) on validation data, table III - V illustrate such performances under different algorithms. Due to the stochastic characteristics in heuristic optimization, the best results from five runs are chosen for comparison. The fast recursive algorithm (first stage of TSS) usually gives worse results than the TSS alternative, so it was only tested in the modelling of bottle shoulder volume. The results also indicate that DE works better than PSO in the shoulder volume modelling. However, PSO outperforms DE in the other two section volume modelling. Extreme learning machine is definitely the most efficient methods which runs much faster than PSO or DE, however the corresponding model performances are less favourable. The prediction of bottle base volume is also shown in Fig. 2, while the associated RBF model parameters are given in table VI.

## VI. CONCLUSION AND FUTURE WORK

Injection stretch-blow moulding is a typical process to produce plastic bottles in the industry. The process is usually controlled by several adjustable parameters, such as the mass flow rate, blow pressure and preform temperature. The quality of resultant bottles can be measured by its top loads, or the section weights distribution. Due to the lack of closed-loop control, large variations can be observed on the quality indicators.

Section weights are found to be the most prospective variable for feed-back control, but cannot be measured directly in a typical process. Thus, a soft-sensor approach based on

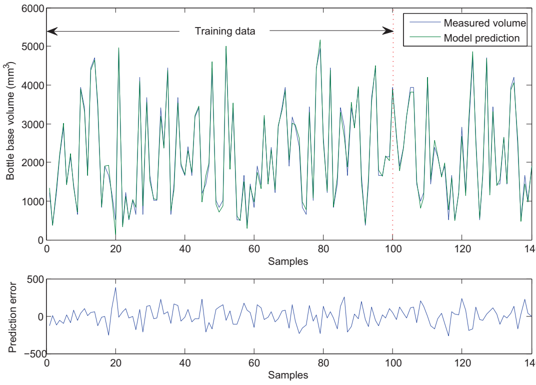

Fig. 2. The bottle base volume model prediction by TSS+PSO (5 hidden nodes were used, the first 100 samples show the training performance while the rest 40 points are model prediction)

an inferential mathematical model becomes an affordable alternative for control implementation. This paper uses a radial basis function network model to predict the bottle section weights. The main issue involved in RBF model construction is the determination of non-liner parameters in the hidden nodes. As the gradient-based approaches require large computational effort, heuristic optimization methods, such as particle swarm optimization, deferential evolution, and extreme learning machine become appropriate alternatives. In this paper, these heuristic optimization methods are effectively integrated with our recently proposed two-stage subset selection algorithm, leading to an efficient RBF model construction algorithm. Experimental results on simulation data has successfully verified the effectiveness of the proposed method. Future work will use practical data to build the models and implement iterative learning control for the ISBM process based on the soft-sensors.

*Abstract*—**Congestion is a problem in real networks. Users do not want to lose information and data should be delivered as fast and reliably as possible. This is really difficult to achieve. Moreover, networks work in changing environments: number of users, type of traffic, delays in transmission, etc. So this paper presents how to design PID controllers that take network changes into account. Non-linear simulations using ns-2 will show the goodness of the approach when compared with classical PID, drop tail and RED.**

## I. INTRODUCTION

Internet is very important in our society. Information, images, videos and data are transmitted from one place to another in a matter of seconds. Nevertheless, there are problems in transmission that affect the quality of the process. Congestion is one of the most annoying obstacles ([1], [2]). It is important to detect this and to act as fast as possible to solve it. Thus, techniques to reduce congestion are of great interest. There are two basic approaches ([3], [4]): c*ongestion control,* which is used after the network is overloaded, and c*ongestion avoidance,* which takes action before the problem appears.

Feedback control can help to solve congestion control. The end-to-end transmission control protocol (TCP), and the active queue management (AQM) scheme define the two parts implemented at the routers' transport layer where congestion control is carried out. The AQM objectives ([5]) are: to minimize the occurrences of queue overflow and underflow, to minimize the time required for a data packet to be serviced by the routing queue and to maintain closed-loop performance in spite of changing conditions (robustness).

AQM schemes enhance the performance of TCP, although they do not work perfectly in every traffic situation. Numerous algorithms have been proposed (a good survey can be found in [4]). RED [6] is the basic algorithm used for comparison. It can detect and respond to long-term traffic patterns, but it cannot detect congestion caused by short-term traffic load changes. The most widely used AQM mathematical models were published in [4]. Since then, several control approaches have been applied, such as fuzzy, predictive control or robust control. The automatic control techniques that have received most attention are the PI controller, followed by the PID ([5]).

AQM techniques should be robust and give good results when the network is not operating in a nominal situation, when the delays are changing, or the number of users or the intensity of the packets' flow vary. So the AQM congestion control algorithm should be robust, stable and do better in a changing environment. If PID is chosen as the AQM algorithm, there are many useful references in the literature ([7]-[9]). These works do not consider what happens with the tuning when the traffic conditions change. They explicitly consider delays in the design of the PIDs and this is the situation that arises when working with networks: a system with delay.

Motivated by these issues, this paper presents how to derive PIDs, with guaranteed stability and robustness, which perform well in a network with changing traffic conditions. The work presented in this paper applies the generic method by [7] for finding stable PID controllers for time delay systems to the dynamic TCP/AQM router model. A linear gain scheduling is included in the design (reducing the gain variation) to enhance the robustness and ensure an adequate behaviour in extreme working scenarios. A similar approach was described in [10], but further study has shown that it can be simplified, as shown in this paper. The metrics applied to study the controller performance are: the router queue size, the link utilization and the probability of packet losses.

Non-linear simulations with ns-2 will show the performance of the technique by applying it to a problem of two routers connected in a Dumbbell topology, which represents a single bottleneck scenario. A comparison between the new PID, a classic PID and the RED approach is performed.

This paper is organized as follows. Section II briefly describes the TCP NewReno modeling. Section III describes a fluid model for the system. Next, the gain scheduling PID, classic PID and RED are explained and their methodology is described. Simulation results are shown in section V. Finally, some conclusions are presented.

## II. TCP/IP Network Modelling

### A. TCP/IP NewReno dynamic model

Now, the TCP/IP NewReno network dynamics is presented. The dynamics of an AQM router are complex due to the number of variables that come into play: packet sources, protocols, etc. Nevertheless, it is possible to obtain a nonlinear model that represents the dynamics of the system ([4]), considering that the protocol used is TCP. The model relates to the average value of the network variables and is described by the following coupled, nonlinear differential equations:

$$\dot{W}(t) = \frac{1}{R(t)} - \frac{W(t)}{2}\frac{W(t-R(t-R(t)))}{R(t-R(t))}p(t-R(t))$$

$$\dot{q}(t) = \begin{cases} -C + \dfrac{N_{TCP}(t)}{R(t)}W(t), & q > 0 \\ \max\left\{0,\ \ -C + \dfrac{N_{TCP}(t)}{R(t)}W(t)\right\}, & q = 0 \end{cases},$$

(1)

where

$W$: average TCP window size (packets),

$\dot{q}$ : average queue length (packets),

$R$: round-trip time = $q/C+T_p$ (secs),

$C$: link capacity (packets/sec),

$T_p$: propagation delay (secs),

$N_{TCP}$: load factor (number of TCP sessions) and

$p$: probability of packet mark.

As explained in [4], the first differential equation in (1) describes the TCP window control dynamic, and the second equation models the bottleneck queue length, as an accumulated difference between the packet arrival rate and the link capacity. The queue length and window size are positive, bounded quantities, i.e., $q \in [0,\bar{q}]$ and $W \in [0,\overline{W}]$, where $\bar{q}$ and $\overline{W}$ denote buffer capacity and maximum window size, respectively. In this formulation, the congestion window size $W(t)$ is increased by one every round-trip time if no congestion is detected, and is halved when congestion is detected.

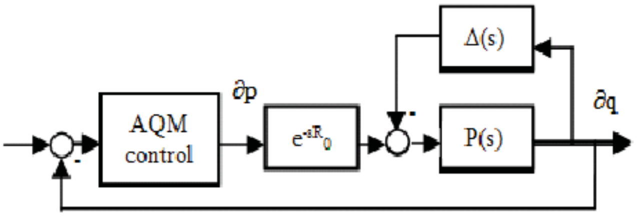

Fig. 1. Block diagram of AQM as a feedback control system

### B. Linearized model

Although an AQM router is a non-linear system, in order to analyze certain types of properties and design controllers, a linearized model is used. To linearize (1), it is assumed that the number of active TCP sessions and the link capacity are constant, i.e., $N_{TCP}(t)= N$ and $C(t)=C$.

The dependence of the time delay argument $t-R$ on queue length $q$ is ignored ([4]) and it is assumed to be fixed at $t-R_0$. This is a big assumption and there will be situations where it may not be acceptable. In [11], the authors deduced that this is a good approximation when the round-trip time is dominated by the propagation delay. This occurs when the capacity $C$ is large. $R_0$ should be chosen such that the above hypothesis can be ensured, so a value that works in the worst case scenario should be advisable. When the model is linearized, the same supposition is made. It cannot be denied that calculations are significantly simplified, but further research in the matter would be advisable. Local linearization of (1) around the operating point results in the following differential equations:

$$\left.\begin{aligned} \partial\dot{W}(t) &= -\frac{N}{R_0^2 C}(\partial W(t) - \partial W(t-R_0)) \\ &\quad - \frac{1}{R_0^2 C}(q(t) - \partial q(t-R_0)) - \frac{R_0^2 C}{2N^2}\partial p(t-R_0) \\ \partial\dot{q}(t) &= \frac{N}{R_0}\partial W(t) - \frac{1}{R_0}\partial q(t) \end{aligned}\right\}, \quad (2)$$

where $\partial\dot{W}(t) = W - W_0$ , $\partial q = q - q_0$ and $\partial p = p - p_0$ , represent the perturbed variables. The operating point for a desired equilibrium queue length $q_0$ is given by:

$$R_0 = \frac{q_0}{C} + T_p\,,\ W_0 = \frac{R_0 C}{N_{TCP}} \text{ and } p_0 = \frac{2}{W_0^2}. \qquad (3)$$

The linearized model (2) can be rewritten by separating the low frequency ('nominal') behaviour $P(s)$ of the window dynamic from the high frequency behaviour Δ(s) which is considered as parasitic.

$$P(s) = \frac{C^2/(2N_{TCP})}{\left(s + (2N_{TCP})/(R_0^2 C)\right)\left(s + 1/R_0\right)},$$

$$\Delta(s) = \frac{2N_{TCP}{}^2}{R_0 C^3}\left(1 - e^{-R_0 s}\right)$$

(4)

Taking (4) as a starting point, Hollot et al. (2002) give a feedback control description of AQM (Fig. 1). The action implemented by an AQM control law is to mark packets with a discard probability $p(t)$, as a function of the measured queue length $q(t)$. The larger the queue, the greater the discard probability becomes.

## III. Design of AQM Controllers

This section introduces the control formulation of an AQM router and how RED, classic PID and the gain scheduling PID can be applied. The latter will be described in depth, as it is the approach that outperforms the other two.

### A. AQM as feedback control

Taking (4) as the starting point, [5] gives a feedback control system of AQM (Figure 1). The action of an AQM control law is to mark packets with probability *p*, as a function of the measured queue length *q*. Following (4), the transfer function Δ(s) denotes the high-frequency window dynamics and *P(s)* (plant dynamics) relates how *p* dynamically affects *q*.

### B. AQM using RED

Random Early Detection (known as RED) was presented in [6]. A RED gateway calculates the average queue size, using a low-pass filter with an exponential weighted moving average. The average queue size is compared to two thresholds (minimum and maximum). When the average queue size is less than the minimum threshold, no packets are marked. When the average queue size is greater than the maximum threshold, every arriving packet is marked. If marked packets are in fact dropped, or if all source nodes are co-operative, this ensures that the average queue size does not significantly exceed the maximum threshold. When the average queue size is between the minimum and the maximum threshold, each arriving packet is marked with probability *p*, where *p* is a function of the measured queue length *q*.

RED does not work with a proper reference, set-point. As explained in [7], RED introduces a range of reference input values, rather than a proper set-point. We will use it as a classic AQM algorithm for the sake of comparison.

### C. AQM using PID control

PID controllers [5] are the most common form of feedback. They can be described by (5). This is the classic formulation.

$$\begin{aligned} u(t) &= K_p\left(e(t)+\frac{1}{T_i}\int_0^t e(\tau)d\tau + T_d\frac{de(t)}{dt}\right) \\ &= K_p e(t) + K_i\int_0^t e(\tau)d\tau + K_d\frac{de(t)}{dt} \end{aligned} \qquad (5)$$

### D. AQM using gain scheduling PID controller

This subsection presents the approach that has been followed to deal with the AQM congestion control problem in a network working with TCP Newreno (it should be noted that the approach can be applied to other TCP variants, [12]) under varying traffic. There are parameters, such as the link capacity *C*, which do not usually change, but the round trip delay, $R_0$, and the number of users, $N_{TCP}$, frequently vary.

The proposed technique is simple, but works well in networks with a wide range of users and varying delays. As network traffic changes constantly, this affects the performance of the system. We tune the PID for a certain set of conditions, but they change. The method proposed here will improve the router's performance no matter how many users or delay there may be in the network.

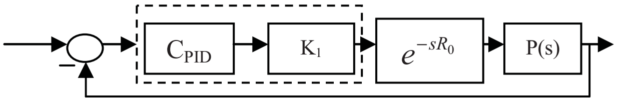

Figure 2: Block diagram of the AQM feedback control system

The PID is tuned following a model-based approach, taking as its starting point the linearized dynamic model of TCP described in the previous section. Figure 2 depicts the block diagram corresponding to the feedback control approach followed in the paper: P(s) is the transfer function obtained in the previous section. The delay $e^{-sR_0}$ is explicitly considered in the design. There are two elements in the controller C(s):

- $C_{PID}(s)$ is a PID controller and
- $K_1$ is a variable gain; a simple gain scheduling that allows the controller to work satisfactorily in a broad range of situations.

The steps in the design are:

- Choose the worst network scenario in terms of $N_{TCP}$ and $R_0$: i.e., the biggest delay and the smallest number of users.
- Choose the best network scenario in terms of $N_{TCP}$ and $R_0$: i.e., the smallest delay and the biggest number of users.
- Design a controller $C_{PID}(s)$ that is stable in these two situations and the scenarios in between.
- Add a simple gain scheduling $K_1$ to improve the system's response, based on the expected variations of the system's gain.

We have chosen the PID controller (6) as the basic AQM congestion control algorithm, as it is the most common form of feedback control technique. The PID should be tuned to be stable in the above mentioned situations. It is also required to have good responses in terms of settling time and overshoot. Taking this into account, the tuning of the controller is done following the method presented in [7]. It is relevant to note that the system can be of any order and the roots can be real or complex. Using the provided Matlab toolbox, a three dimensional region is obtained. If $K_p$, $K_i$ and $K_d$ are chosen inside this region, the closed-loop response is stable.

The simple gain scheduling approach that we propose takes into consideration the big gain variation that the AQM dynamic model has:

$$\frac{-C^2}{2N} \qquad (7)$$

Moreover, if a fair comparison among all the network configurations is to be done, the open-loop gain of the systems should be the same, so the independent term of the denominator of the transfer function should be included:

$$\frac{2N}{C\cdot R_0^3} \qquad (8)$$

This term greatly affects the size of the stable region and the magnitude of the PID's tuning parameters (as will be shown in next section). So we take out this term from P(s) and calculate the stable region for:

$$P_{normalized}(s)=P_n(s)=\frac{1}{s^2+a\cdot s+1},\qquad a=\frac{2N}{R_0^2C}+\frac{1}{R_0} \tag{9}$$

And:

$$\begin{aligned} P(s)&=\frac{-\dfrac{C^2}{2N}}{\dfrac{2N}{C\cdot R_0^3}}P_n(s)\\ &=-\frac{C^3R_0^3}{4N^2}P_n(s) \qquad (10)\\ &=P_{cte}\cdot P_n(s) \end{aligned}$$

So, the gain scheduling term is given by (11).

$$K_1=-\frac{4N^2}{C^3R_0^3} \tag{11}$$

It is important to choose the worst and best scenarios properly. A good knowledge of the network is required. Section IV defines the network parameters. The stable regions are depicted and the PID tuned. Then linear and non-linear simulations will show the goodness of the method.

## IV. Simulations

This Section presents how the new PID is tuned. A comparison between the proposed approach and a classical PID is shown using a linear simulation. Finally, ns-2 is used to test the new controller and to compare it with a classical PID and the AQM/RED congestion control technique.

### A. *Tuning the Controller*

The basic network topology, used as an example to test the controller, is depicted in Figure 3. It is a typical, single bottleneck topology. Although the network capacity C could change, its adjustments are more related with network updates than with everyday traffic conditions. The different scenarios come from changing the number of users (*N=N<sub>TCP</sub>*) and the round trip time (*R<sub>0</sub>*) (see Table I). For each of the values in Table 1, the link capacity takes two values: 1875 and 940 packets/sec.

TABLE I.

|  | N | $R_0$ | Results (Fig. 4) |
|---|---|---|---|
| Case 1 | 100 | 0.5 | Red |
| Case 2 | 150 | 0.4 | Green |
| Case 3 | 40 | 0.9 | Blue |
| Case 4 | 60 | 0.24 | Yellow |

The situations deal with a broad range of conditions: few users and big delay, many users and small delay and in-between situations. In [13] and [14], the effect of N and $R_0$ on the size of the controller's stability region was studied. They concluded (and our experiments also agree) that the smallest stability region is obtained for the smallest number of users (N) and the minimum round trip delay ($R_0$)

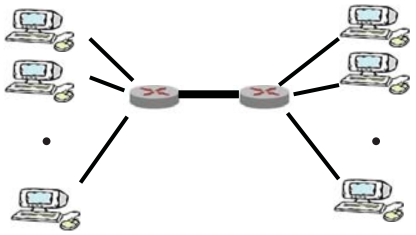

Figure 3: Dumbbell topology

Figure 4 shows the open loop poles of the system, without considering the delay. The lower graph depicts the open loop poles and zeros if a Padé approximation of first order is used for the delay of each of the scenarios.

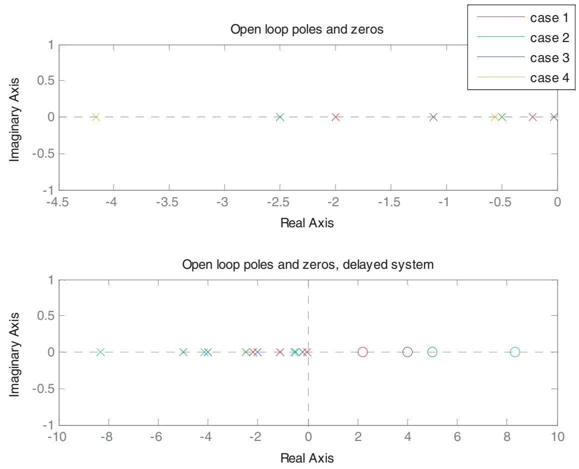

Figure 4: Open loop poles and zeros

The open loop step response for each of the studied scenarios of the original linear system (*P(s)*) and the normalized one (*P<sub>n</sub>(s)*) are shown in Figure 5 (upper and lower, respectively). Both systems have the same settling time, but the behaviour will be very different once the loop is closed. Case 3 gives the slowest open loop response (settling time: 150 sec.) and case 4 gives the fastest (settling time: 7.53 sec.).

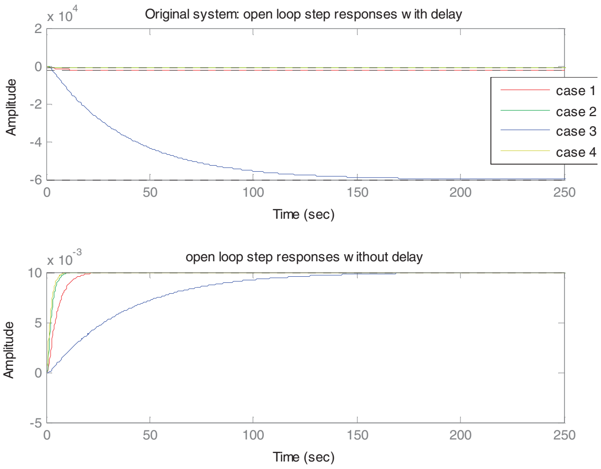

Figure 5: Step responses

TABLE II. PID PARAMETERS

| | Normalized | Standard |
|---|---|---|
| Kp | 1.2 | -0.000006 |
| Ki | 0.2 | -0.0000012 |
| Kd | 0.05 | -0.00000432 |

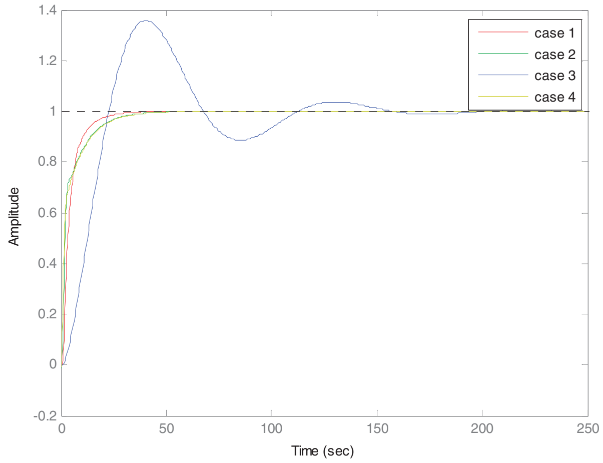

Figure 8: Closed-loop step response with proposed method

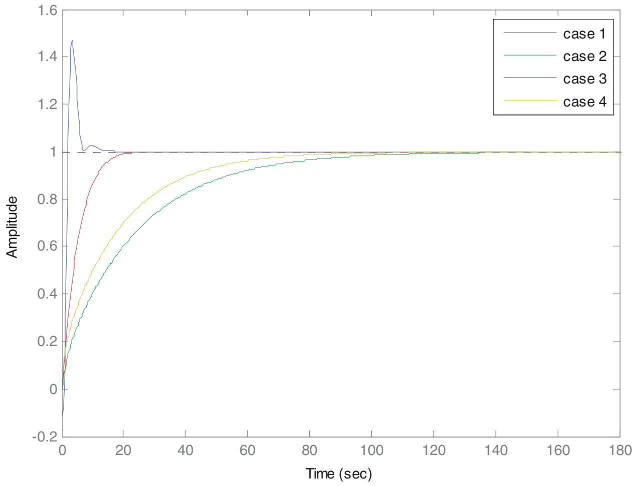

Figure 9: Closed-loop step response with classical approach

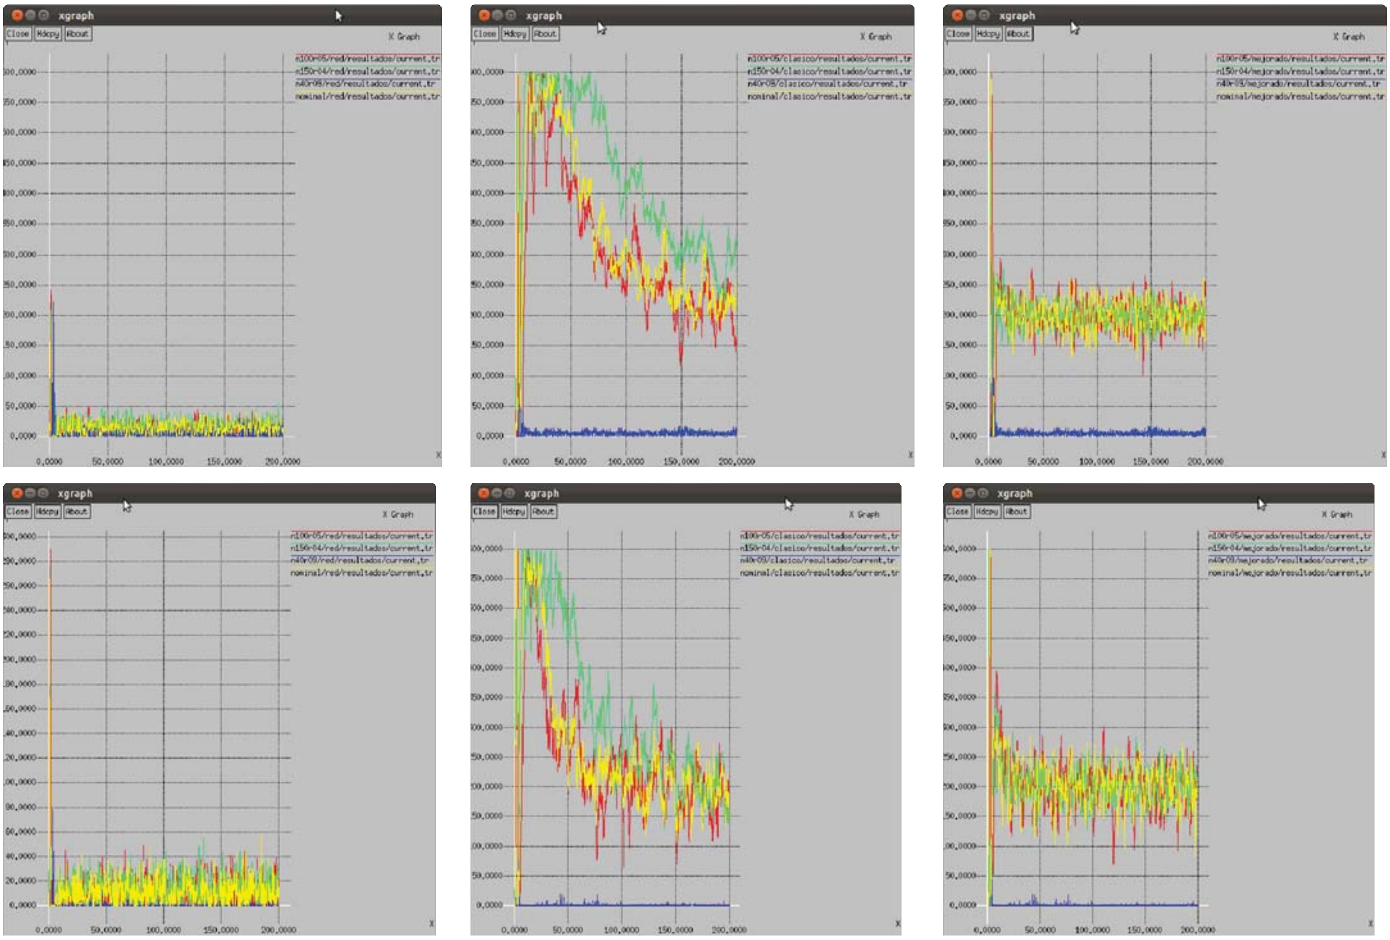

Figure 10: Non-linear simulations in ns-2

Using the approach in [7], a PID is tuned for both linear systems (Table II). The closed loop for these settings is stable for both approaches: the classical and the one presented in the paper. This system has negative gain. With the new PID, the sign is included in the gain scheduling, but the classic PID should be taken into account.

### B. Linear Simulations

Figures 8 and 9 show the closed loop step response of the normalized and classical systems. The proposed PID greatly improves the response when the network deals with cases 1, 2 and 4. Case 3 results are slower than when the classical approach is used.

### C. Non-linear simulations

This sub-section shows a comparison between the PID proposed in the paper, a classical PID and RED. Table I summarizes the different network parameters that have been used. The PIDs have been tuned as in Table II. RED minimum and maximum thresholds are set to 180 and 220, respectively.

Figure 10 depicts the results of the non-linear simulations that have been carried out using the very well known ns-2. The results with the link capacity C set to 1875 packet/sec are shown in the first row of Figure 10. The second row depicts the results when C=940 packets/sec. In both cases the reference is set to 200 packets, i.e., the queue at the router should take this value. The simulation lasts 200 seconds. The first column illustrates the RED algorithm; the classic PID is in the second column and the results of the gain scheduling discussed in the paper correspond to the third column.

The experiment has been carried out for the four scenarios described at the beginning of this section. The RED algorithm cannot deal properly with the requirements. This is logical because this technique is not intended for following a reference. Packets are marked following the steps described in Section III.

The classic PID gives good results, but it is slow. If C=940 packets/sec., the queue does not reach the reference value at any of the scenarios until t=150 sec. This would be almost unacceptable in a real network. When, in case 3 (blue line), the link is not congested, no packets are queued at the router.

Finally, the gain scheduling PID gives the best results. The response is very fast and there is almost no difference (in terms of settling time or final value) for any of the scenarios. As in the classic PID approach, when N=40 and the delay is 0.9 sec., the link is not congested. Results are very promising and further tests would give us a better insight.

## V. Conclusion

This paper has presented a comparison between a PID with linear gain scheduling and normalized values, a classic PID and an AQM/RED algorithm using the non-linear simulation environment ns-2. The controller is tuned for the worst scenario and works properly in a wide range of situations.

The main goal was to show that when traffic network changes and the delay, the number of users or the link's capacity are not the nominal values, the controller gives good results. The proposed PID outperforms the other approaches, as linear and non-linear simulations confirm.

The technique presented in the paper gives more uniform results than the classical approach. It does not matter if the scenario is close to the nominal situation or if it is a worst case setting, the controller reacts adequately and the settling times are all of the same order, whereas the classic approach cannot deal well with extreme situations. The RED algorithm gives the worst results of the three.

Future work will include testing the technique in a network with more congested routers.

*Abstract*—**An output feedback model reference adaptive controller is developed for a class of linear systems with multiple unknown time-varying state delays and in the presence of actuator failures. The adaptive controller is designed based on SPR-Lyapunov approach and is robust with respect to multiple unknown time-varying plant delays and to an external disturbance with unknown bounds. Closed-loop system stability and asymptotic output tracking are proved using suitable Lyapunov-Krasovskii functional and Simulation results are provided to demonstrate the effectiveness of the proposed controller.**

***Keywords- Robust adaptive control, Output feedback, Actuator failure, State delay systems.***

## I. INTRODUCTION

Component failures occur in many practical systems and may cause performance deterioration and catastrophic accidents. There have been many studies in the literature on control of systems with component failures [1]-[11]. In these papers, different design methods including multiple model, switching and tuning designs, fault detection and diagnosis designs, robust control designs and adaptive designs are used. Compared to other approaches, the direct adaptive control approach has the key advantage that it can provide theoretically provable asymptotic tracking in addition to stability, in the presence of large parameter variation and uncertainties. Important results for direct adaptive control of systems with actuator failures exist in [8]-[11].

Delay phenomena are frequently encountered in mechanics, physics, applied mathematics, biology, economics and engineering systems. In the presence of time delay, the design of fault tolerant controller becomes more complex. Therefore, the problem of fault tolerant adaptive control of delay systems has received little attention. For example, in [12] a fault detection and accommodation method is considered for nonlinear state delay systems, based on an iterative design of an observer which monitors the variations of the system dynamics and the control signal is formed by treating component failures as uncertainties. In [13] and [14], state feedback controllers are developed within the framework of Linear Matrix Inequalities for a class of linear systems with time delay in control inputs and constant actuator failures of stuck-type. A direct state feedback adaptive control scheme is introduced in [15] for linear state delay systems with unknown plant dynamics and unknown constant stuck failures in actuators. The same problem is solved for decentralized systems in [16]. Based on a linear matrix inequality technique and an adaptive method, [17] suggests adaptive reliable controllers against loss of effectiveness unknown actuator failures, but with the assumption that the system parameters are known.

In a recent work [18], an output feedback adaptive controller is designed for state delay systems with unknown parameters and unknown constant failures of stuck-type. To the best knowledge of authors, it is the first output-feedback model reference adaptive controller for compensating actuator failures in time delay systems. In this study, a new controller structure is developed to have robustness with respect to an external bounded disturbance with unknown bounds in addition to multiple unknown time-varying plant delays.

## II. PROBLEM FORMULATION

In this section, the control problem is formulated. Consider a linear state delay plant described by

$$\begin{aligned}&\dot{x}(t)=Ax(t)+Bu(t)+\sum_{l=1}^{M}A_{dl}x(t-d_l(t))+b_f f(t),\\&x(\theta)=x_0,\ \ \theta\in[-d_{\max},0]\\&y(t)=cx(t)\end{aligned}\tag{1}$$

where $x(t)\in\Re^n$ is the state vector, $y(t)\in\Re$ is the plant output and $u(t)=[u_1,...,u_m]^T\in\Re^m$ is the input vector whose elements may fail during system operation. $f(t)\in\Re$ is the external disturbance with $|f(t)|\le f^*$ . The constant matrices $A\in\Re^{n\times n}$ , $A_{dl}\in\Re^{n\times n}$, $l=1,...,M$ and $B=[b_1,...,b_m]\in\Re^{n\times m}$ and the vectors $c\in\Re^{1\times n}$ and $b_f\in\Re^{n\times 1}$ are unknown. The time delays $d_l(t)$ are nonnegative differentiable functions, satisfying

$$0 \le d_l(t) \le d_{\max}, \qquad \dot{d}_l(t) \le \bar{d} \; < 1, \quad l = 1,...,M \tag{2}$$

where $d_{\max}$ and $\bar{d}$ are some unknown positive constants.

In this paper, one important type of actuator failure modeled as

$$u_j(t) = \bar{u}_j, \qquad j \in \{1,2,...,m\} \tag{3}$$

is considered, where the constant values $\bar{u}_j$ and the failure time instants $t_j$ are unknown. With this type of actuator failure, the input $u(t)$ is defined as

$$u(t) = v(t) + \sigma(\bar{u} - v(t)) \tag{4}$$

where $\bar{u} = [\bar{u}_1,...,\bar{u}_m]^T$,

$$\sigma = diag\{\sigma_1, \sigma_2,...,\sigma_m\}, \quad \sigma_i = \begin{cases} 1, & u_i(t) = \bar{u}_i \\ 0, & u_i(t) \ne \bar{u}_i \end{cases}$$

and $v(t)$ is an applied control input to be designed. For this important type of actuator failure it is a basic assumption that [8]:

(A1)- If the system parameters and actuator failures (up to $m-1$ failures) are known, the remaining actuators can still achieve a desired control objective.

The adaptive control objective is to determine an output feedback $v(t)$ for the plant (1) with unknown parameters and unknown actuator failures (3) such that despite the control error $u - v = \sigma(\bar{u} - v)$, all signals of the closed-loop system remain bounded and the plant output $y(t)$ follows the output $y_m(t)$ of a stable reference model with the transfer function

$$y_m(t) = W_m(s)r(t), \qquad W_m(s) = \frac{1}{D_m(s)} \tag{5}$$

asymptotically; i.e., $\lim_{t\to\infty} e(t) = \lim_{t\to\infty}(y(t) - y_m(t)) = 0$. In the above equation, $D_m(s)$ is a monic Hurwitz polynomial and $r(t)$ is the reference input which is assumed to be uniformly bounded and piecewise continuous.

For simplicity the "equal control" design

$$v_1(t) = v_2(t) = ... = v_m(t) \equiv v_o(t) \tag{6}$$

which assumes that the control inputs to all actuators are the same, is used. It is reasonable in many practical applications.

Consider the transfer function of the system without delay as

$$y(t) = \sum_{j=1}^{m} \frac{k_{pj} N_j(s)}{D(s)} u_j(t), \quad c(sI - A^{-1})b_j = k_{pj} \frac{N_j(s)}{D(s)} \tag{7}$$

where $k_{pj}$ is a scalar, $N_j(s)$ is a monic polynomial and $D(s)$ is a monic polynomial of degree $n$.

With the assumption that $p$ (up to $m-1$) actuators fail and from (4) and (6) the closed-loop system (7) can be expressed as

$$y(t) = W_o(s)v_o(t) + \bar{y}(t) \tag{8}$$

where

$$\bar{y}(t) = \sum_{j=j_1,...,j_p} \frac{k_{pj} N_j(s)}{D(s)} \bar{u}_j(t),$$

$$W_o(s) = \frac{\sum_{j \ne j_1,...,j_p} k_{pj} N_j(s)}{D(s)} \equiv \frac{k_p N_{uf}(s)}{D(s)} = c(sI - A)^{-1} b, \tag{9}$$

$$b = \sum_{j \ne j_1,...,j_p} b_j \;,$$

To achieve control objective, it is assumed that $W_o(s)$ satisfies the following assumptions:

(A2)- $N_{uf}(s)$ is stable for each number of failures.

(A3)- The high-frequency gain $k_p$ has the same sign for each number of failures and $sign[K_r^*] = sign[k_p]$.

(A4)- The relative degree of the transfer function $W_o(s)$ is $n^* = 1$ for each number of failures.

## III. Error Equation

In order to design the adaptive controller, a suitable error equation parameterization is obtained in this section. For this purpose, first consider the system without delay (7) and when the plant parameters and actuator failures are known. The controller structure is defined as

$$\begin{aligned} &v_o^*(t) = K_e^* y(t) + K_1^{*T} x_1(t) + K_2^{*T} x_2(t) + K_r^* r(t) + K_3^*, \\ &x_1(t) = H(s)v_o(t), \;\; x_2(t) = H(s)y(t), \\ &H(s) = \frac{\alpha(s)}{\Lambda(s)}, \end{aligned} \tag{10}$$

in which $\Lambda(s)$ is a monic Hurwitz polynomial of degree $n$, $K_1^* \in \Re^{n-1}, K_2^* \in \Re^{n-1}, K_r^* \in \Re$, $K_e^* \in \Re$ are the parameters of the standard controller structure for MRAC of systems without delay and $\alpha(s) = [1, s, \ldots s^{n-2}]^T$.

In order to drive the error equation, $y(t)$ from (8) is substituted in (10) and the closed-loop system is obtained as

$$\begin{aligned} y(t) = W_o(s)(1 - K_1^{*T} H(s) - K_2^{*T} H(s) W_o(s) \\ - K_e^* W_o(s))^{-1} \times [K_2^{*T} H(s)\bar{y} + K_e^* \bar{y} + K_r^* r + K_3^*] + \bar{y}(t). \end{aligned} \qquad (11)$$

Now suppose that there exist constant matrices $a_{dl}^*$ and $F$ of appropriate dimensions such that

$$A_d = b a_{dl}^{*T}, \quad b_f = bF.$$

Using directly the analysis in [18] and [19], the tracking error $e(t) = y(t) - y_m(t)$ can be written as

$$\begin{aligned} e(t) = \frac{k_p}{D_m(s)}[v_0(t) - K_1^{*T} x_1(t) - K_2^{*T} x_2(t) \\ - K_e^* y(t) - K_3^* + (1 - K_1^{*T} H(s)) F f(t) \\ + \sum_{l=1}^{M} a_{dl}^{*T} x(t - d_l) - K_1^{*T} H(s) \sum_{l=1}^{M} a_{dl}^{*T} x(t - d_l)]. \end{aligned} \qquad (12)$$

To find a suitable error equation parameterization the dynamic system

$$z(t) = \sum_{l=1}^{M} K_1^{*T} H(s)[a_{dl}^{*T} x(t - d_l)] = \sum_{l=1}^{M} K_{zl}^{*T} z_{xl}(t) \qquad (13)$$

is defined in which,

$$\begin{aligned} K_{zl}^{*T} &= [K_1^{*1T} a_{dl}^{*T}, K_1^{*2T} a_{dl}^{*T}, \ldots, K_1^{*(n-1)T} a_{dl}^{*T}], \\ z_{xl}(t) &= H_n(s)[x(t - d_l)], \\ H_n(s) &= \frac{[I_{n\times n} s^{n-2}, \ldots, I_{n\times n} s, I_{n\times n}]}{\Lambda(s)} \in \Re^{n(n-1)\times n}. \end{aligned}$$

By decomposing $z_{xl}(t)$ into two components we have

$$\begin{aligned} z_{xl}(t) &= z_{el}(t) + z_{ml}(t), \\ z_{ml}(t) &= H_n(s)[x_{ml}(t - d_l)], \\ z_{el}(t) &= H_n(s)[e_x(t - d_l)], \\ e_x(t - d_l) &= x(t - d_l) - x_m(t - d_l), \end{aligned} \qquad (14)$$

Using (13) and (14), the error equation (12) can be rewritten as follows

$$\begin{aligned} e(t) = \frac{k_p}{D_m(s)}[v_0(t) - K^{*T} w(t)] - \frac{k_p}{D_m(s)}[K_m{}^{*T} w_m(t) \\ + \sum_{l=1}^{M} K_{dl}{}^{*T} e_x(t - d_l(t)) + \sum_{l=1}^{M} K_{zl}{}^{*T} z_{el}(t) \\ + (1 - K_1^{*T} H(s)) F f(t)] \end{aligned} \qquad (15)$$

where $K_{dl}^* = -a_{dl}^*$ and

$$\begin{aligned} K^* &= [K_e^*, K_1{}^{*T}, K_2{}^{*T}, K_r^*, K_3{}^*]^T, \\ w(t) &= [e, x_1{}^T, x_2{}^T, r, 1]^T, \\ K_m^* &= [K_{x_m}^{*T}, K_d{}^{*T}, K_z^{*T}]^T, \;\; K_{x_m}^* = c_m^T K_e^{*T} \\ w_m(t) &= [x_m^T(t), x_m{}^T(t - d(t)), z_m{}^T(t)]^T. \end{aligned}$$

## IV. Adaptive Controller design

For system with state delays and unknown parameters and actuator failures, the adaptive controller is designed in this section. Using the error equation (17) the controller structure

$$v_0(t) = K^T(t) w(t) - K_I \operatorname{sgn}(e(t)) \int_0^t |e(t)| dt, \qquad (16)$$

is suggested, in which $K(t) = [K_e, K_1{}^T, K_2{}^T, K_r, K_3]^T$ is the estimate of the unknown parameter vector $K^*$ and $K_I$ is a positive constant scalar. This control law is composed of two terms. The first component $K^T(t)w(t)$ has the standard structure for output feedback control of systems with actuator failures [9]. The integral term $K_I \operatorname{sgn}(e(t)) \int_0^t |e(t)| dt$ is used to achieve robustness with respect to unknown plant delays and external disturbance [20].

Introducing the parameter error $\tilde{K}(t) = K(t) - K^*$ and using (16), the tracking error (15) can be expressed as

$$\begin{aligned} e(t) = \frac{k_p}{D_m(s)}[\tilde{K}^T w(t) - K_I \operatorname{sgn}(e(t)) \int_0^t |e(t)| dt] \\ - \frac{k_p}{D_m(s)}[K_m{}^{*T} w_m(t) + \sum_{l=1}^{M} K_{dl}{}^{*T} e_x(t - d_l(t)) \\ + \sum_{l=1}^{M} K_{zl}{}^{*T} z_{el}(t) + (1 - K_1^{*T} H(s)) F f(t)] \end{aligned} \qquad (17)$$

As the usual design method of MRAC for systems without delay, the augmented state vector $\hat{x}=[x^T, x_1^T, x_2^T]^T$ is defined. Let $\hat{e}=\hat{x}-\hat{x}_m$ where $\hat{x}_m(t)$ is the state of a nonminimal realization $\hat{c}(sI-\hat{A})^{-1}\hat{b}K_r^*$ of $W_m(s)$. Then the state space representation

$$\begin{aligned}
\dot{\hat{e}}(t) &= \hat{A}\hat{e}(t)+\hat{b}[\tilde{K}^T(t)w(t)-K_I\,\mathrm{sgn}(e(t))\int_0^t |e(t)|\,dt] \\
&\quad -\hat{b}[K_m^{*T}w_m(t)+\sum_{l=1}^{M} K_{dl}^{*T}L^T\hat{e}(t-d_l(t)) \\
&\quad +\sum_{l=1}^{M} K_{zl}^{*T}C_e\hat{z}_{el}(t)+(1-K_1^{*T}H(s))Ff(t)], \qquad (18)\\
\dot{\hat{z}}_{el}(t) &= A_e\hat{z}_{el}(t)+B_eL^T\hat{e}(t-d_l(t)),\\
z_{el}(t) &= C_e\hat{z}_{el}(t),\\
e(t) &= \hat{c}\hat{e}(t),
\end{aligned}$$

is obtained for (17), where $L=[I_{n\times n}, 0_{n\times(n-1)}, 0_{n\times(n-1)}]^T$ and the triple $(A_e, B_e, C_e)$ is a minimal state space realization for the stable transfer matrix $H_n(s)$.

Because the relative degree is assumed to be one, $W_m(s)=\hat{c}(sI-\hat{A})^{-1}\hat{b}K_r^*$ is SPR. Therefore, according to MKY lemma [21], for any symmetric positive definite matrix $L_c = L_c^T > 0$, there exist a symmetric positive definite matrix $P=P^T>0$, a positive scalar $\upsilon>0$ and a vector $q$ such that

$$\begin{aligned}
\hat{A}^TP+P\hat{A} &= -qq^T-\upsilon L_c,\\
P\hat{b}K_r^* &= \hat{c}^T.
\end{aligned} \qquad (19)$$

Since $A_e$ is stable, there exist symmetric positive definite matrices $P_{zl}=P_{zl}^T>0$ and $Q_{zl}=Q_{zl}^T>0$ that satisfy

$$A_e^TP_{zl}+P_{zl}A_e=-Q_{zl}, \quad l=1,\ldots,M \qquad (20)$$

Now we are ready to state the following theorem.

**Theorem 1:** Consider the system (1) with actuator failures (3) and the reference model (5). Suppose that assumptions (A1) to (A4) hold. Then for any positive number $\gamma$ and positive definite matrix $\Gamma=\Gamma^T>0$, the adaptive control (16) with coefficients

$$\begin{aligned}
\dot{K}(t) &= -\mathrm{sgn}(\rho^*)\Gamma e(t)w(t),\\
K_I &= \gamma\,\mathrm{sgn}(\rho^*),
\end{aligned} \qquad (21)$$

assures that all the closed-loop signals are bounded and the tracking error $e(t)$ converges to zero asymptotically.

**Proof** To prove this theorem, choose the Lyapunov-Krasovskii functional

$$\begin{aligned}
V(t) &= \hat{e}^T(t)P\hat{e}(t)+\sum_{l=1}^{M}\hat{z}_{el}^T(t)P_{zl}\hat{z}_{el}(t)\\
&\quad +\sum_{l=1}^{M}\int_{t-d_l(t)}^{t}\hat{e}^T(s)\upsilon L_c\hat{e}(s)\,ds+\frac{|\rho^*|}{\gamma}(-\gamma\int_0^t|e(t)|\,dt+\eta^*)^2 \qquad (22)\\
&\quad +(\tilde{K}(t)-\hat{K}_1)^T\Gamma^{-1}(\tilde{K}(t)-\hat{K}_1)|\rho^*|
\end{aligned}$$

in which $\gamma>0$ is a constant scalar and $\rho^*=K_r^{*-1}$. The vector $\hat{K}_1$ is defined as $\hat{K}_1=-\frac{r}{2}[\rho^*, 0, \ldots, 0]^T$. The parameters $r>0$ and $\eta^*>0$ with arbitrary values will be defined later.

According to the update law (21) and using (19) and (20), the time derivative of $V(t)$ along (18) is

$$\begin{aligned}
\dot{V}(t) &= -\hat{e}^T(t)qq^T\hat{e}(t)-r\hat{e}^TP\hat{b}\hat{b}^TP\hat{e}\\
&\quad -\sum_{l=1}^{M}\nu(1-\dot{d}_l(t))\hat{e}^T(t-d_l(t))L_c\hat{e}(t-d_l(t))\\
&\quad -\sum_{l=1}^{M}\hat{z}_{el}^T(t)Q_{zl}\hat{z}_{el}(t)-2\sum_{l=1}^{M}\hat{e}^TP\hat{b}K_{dl}^{*T}L^T\hat{e}(t-d_l(t))\\
&\quad -2\sum_{l=1}^{M}\hat{e}^TP\hat{b}K_{zl}^{*T}c_e\hat{z}_{el}+2\sum_{l=1}^{M}\hat{z}_{el}^TP_{zl}B_eL^T\hat{e}(t-d_l(t)) \qquad (23)\\
&\quad -2\hat{e}^TP\hat{b}K_m^{*T}w_m-2\hat{e}^TP\hat{b}K_I\,\mathrm{sgn}(e(t))\int_0^t|e(t)|\,dt\\
&\quad -2|\rho^*||e(t)|(-\gamma\int_0^t|e(t)|\,dt+\eta^*)+2\hat{e}^TP\hat{b}(1-K_1^{*T}H(s))Ff(t)
\end{aligned}$$

for $t\in(T_i, T_{i+1})$, $i=0,1,\ldots,m_0$.

Because $D_m(s)$ and $H_n(s)$ are stable and the reference input $r(t)$ is bounded, the reference signals $x_m(t)$, $x_m(t-d)$ and $z_m(t)$ are bounded. Therefore there exists a constant $w_m^*$ such that $\|w_m(t)\|\le w_m^*$ and the following inequality can be written for the eighth term of (23).

$$\begin{aligned}
-2\hat{e}^TP\hat{b}K_m^{*T}w_m &\le 2|\hat{e}^TP\hat{b}K_r^*||\rho^*|\|K_m^{*T}\|\|w_m\|\\
&\le 2|e(t)||\rho^*|\|K_m^{*T}\|w_m^*
\end{aligned} \qquad (24)$$

By choosing $\eta_1^* = \left\|K_m^{*T}\right\| w_m^*$,

$$-2\hat{e}^T p\hat{b}K_m{}^{*T} w_m \le 2\eta_1^* \left|\rho^*\right|\left|e(t)\right|. \tag{25}$$

For the last term of (23) the following inequality can be written.

$$\begin{aligned} &2\hat{e}^T P\hat{b}(1-K_1^{*T}H(s))Ff(t) \\ &\le \left|e(t)\right|\left|\rho^*\right|\left\|2(1-K_1^{*T}H(s))F\right\| f^* = 2\eta_2^*\left|\rho^*\right|\left|e(t)\right| \end{aligned} \tag{26}$$

According to the known inequality

$$\pm 2x^T y \le x^T Sx + y^T S^{-1} y$$

that is true for any vectors $x, y$ and any positive definite matrix $S$, the following expressions can be written for the fifth, sixth and seventh terms

$$\begin{aligned} &-2\sum_{l=1}^{M} \hat{e}^T p\hat{b}K_{dl}{}^{*T} L^T \hat{e}(t-d_l(t)) \\ &\le \hat{e}^T(t)P\hat{b}\Phi_1\hat{b}^T P\hat{e}(t) + \sum_{l=1}^{M} \hat{e}^T(t-d_l(t))S\hat{e}(t-d_l(t)), \\ &-2\sum_{l=1}^{M} \hat{e}^T p\hat{b}K_{zl}{}^{*T} c_e\hat{z}_{el} \\ &\quad \le \hat{e}^T(t)P\hat{b}\Phi_2\hat{b}^T P\hat{e}(t) + \sum_{l=1}^{M} \hat{z}_e^T S\hat{z}_e, \\ &2\sum_{l=1}^{M} \hat{z}_{el}^T P_{zl}B_e L^T \hat{e}(t-d_l(t)) \\ &\quad \le \sum_{l=1}^{M} \hat{z}_{el}^T\Phi_3\hat{z}_{el} + \sum_{l=1}^{M} \hat{e}^T(t-d_l(t))S\hat{e}(t-d_l(t)), \end{aligned} \tag{27}$$

where

$$\begin{aligned} \Phi_1 &= \sum_{l=1}^{M} K_{dl}{}^{*T} L^T S^{-1} LK_{dl}^* \\ \Phi_2 &= \sum_{l=1}^{M} K_{zl}{}^{*T} c_e S^{-1} c_e^T K_{zl}^* \\ \Phi_3 &= P_{zl}B_e L^T S^{-1} LB_e^T P_{zl}^T. \end{aligned}$$

Using (25), (26) and (27), choosing the coefficient $K_I$ from (21) and defining $\eta^* = \eta_1^* + \eta_2^*$, the inequality

$$\begin{aligned} \dot{V}(t) &\le -\hat{e}^T(t)qq^T\hat{e}(t) \\ &-\sum_{l=1}^{M} \hat{e}^T(t-d_l)(v\,d^* L_c - 2S)\hat{e}(t-d_l(t)) \\ &-\hat{e}^T P\hat{b}(r-\Phi_1-\Phi_2)\hat{b}^T P\hat{e} \\ &-\sum_{l=1}^{M} \hat{z}_{el}^T(t)(Q_{zl}-\Phi_3-S)\hat{z}_{el}(t) \end{aligned} \tag{28}$$

with $d^* = 1-\bar{d}$ is obtained. By choosing the arbitrary values $L_c$, $r$ and $Q_{zl}$ as

$$\begin{aligned} &\lambda_{\min}(vL_c) > \lambda_{\max}(2S), \\ &r > \lambda_{\max}(\Phi_1+\Phi_2), \\ &\lambda_{\min}(Q_{zl}) > \lambda_{\max}(\Phi_3+S) \end{aligned}$$

we have $\dot{V}(t) \le 0$ for $t \in (T_i, T_{i+1})$ , $i = 0,1,\ldots,m_0$.

Since there are only a finite number of failures in system, $V(T_{m_0})$ is finite and from

$$\dot{V}(t) \le 0, \quad t \in (T_{m_0}, \infty) \tag{29}$$

we have $V(t) \in L_\infty$ and therefore $\hat{e}(t)$ , $e(t)$ , $\hat{z}_e(t)$ , $K(t)$ , $\tilde{K}(t) \in L_\infty$. Using directly the analysis method in [21], it can be proved that all the closed loop signals are bounded and $\lim_{t\to\infty} e(t) = 0$. ■

## V. Simulation Example

Consider system (1) with parameters

$$A = \begin{bmatrix} -1 & 0 & 0 \\ 0 & 0.5 & 0 \\ 0 & 0 & -2 \end{bmatrix}, \; B = \begin{bmatrix} 1 & 2 & 1 \\ 1 & 1 & 3 \\ 0 & 0 & 0 \end{bmatrix},$$

$$c = \begin{bmatrix} 1 & 1 & 0.5 \end{bmatrix}, \quad b_f = \begin{bmatrix} 1 & 2 & 0 \end{bmatrix}^T$$

$$A_{d1} = \begin{bmatrix} 0.1 & -0.4 & 0.4 \\ 0.1 & -0.7 & 0.3 \\ 0 & 0 & 0 \end{bmatrix}, \; d_1(t) = 4 + 0.5\sin(t)$$

$$A_{d2} = \begin{bmatrix} -0.2 & 0.1 & 0 \\ 0.4 & 0.1 & -0.4 \\ 0 & 0 & 0 \end{bmatrix}, d_2(t) = 6 + 0.4\sin(t)$$

$$x(0) = \begin{bmatrix} 0.5 & 0 & 0 \end{bmatrix}^T$$

and the external disturbance $f(t) = 0.2\sin(0.5t) + 0.3$ and let the transfer function of the reference model be given by

$$W_m(s) = \frac{1}{s+1}.$$

All parameters of system and the delay value are assumed to be unknown to the controller. Simulation results are obtained with the adaptive control (16) with coefficients (21), reference input $r(t) = \sin(0.2t)$ and by choosing $\Gamma = 10I$, $\gamma = .001$ and $\Lambda(s) = (s+1)^2$, for one and two actuator failure cases, respectively. The results for the case of one actuator failure: $u_1(t) = .5,\ t \geq 50$, are shown in Fig. 1. In Fig. 2, the simulation results are shown for the case when two actuators fail: $u_1(t) = 1,\ t \geq 30, \quad u_2(t) = 0,\ t \geq 70$.

## VI. Conclusion

A robust output-feedback adaptive controller is presented for state delayed systems with unknown parameters and unknown actuator failures. The controller structure is composed of two terms. The first term is defined for compensating actuator failures. The second integral term is used to achieve robustness against unknown delay values and an external disturbance with unknown bounds. The results of this paper can be extended to higher relative degrees using normalized MRAC scheme.

# Invariant Control of Non-Linear Elements in a Stacked High Redundancy Actuator

T. Steffen, R. Dixon, R. Goodall
Department of Aeronautical and Automotive Engineering,
Department of Electronic and Electrical Engineering,
Loughborough University, LE11 3TU, UK

***Abstract*—The High Redundancy Actuator (HRA) concept aims to provide a single actuator comprising many cooperating actuation elements. The potential benefits of this include improved overall reliability, availability, and reduced need for oversizing of actuators in safety critical applications. This paper deals with the question of distributing the load evenly between a stack of elements despite non-linear characteristics.**

**The approach is to separate the state space into a high dimensional internal and a low dimensional invariant (or external) subspace. If the internal states can be decoupled and damped, the input-output behaviour only depends on the few states of the invariant subspace. In other words: the high redundancy actuator with many redundant elements behaves just like a conventional single actuator, and classical control strategies can then be applied.**

**This approach is demonstrated here for an HRA constructed from simple spring-damper-actuator elements. The non-linear behaviour is required to simulate the element behaviour at the end of the available travel. Without equalisation, excessive accelerations are caused by individual elements hitting the end stop, and this can be avoided by applying the proposed element tuning.**

***Index Terms*—electromagnetic actuation, fault tolerance, multi-variable control, non-linear control**

## I. High Redundancy Actuation

High Redundancy Actuation (HRA) is a novel approach for designing a fault tolerant actuator that comprises a relatively large number of actuation elements (see Figure 1). As a result, faults in the individual elements can be inherently accommodated without resulting in a failure of the complete actuator system.[1]

The concept of the High Redundancy Actuation (HRA) is inspired by the human musculature. A muscle is composed of many individual muscle cells, each of which provides only a minute contribution to the force and the travel of the muscle. These properties allow the muscle as a whole to be highly resilient to damage of individual cells. The aim of this project is not to replicate muscles, but to use the same principle of co-operation with existing technology to provide intrinsic fault tolerance.

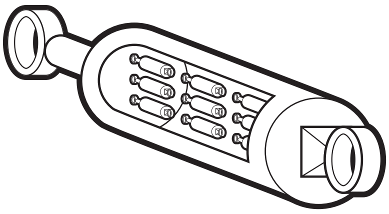

Figure 1. High Redundancy Actuator

An important feature of the High Redundancy Actuator is that the elements are connected both in parallel and in series. While the parallel arrangement is commonly used, the serial configuration is rarely employed, because it is perceived to be less efficient. However, the use of elements in series is the only configuration that can deal with the lock-up of an element. In a parallel configuration, this would immediately render all elements useless, but in the series configuration it only leads to a slight reduction of available travel (see Steffen et al. 2007, 2008a for details).

The paper is organised as follows: it starts with the motivation and background in Section 2, followed by the non-linear model of an actuator stack consisting of elements with a non-linear characteristic in Section 3. The control goal is presented in Section 4, followed by the solution in Section 5. Sections 6 presents a simulation example, and Section 7 proposes an extension for more complex HRA configurations.

## II. Motivation

While the parallel configuration of actuation elements is well established and researched, the dynamic behaviour of elements in series is very different. The

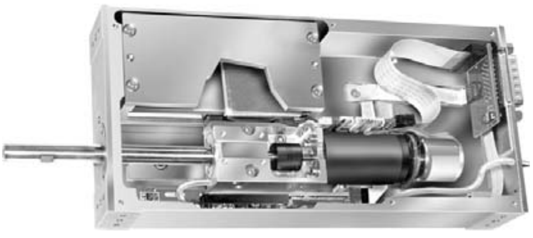

Figure 2. Electromechanical actuator

[1] This project is a cooperation of the Control Systems group at Loughborough University, the Systems Engineering and Innovation Centre (SEIC), and the actuator supplier SMAC Europe limited. The project was funded by the Engineering and Physical Sciences Research Council (EPSRC) of the UK under reference EP/D078350/1.

reason is that between each element in series, there is a moving mass. This creates a high number of mechanical degrees of freedom, in turn leading to a high order dynamic model. The model needs to describe the position and speed of each mass separately, and there may also be further states internal to each element.

For the envisioned number of elements (10x10 or more), this may lead to a model with hundreds of states. Dealing with this complexity constructively is crucial for the success of the high redundancy actuator, because the standard approach of using sophisticated instrumentation may not be suitable. The goal of this paper is to reduce the model and instrumentation complexity to a level comparable to a conventional actuator.

### A. Approach

The basic idea is to split the travel equally between all actuation elements. If this is achieved, the states of the elements are no longer individual variables, and they can all be reduced into a single simple model. In other words: because the whole system behaves like a single conventional actuator, a simple conventional actuator model is sufficient to describe it.

This approach is not trivial, because the elements experience different effective loads. The element at the bottom of the assembly for example experiences a higher load, because it needs to move all the other elements in addition to the load. This paper will present a number of ways to address this problem using active and passive, feedforward and feedback approaches. The relative advantages and disadvantages are discussed, and two approaches are considered in more detail. Based on this set of options, a specific solution or combination of solutions can be selected as appropriate according to the practical requirements.

### B. Literature Overview

High Redundancy Actuation is a novel approach to fault tolerance, and consequently the specific problem formulated in this paper has not been previously considered.

Previous work on High Redundancy Actuation did look into the possibility of aligning dynamics using different methods (see Steffen et al., 2008b, 2010), but without using the geometric approach. This leads to results that are much less general than the approach presented here.

A similar approach is used in rotary actuation with torque summing and velocity summing gears, see for example Ting et al. [1994], Bennett et al. [2004]. The approach has a number of characteristic differences to the systems studied in this paper: it only works for rotary motion, and the problem of complexity is much less prominent because, due to the symmetrical structure, all elements act and behave in exactly the same way. Thus the parameter tuning described in this paper is not applicable.

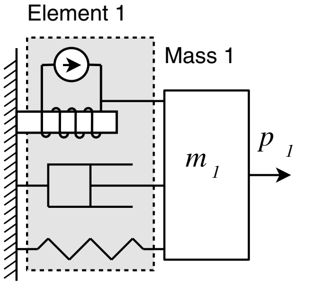

Figure 3. Dynamic components of a single element

A related problem has been studied in the dynamic behaviour of axial stacks of piezoelectric actuators by Jalili [2009]. The author models the stack as a distributed system with partial differential equations (compared to the lumped elements in this paper), which leads to similar results concerning the internal mode. However, the author makes no apttempt to control or decouple these modes internally.

The basis for decoupling internal modes is the geometric approach, because it creates a connection between the dynamics of the system and constraints formulated in terms of the states of the system. This approach was introduced by Wonham [1985] and later extended by Basile and Marro [1992]. It provides the standard solution for the disturbance decoupling problem (see Commault et al., 1997), which is the class of control problems at the heart of this paper. The geometric approach has previously been used for adaptive control of a High Redundancy Actuator in Steffen et al. [2009].

### C. Symbols

| | |
|---|---|
| diag{} | diagonal matrix |
| $f_j$ | force produced by element $j$ |
| $g_j$ | strength factor for element $j$ |
| $F_i$ | force total for mass $m_i$ |
| $f$ | characteristic element function (non-linear model) |
| $k_d\, k_r$ | damping and force constant (linear model) |
| $m_i$ | mass of moving mass number $i$ |
| $n_i\ n_j$ | number of masses and elements |
| $\mathbf{Q}$ | the connection matrix $\in \{-1, 0, -1\}^{j \times i}$ |
| $\mathbb{R}$ | set of real numbers |
| $t$ | time |
| $u_j$ | input of element $j$ |
| $x_i\ \dot{x}_i\ \ddot{x}_i$ | position, speed and acceleration of mass $m_i$ |

## III. System Model

The basic components of an electromechanical actuation element are shown in Figure 3. From a modelling perspective, it is a typical actuated spring-mass-damper system, which can be described by NEWTONian mechanics. Three forces act upon the mass: the electromagnetic force $F_{el}$, the damping force $F_d$, and the

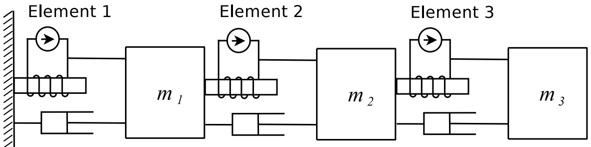

Figure 4. 3 Elements in Series

spring force $F_s = rx$ (see Davies et al. 2008 for more details). Damping and spring for are often assumed to be linear, but in reality that is rarely the case, and there are always limits to the linear region which may be relevant. Therefore, a nonlinear model is used here, using a characteristic function $f(x,\dot{x})$ to describe the behaviour of the spring and the damper:

$$m\ddot{x} = f(x,\dot{x},u) \quad .$$

Choosing $x$ and $\dot{x}$ as states leads to a full state space model:

$$\frac{d}{dt}\mathbf{x} = \mathbf{f}(\mathbf{x},\mathbf{u})$$

with

$$\mathbf{x} = \begin{pmatrix}\dot{x}\\ x\end{pmatrix}$$

$$\mathbf{f}(\mathbf{x},\mathbf{u}) = \begin{pmatrix}f(x,\dot{x},u)\\ \dot{x}\end{pmatrix}$$

$$\mathbf{u} = \begin{pmatrix}u\end{pmatrix} \quad .$$

Once several actuator elements are stacked, it is worth distinguishing between the mass (inertia) and the connection part of an element (generating the there forces). The connection part is attached to the element (or ground) below, so each element is subject to forces from both sides (except for the top one, as shown in Figure 4). The resulting model for actuation elements in series is:

$$\mathrm{diag}\{\mathbf{m}\}\ddot{\mathbf{x}} \;= -\mathbf{Q}f(\mathbf{Q}^T\mathbf{x},\mathbf{Q}^T\dot{\mathbf{x}},\mathbf{u}) \qquad (1)$$

where

$$\mathbf{Q} = \begin{pmatrix}1 & -1 & 0\\ 0 & 1 & -1\\ 0 & 0 & 1\end{pmatrix}$$

is the connection matrix defining the connections between the actuators and the masses. The notation $f(\mathbf{Q}^T\mathbf{x},\mathbf{Q}^T\dot{\mathbf{x}})$ indicates that the same function $f$ is applied element wise to the elements of $\mathbf{Q}^T\mathbf{x}$ and the derivative. More complicate configuration including parallel configurations can be modelled by supplying the corresponding connection matrix $\mathbf{Q} \in \mathbb{R}^{n_j \times n_i}$, but only stacks will be considered here with $n_i = n_j = n$, and $\mathbf{Q}$ a band diagonal matrix of the same structure as above. The time variables $\mathbf{u}$, $\mathbf{x}$, and $\mathbf{m}$ are vectors describing the input and the position of the elements, while the parameter vector $\mathbf{m}$ specifies the mass of the elements. This model is in state space form, and the state variable consists of the velocity and the position components

$$\begin{pmatrix}\dot{\mathbf{x}}\\ \mathbf{x}\end{pmatrix} \in \mathbb{R}^{2n} \quad .$$

Internal states of the elements (e.g. current in the coil) can be modelled in the same way if necessary.

The scalar equations behind this vector equation are

$$m_i\ddot{x}_i = -\mathbf{q}_i\mathbf{f}$$

and

$$f_j = f(\mathbf{q}_j^T\mathbf{x},\mathbf{q}_j^T\dot{\mathbf{x}},\mathbf{u})$$

where $\mathbf{q}_i$ is the $i$th row of $\mathbf{Q}$, $\mathbf{q}_j^T$ is the transpose of the $j$th column of $\mathbf{Q}$, and $\mathbf{f}$ is a column vector of all $f_j$.

In fact one further term is required to solve this problem, because using equal elements will not generally be sufficient. Because the elements close to the ground have a higher load, they need to be stronger, and this is modelling using a strength factor $\mathbf{l}$. The characteristic function is scaled with this factor:

$$f_j = g_j f(\mathbf{q}_j^T\mathbf{x},\mathbf{q}_j^T\dot{\mathbf{x}})$$

or

$$\mathrm{diag}\{\mathbf{m}\}\ddot{\mathbf{x}} \;= -\mathbf{Q}\mathrm{diag}\{\mathbf{g}\}f(\mathbf{Q}^T\mathbf{x},\mathbf{Q}^T\dot{\mathbf{x}},\mathbf{u}) \qquad (2)$$

## IV. Alignment Goal

One of the goals of high redundancy actuation is that all elements work together to perform the actuation task. This requires that they move in a coordinated and generally synchronous motion. This is called the alignment goal.

The key obstacle that the elements are not equal, because they at different positions along the stack and therefore subject to different accelerations. The naive approach of applying the same input signal to all elements does not achieve the alignment of motion. Instead, the force created by two elements cancels out for all masses except the load mass. The top element ($x_3$) responds first, then the middle element ($x_2$) begins to move, and finally the element on the base ($x_1$) will respond. So the input responses ripples through the system like a longitudinal wave. This phenomenon is already known from stacks of piezoelectric actuators.

An example is shown in Figure 5 for a nominal system with $f(x,\dot{x},u) = u - 2\dot{x} - 0.5x$, $m_1 = m_2 = 0.5$ and $m_3 = 1$. A simple single input/single output (SISO) proportional controller with a phase lead compensator is used $K(s) = 2\frac{0.4s+1}{4s+1}$, and a reference step of 30 mm (10 mm per element) is used in this simulation.

This kind of wave propagation complicates the control of the actuator, because it leads to situations where the elements work against each other, and not in cooperation. It can also cause elements to run into mechanical limits, which may create further vibrations and reduce the lifetime of the system significantly.

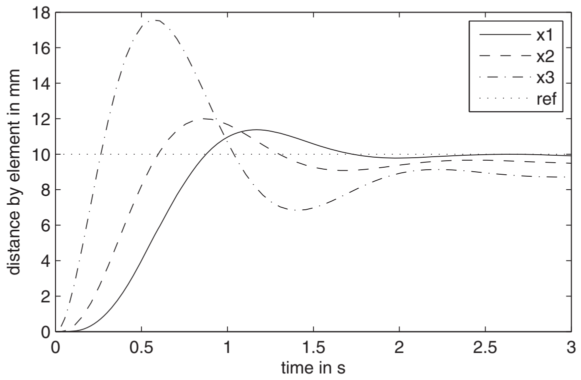

Figure 5. Delay between elements

To avoid this, the alignment goal is introduced. It states that all elements should follow a synchronous motion. Let $\Delta x_i = x_i - x_{i-1}$ denote the extensions of element number $i$, then the alignment goal is

$$\Delta x_1 = \Delta x_2 = \ldots = \Delta x_{n_j} \tag{3}$$

In the case of stacked elements, this can be reformulated as follows.

**Definition 1.** The alignment goal is to distribute the extension of the stack equally between all elements

$$\forall i : n\Delta x_i = x_n \quad . \tag{4}$$

Error signals for this goal can be defined either on the extension

$$e_i = n\Delta x_i - x_n$$

or on the position

$$e_i = x_i - \frac{i}{n} x_n \quad .$$

The following section will present a number of solutions to achieve this goal.

## V. Solution

There are several approaches that can be used either individually or in combination to address the alignment goal. For an overview see [to be published], it lists a number of active and passive approaches. This paper focuses on element tuning with the goal of creating an invariant subspace. Only the strength of the elements is changed here, while the characteristics are assumed to be identical across all elements.

The feedforward approach presented here is not about controlling the deviations, but making sure that they do not occur in the first place. So the goal becomes to equalise the derivatives:

$$\Delta \ddot{x}_1 = \Delta \ddot{x}_2 = \ldots = \Delta \ddot{x}_{n_j} \tag{5}$$

assuming that all $\Delta x_j$ and $\Delta \dot{x}_j$ are equal. This is the basic idea of invariant control: once the invariant condition is satisfied, invariant control can ensure that it remains valid.

In a stack, the travel of an element $\Delta x_j$ can be calculated as $\mathbf{q}_j^T \mathbf{x}$. Inserting the model equation results in

$$\Delta x_j = -\mathbf{q}_j^T \mathrm{diag}^{-1}\{\mathbf{m}\}\mathbf{Q}\mathrm{diag}\{\mathbf{g}\}\mathbf{f}$$

with

$$f_j = f(\mathbf{q}_j^T \mathbf{x}, \mathbf{q}_j^T \dot{\mathbf{x}}, \mathbf{u}) \quad .$$

Because of the assumption, all $f_j$ are equal, so the goal can be achieved if all elements of

$$\mathbf{Q}^T \mathrm{diag}^{-1}\{\mathbf{m}\}\mathbf{Q}_i \mathbf{g}$$

are equal, or

$$\mathbf{g} = \left(\mathbf{Q}^T \mathbf{Q}\right)^{-1} (1\ 1\ \cdots\ 1)^T \quad .$$

Since $\mathbf{Q}$ is invertible for the stack configuration considered here, this can be rewritten as:

$$\mathbf{g} = \mathbf{Q}^{-1} \mathbf{diag}\{\mathbf{m}\} \mathbf{Q}^{-1,T} (1\ 1\ \cdots\ 1)^T \quad .$$

With

$$\mathbf{Q}^{-1} = \begin{pmatrix} 1 & & \\ \vdots & 1 & \\ 1 & \cdots & 1 \end{pmatrix}$$

this can be rewritten as

$$g_j = \sum_{k=j}^{n} k m_k \quad .$$

In the example with three elements, this means

$$\begin{aligned} g_1 &= m_1 + 2m_2 + 3m_3 \\ g_2 &= 2m_2 + 3m_3 \\ g_3 &= 3m_3 \quad . \end{aligned}$$

The result of this tuning is shown in Figure 6. The parameters of the third element are equal to the step response in Figure **??**, and the other elements are tuned accordingly. Clearly the delay between the elements has been eliminated, and they all respond at the same time. The disturbance response (at $t = 5$) still deviates slightly between the elements, but the difference is small and not significant for most practical purposes.

## VI. Simulation Results

As an example, a stack of three elements is simulated. The non-linear characteristic of each element is used to include a linear damping term, a linear spring term, and a non-linear spring term representing end stops:

$$f(\dot{x}, x, u) = u - 2\dot{x} - 0.1x - 10000h(x)$$

where

$$h(x) = \begin{cases} x & \text{if } x < 0 \\ 0 & \text{if } x \in [0, 0.35] \\ x - 0.35 & \text{if } x > 0.35 \end{cases} \quad .$$

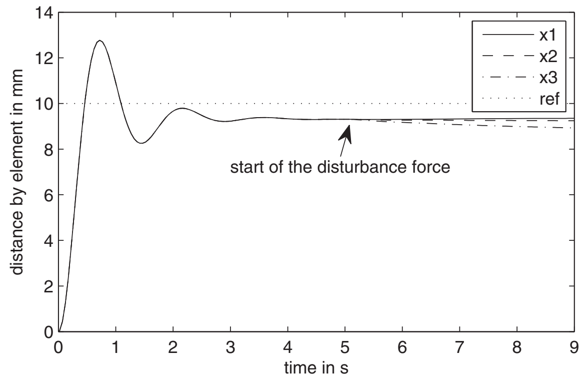

Figure 6. Step response after parameter tuning

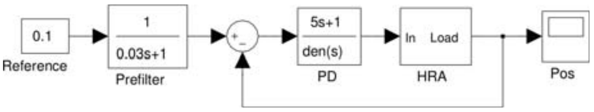

Figure 7. Simulation Control Structure

A simple PD type controller with a slight prefilter is used to control the stack as shown in Figure 7. This may not be the controller of choice for practical applications (for example because it does not provide reference tracking), but the simplicity makes the analysis of the system behaviour easier. With equal elements (without tuning), the simulation in Figure 8 shows a strong chattering effect caused by the end stops becoming active at an extension of $\Delta x = 0.35$. The state trace in Figure 9 also demonstrates that the travel is by no means equally distributed between the elements. This kind of chatter has also been observed in an experimental demonstrator of the HRA. The forces caused by the end stops and acting on the individual masses can be significant, so much so that they destroy the assembly.

Adjusting the strength of the three elements according to the methodology shown above changes the situation dramatically. The three weights are $m_1 = m_2 = 0.1\,\mathrm{kg}$ and $m_3 = 1\,\mathrm{kg}$, therefore the strength coefficients are

$$\begin{aligned} g_1 &= 3.3 \\ g_2 &= 3.2 \\ g_3 &= 3 \quad . \end{aligned}$$

In the implementation, these are scaled by $g_3$ such that $g_3$ becomes equal to 1. As can be seen in Figure 10, all elements of the adjusted HRA move in synchronose motion. Because the overall travel is well within the reach of the HRA, the end stops do not become relevant.

## VII. Generalised Configurations

This approach is not limited to stacks of actuators - it can be applied to any network of actuators. For example the system in Figure 12 has a connection matrix of the form

$$\mathbf{Q} = \begin{pmatrix} 1 & 0 & -1 & 0 \\ 0 & 1 & 0 & -1 \\ 0 & 0 & 1 & 1 \end{pmatrix} \quad .$$

The equalisation can be calculated in the same way, but since $\mathbf{Q}$ is not square, the left side inverse is not unique. This agrees with the intuitive interpretation: both stacks can have the same or different strength, and the alignment goal can be achieved in either case. If the pseudo-inverse is used, they will both have the

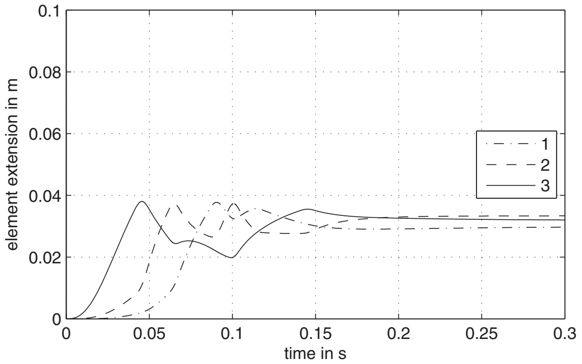

Figure 8. Simulation Results, unmatched

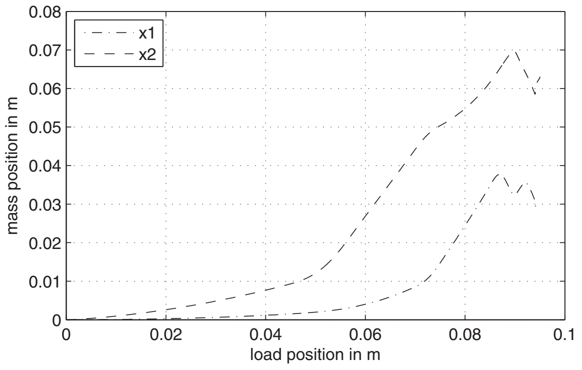

Figure 9. State trace, unmatched

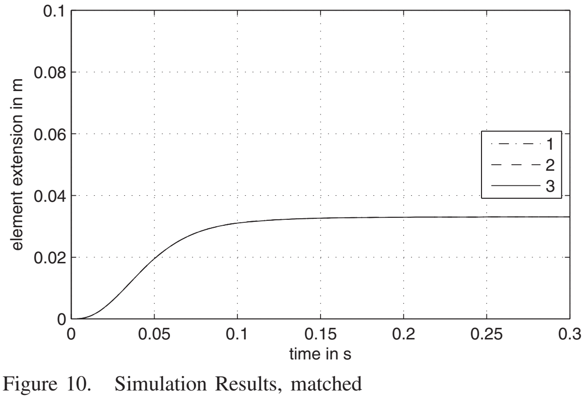

Figure 10. Simulation Results, matched

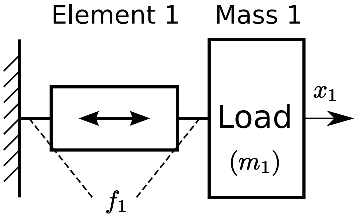

Figure 11. Abstracted Model of a Single Element

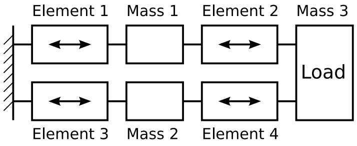

Figure 12. Example 2×2 Configuration

same strength:

$$\mathbf{Q}^* = \frac{1}{4}\begin{pmatrix} 3 & 1 & 2 \\ 1 & 3 & 2 \\ -1 & 1 & 2 \\ 1 & -1 & 2 \end{pmatrix}$$

and

$$\mathbf{g} = \lambda (m_{1,2} + m_3 \;\; m_{1,2} + m_3 \;\; m_3 \;\; m_3)^T \quad .$$

## VIII. Conclusion

Starting from a model of an actuator stack, it is shown how a desired equal distribution of the speed and travel between the elements can be formulated as an invariance condition called alignment goal. The invariance can be achieved by tuning the strength of the actuation elements according to their position in the stack. While this approach is obvious within a linear framework, it is equally applicable to elements with a non-linear characteristic, as long as the characteristic is the same for all elements.

Once the alignment goal is achieved, all elements move synchronously “as one”, and the stack of actuators behaves exactly the same way as a comparable single (larger) actuator. Further modes still exist in the system, but they are stable and decoupled from the inputs. Therefore it is possible to use a simple PID class controller to control an HRA.

The presented methods can be extended to more complex configurations by relaxing some of the assumptions. A simple 2x2 configuration is demonstrated, but it also covers much more extensive configuration.

***Abstract*—For the chaotic systems with uncertain parameters and stochastic disturbance, in order to satisfy some optimal performance index when chaos control is achieved, the Lyapunov-based model predictive control (LMPC) is introduced. The LMPC scheme is concerned with an auxiliary controller which is constructed in advance. Based on the auxiliary controller and stochastic stability theory, it is shown that the chaotic systems with uncertain parameters and stochastic disturbance are practical stable. With the help of the auxiliary controller, the stability of LMPC can be guaranteed as well as some optimality property. As an example, the unified chaotic system with uncertain parameter and stochastic disturbance is considered and simulation results show the effectiveness of the proposed method.**

***Index Terms*—chaos, predictive control, uncertain parameters, stochastic disturbance, optimization.**

## I. Introduction

Chaos is a complex nonlinear phenomenon that the behavior of dynamical systems is highly sensitive to initial conditions, which is also referred to as the butterfly effect. It exists in many practical fields such as biology, economics, engineering, finance, physics, oscillating chemical reactions, fluid and so on. Because of the sensitiveness on initial conditions, chaos is unpredictable in the long time and may be undesired in some applications. In order to suppress this undesirable behavior, Ott, Grebogi and Yorke first presented a kind of controlling chaos method, which is so called OGY control method [1]. Since then, chaos control has been a hot issue and many techniques have been presented [2], for example, delayed feedback control method [3], adaptive control method [4], linear and nonlinear control methods [5]–[7], active control method [8], etc.

In real systems or experimental situations, it is difficult to obtain the exact model. Instead, people usually only know the approximate system model, and uncertain or/and stochastic disturbance exists inevitably. It is important and necessary to discuss the control problem when the systems include uncertain or/and stochastic disturbance. On the other hand, in many practical control fields such as economics, engineering, finance and so on, the control problem is often connected with some optimal performance index for example saving costs (money, energy), gaining the most profits, and even some constraints. Obviously, the above question is concerned with the optimal control problem of the systems with uncertain or/and stochastic disturbance. In many application fields, model predictive control [9] is adopted widely when the control problem includes optimal performance, constraints, uncertainty, etc. MPC is a kind of optimal control technique, but where it differs from the traditional optimal control method is that it solves the standard optimal control problem on-line in a finite horizon, rather than determining off-line a feedback law. Also, when the on-line solution is obtained, MPC typically sends out the first control action to be implemented, and repeats the calculation at the next instant. The advantages of MPC are that it can handle constraints, owns the ability of prediction especially when there exists time delay, and to some extent overcomes the effect of uncertainty on the systems.

Motivated by the above discussions, in this paper, we consider the optimization and control problem of chaotic systems with uncertain parameters and stochastic disturbance by the Lyapunov-based model predictive control [10]–[16]. By using a previously designed Lyapunov controller, the stability is discussed and proved by stochastic Lyapunov stability theory. As a typical example, the unified chaotic system with the uncertain parameter and stochastic disturbance is considered and simulation results show the effectiveness of the proposed method.

## II. Control of chaotic systems with uncertain parameters and stochastic disturbance by LMPC

In many MPC formulations there often exist two important issues that how to guarantee the closed-loop stability and initial conditions starting from where the control is feasible. In order to solve these problems, the Lyapunov-based model predictive control(LMPC) is presented [10]–[16]. The idea of LMPC is that a Lyapunov-based controller $h(x)$ is designed previously, and the closed-loop stability and the optimization are based on the controller $h(x)$. With the help of the controller $h(x)$, the stability of LMPC can be inherited and the region of optimization feasibility can be explicitly characterized.

Let us consider the control problem of the following chaotic systems

$$\dot{x}(t) = f_0(x(t)) + f_1(x(t))\theta(x(t)) + l(x(t))\xi(t) + g(x(t))u(t) \tag{1}$$

where $f_0(0) = f_1(0) = l(0) = g(0) = 0$, namely the origin is the equilibrium point; $\theta(x(t))$ is the uncertain parameter and there exists $\theta_b > 0$ such that $\|\theta(x(t))\| \leq \theta_b$; $\xi(t)$ denotes

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

the standard Gaussian white noise which can be expressed as the formal derivative of Wiener process $w(t)$; $u(t)$ is the controller. We suppose that all the states of the system are available, $f_0(x), f_1(x), \theta(x), l(x), g(x)$ are continuous functions, and compared to the originally deterministic system $f_1(x(t))\theta(x(t)) + l(x(t))\xi(t)$ can be viewed as the small disturbance.

For a candidate Lyapunov function $V(x)$, the following feedback control law $u(t) = h(x(t))$ can be constructed

$$h(x) = \begin{cases} 0, & if\ L_gV(x) = 0 \\ -\frac{\omega+\sqrt{\omega^2+(L_gV(L_gV)^T)^2}}{L_gV(L_gV)^T}(L_gV)^T, & else \end{cases} \tag{2}$$

where $\omega = L_{f_0}V(x) + ||L_{f_1}V(x)||\theta_b + \frac{1}{2}Trace\left\{l^T\frac{\partial V^2}{\partial x^2}l\right\} + \rho V(x)$, $\rho > 0$, $L_{f_i}V(x) = \frac{\partial V(x)}{\partial x}f_i(x)(i = 0, 1)$ and $L_gV(x) = \frac{\partial V(x)}{\partial x}g(x)$. It can be investigated that if $V(x)$ is a control Lyapunov function, then $h(x)$ is optimal in some sense [16]–[18].

The LMPC can be designed as follows

$$\min_{u(\tau)\in S(\Delta)} \int_{t_k}^{t_k+T} (\hat{x}^T(\tau)Q\hat{x}(\tau) + u^T(\tau)Ru(\tau))d\tau \tag{3}$$

$$\dot{\hat{x}}(\tau) = f_0(\hat{x}(\tau)) + g(\hat{x}(\tau))u(\tau) \tag{4}$$

$$\hat{x}(t_k) = x(t_k) \tag{5}$$

$$\frac{\partial V(x(t_k))}{\partial x}g(x(t_k))u(t_k) \le \frac{\partial V(x(t_k))}{\partial x}g(x(t_k))h(x(t_k)) \tag{6}$$

where $S(\Delta)$ is the family of piece-wise constant functions with sampling period $\Delta$, which means that the controller is applied in a sample-and-hold fashion. $Q, R$ are positive definite weight matrices. LMPC is unnecessary to use a terminal penalty term, but needs an auxiliary Lyapunov-based control law $h(x)$ that gives the contractive constrains of the Lyapunov-based model predictive controller. With the help of the controller $h(x)$, the initial feasibility of the optimization is satisfied automatically. In the following section, we will prove the stability of the system (1) under the control action $u(t_k)$, which further implies that the optimization is consecutively feasible.

In order to make the theory analysis easily, we give the following assumption:

Assumption 1:

(1) $\|\Psi(y, \theta(y), u) - \Psi(x, \theta(x), u)\| \le \eta_\Psi \|y - x\|$, $\eta_\Psi > 0$. where $\Psi(x, \theta(x), u) = L_{f_0}V(x) + L_{f_1}V(x)\theta(x) + \frac{1}{2}Trace\left\{l(x)^T\frac{\partial V^2}{\partial x^2}l(x)\right\} + L_gV(x)u(t)$.

(2) $\|F(x, \theta(x), u)\| \le M_1$,$\|l(x(t))\| \le M_2$, $(M_1 > 0, M_2 > 0)$. where $F(x, \theta(x), u) = f_0(x) + f_1(x)\theta(x) + g(x)u(t)$.

Remark 1: For the chaotic system, its attractor is a bounded compact set. When the control input is added and not too large, usually the boundedness can be kept. Based on the properties that the functions $f_0(x), f_1(x), \theta(x), l(x), g(x)$ are continuous, then we can conclude the assumption (2) holds. Finally,if the function $\Psi(x, \theta(x), u)$ is further differential in $x$ for each $u$, we can obtain $\Psi(x, \theta(x), u)$ satisfies the Lipschitz property in the assumption(1). Thus, through the above discussion we know that Assumption 1 is not difficult to be satisfied.

*Lemma 1:* If $\dot{x}(t) = F(x(t), \theta(x(t)), u(t_k)) + l(x(t))\xi(t), t \in [t_k, t_{k+1})$, where $F(x(t), \theta(x(t)), u(t_k)) = f_0(x(t)) + f_1(x(t))\theta(x(t)) + g(x(t))u(t_k))$, then there exists a constant $\gamma > 0$ such that the following inequality holds $E\|x(t) - x(t_k)\| \le \gamma\sqrt{\Delta}$.

Proof.

$$\dot{x}(t) = F(x(t), \theta(x(t)), u(t_k)) + l(x(t))\xi(t),\ t \in [t_k, t_{k+1})$$

Integrating the above formula, we get $x(t) - x(t_k) = \int_{t_k}^{t} F(x(\tau), \theta(x(\tau)), u(t_k))d\tau + \int_{t_k}^{t} l(x(\tau))dw$

Applying the inequality $\|a + b\|^2 \le 2\|a\|^2 + 2\|b\|^2$, then

$$\begin{aligned} &E\left(\|x(t) - x(t_k)\|^2\right) \\ &= E\left\|\int_{t_k}^{t} F(x(\tau), \theta(x(\tau)), u(t_k))d\tau + \int_{t_k}^{t} l(x(\tau))dw\right\|^2 \\ &\le 2E\left\|\int_{t_k}^{t} F(x(\tau), \theta(x(\tau)), u(t_k))d\tau\right\|^2 \\ &\quad +2E\left\|\int_{t_k}^{t} l(x(\tau))dw\right\|^2 \end{aligned}$$

Using Cauchy-Schwarz inequality and Assumption 1, we can obtain

$$\begin{aligned} &E\left(\left\|\int_{t_k}^{t} F(x(\tau), \theta(x(\tau)), u(t_k))d\tau\right\|^2\right) \\ &\le (t - t_k)E\left(\int_{t_k}^{t} \|F(x(\tau), \theta(x(\tau)), u(t_k))\|^2 d\tau\right) \\ &= (t - t_k)\int_{t_k}^{t} E\left(\|F(x(\tau), \theta(x(\tau)), u(t_k))\|^2\right)d\tau \\ &\le M_1^2(t - t_k)^2 \le M_1^2\Delta^2 \end{aligned}$$

$$\begin{aligned} &E\left(\left\|\int_{t_k}^{t} l(x(\tau))dw\right\|^2\right) = E\left(\int_{t_k}^{t} \|l(x(\tau))\|^2 d\tau\right) \\ &\le M_2^2(t - t_k) \le M_2^2\Delta \end{aligned}$$

Thus

$$E\left(\|x(t) - x(t_k)\|^2\right) \le 2(M_1^2\Delta + M_2^2)\Delta$$

If we let $\gamma^2 = 2(M_1^2\Delta + M_2^2)$, then by Jensen's inequality we get

$$\begin{aligned} &E\|x(t) - x(t_k)\| = E\sqrt{\|x(t) - x(t_k)\|^2} \\ &\le \sqrt{E\left(\|x(t) - x(t_k)\|^2\right)} \le \gamma\sqrt{\Delta}. \end{aligned}$$

*Theorem 1:* Consider the trajectory $x(t)$ of the system (1) under the control law $u(t)$, which satisfies the conditions of Assumption 1 and is implemented in a sample-and-hold fashion:

$$\dot{x}(t) = f_0(x(t)) + f_1(x(t))\theta(x(t)) + l(x(t))dw + g(x(t))u(t_k) \tag{7}$$

where $t \in [t_k, t_{k+1})$ and $t_k = t_0 + k\Delta, k = 1, 2, ...$

Then the origin of the system (1) is practically stable in some mean sense.

Proof. The time derivative of the Lyapunov function $V(x)$ along the trajectory $x(t)$ of the system (1) in $t \in [t_k, t_{k+1})$ is given by

$$\dot{V}(x(t)) = \Psi(x(t), \theta(x(t)), u(t_k)) + \frac{\partial V(x(t))}{\partial x} l(x(t))dw$$

Adding and subtracting $\Psi(x(t_k), \theta(x(t_k)), u(t_k))$, and taking into account Assumption 1 and the constraint (6), we obtain

$$\begin{aligned}
&\dot{V}(x(t)) \leq -\rho V(x(t_k)) + \Psi(x(t), \theta(x(t)), u(t_k)) \\
&-\Psi(x(t_k), \theta(x(t_k)), u(t_k)) + \tfrac{\partial V(x(t))}{\partial x} l(x(t))dw \\
&\leq -\rho V(x(t_k)) + \eta_\Psi ||x(t) - x(t_k)|| + \tfrac{\partial V(x(t))}{\partial x} l(x(t))dw
\end{aligned}$$

Taking the expectation of the above inequality and using Lemma 1, it leads to

$$\begin{aligned}
&E\dot{V}(x(t)) \\
&\leq -\rho EV(x(t_k)) + \eta_\Psi E||x(t) - x(t_k)|| \\
&\leq -\rho EV(x(t_k)) + \gamma\eta_\phi \sqrt{\Delta}
\end{aligned}$$

When the right side of the above inequality is less than zero, we know that the value of $EV(x(t))$ will decrease. Therefore, if we take $r_1 > r_2 > 0$ and a small constant $\varepsilon > 0$ such that $r_2 = (\varepsilon + \gamma\eta_\Psi\sqrt{\Delta})/\rho$, $\Omega_{r_1} = \{x : EV(x(t)) \leq r_1\}$, $\Omega_{r_2} = \{x : EV(x(t)) \leq r_2\}$, then for $x(t) \in \Omega_{r_1}/\Omega_{r_2}$, the state will converge to $\Omega_{r_2}$ in some mean sense. If we further take $r_{\min} < r_1$ and $r_{\min} = \max\limits_{\Delta_1 \in [0,\Delta]} \{EV(x(t + \Delta_1)) : EV(x(t)) \leq r_2\}$, then once the state converge to $\Omega_{r_2} \subseteq \Omega_{r_{\min}}$, it will remains inside $\Omega_{r_{\min}}$ for all times. That is to say $\lim\limits_{t\to\infty} supEV(x(t)) \leq r_{\min}$.

## III. Example

Let us consider the control problem of the unified chaotic system with the uncertain parameter $\theta$ and stochastic disturbance $l(x)\xi(t)$.The system (8) is called the unified chaotic system when the right of (8) only includes $f(x(t), \theta)$ and $\theta \in [0, 1]$. As shown in [19], if $\theta \in [0, 0.8)$, it is called the generalized Lorenz chaotic system; if $\theta = 0.8$, it is called Lu chaotic system; if $\theta \in (0.8, 1]$, it becomes the generalized Chen system. Therefore, the parameter $\theta$ plays an important role in the unified chaotic system, and it's natural to discuss the control problem when the parameter $\theta$ is uncertain [20], [21]. Furthermore, stochastic disturbance exists inevitably in practice. It is necessary to discuss the control problem of the unified chaotic system with uncertain parameter and stochastic disturbance.

$$\dot{x}(t) = f(x(t), \theta) + l(x(t))\xi(t) + Bu(t) \tag{8}$$

where

$$f(x, \theta) = \begin{pmatrix} (25\theta + 10)(x_2 - x_1) \\ (28 - 35\theta)x_1 + (29\theta - 1)x_2 - x_1x_3 \\ -(8 + \theta)x_3/3 + x_1x_2 \end{pmatrix} \tag{9}$$

$$l(x(t))dw = \begin{pmatrix} \sigma_1 x_1 & 0 & 0 \\ 0 & \sigma_2 x_2 & 0 \\ 0 & 0 & \sigma_3 x_3 \end{pmatrix} \begin{pmatrix} dw_1 \\ dw_2 \\ dw_3 \end{pmatrix} \tag{10}$$

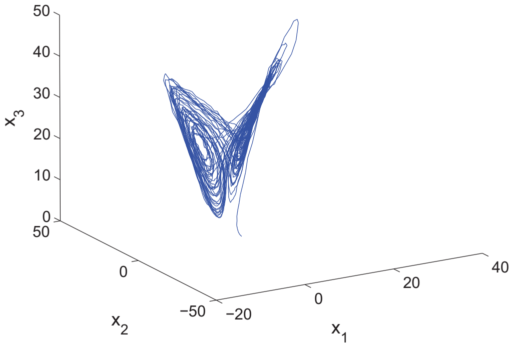

Fig. 1. Phase portrait of chaotic attractor in $(x_1, x_2, x_3)$ space.

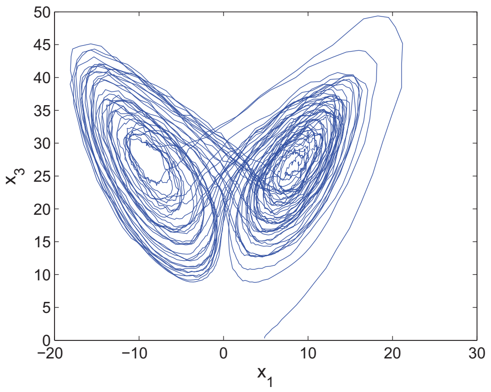

Fig. 2. Projective portrait of chaotic attractor in $(x_1, x_3)$ plane.

$$B = \begin{pmatrix} 0 \\ 1 \\ 0 \end{pmatrix} \tag{11}$$

In this example, we take $l(x)$ and $B$ as (10) and (11), respectively. Choosing $V(x) = \frac{1}{2}(x_1^2 + x_2^2 + x_3^2)$, we get $\Psi(x, \theta, u) = a(x, \theta) + x_2 u$, where

$$\begin{aligned}
&a(x, \theta) = (x_1, x_2, x_3)f(x, \theta) + \tfrac{1}{2}(\sigma_1^2 x_1^2 + \sigma_2^2 x_2^2 + \sigma_3^2 x_3^2) \\
&= (38 - 10\theta)x_1x_2 + (29\theta - 1)x_2^2 - (10 + 25\theta)x_1^2 - \tfrac{8+\theta}{3}x_3^2 \\
&+ \tfrac{1}{2}(\sigma_1^2 x_1^2 + \sigma_2^2 x_2^2 + \sigma_3^2 x_3^2)
\end{aligned}$$

when $x_2 = 0, x \neq 0$, and $\theta \in [0, 1], \sigma_1 < 2\sqrt{5}, \sigma_3 < 4/\sqrt{3}$,

$$\alpha(x, \theta) = -(25\theta + 10 - \frac{1}{2}\sigma_1^2)x_1^2 - (\frac{8 + \theta}{3} - \frac{1}{2}\sigma_3^2)x_3^2 < 0$$

Thus, $V(x) = \frac{1}{2}(x_1^2 + x_2^2 + x_3^2)$ is a control lyapunov function [17], and the auxiliary controller $h(x)$ is taken as (2).

In numerical simulations, we take the initial value $x(0) = (2, -1, 1)^T$ and the parameters $\sigma_1 = \sigma_2 = \sigma_3 = 0.1, \theta(x) = 0.1\,|\sin(x_1)|\,, \rho = 0.001, Q = I, R = 1.0, \Delta = 0.02, T = 100\Delta$, to investigate the proposed method. Figs. 1-2 displays the phase portrait of the uncertain and stochastic chaotic attractor when the system (8) is without control input. When

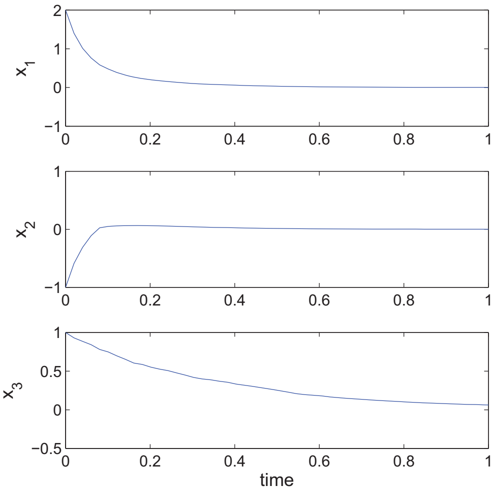

Fig. 3. The evolution of system states under LMPC.

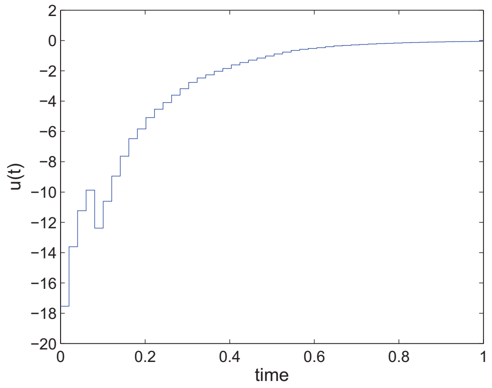

Fig. 4. The varying curve of control input by LMPC.

the control law of LMPC is applied to the chaotic system, from Figs. 3-4 one can see that the state trajectories of the chaotic system and the control action will approach to the neighborhoods of zero points as time increases. These results investigate the effectiveness of the proposed method for the chaotic systems with uncertain parameters and stochastic disturbance.

## IV. Conclusion

Chaos is usually undesirable in real systems, therefore many methods are proposed to control it. In this paper, for the chaotic systems with uncertain parameters and stochastic disturbance, we discussed the chaotic control problem by using the Lyapunov-based model predictive control (LMPC). Through introducing the auxiliary control law $h(x)$, the stability of LMPC is discussed and proved by stochastic Lyapunov stability theory. Compared to other chaotic control schemes, the advantage of the proposed method is that the optimality can be considered and guaranteed as well as the close-loop stability. Simulation results show the effectiveness of the proposed method.

*Abstract*— **This paper evaluates the possibility of applying a geno-fuzzy control strategy to a magnetorheological semi-active damper for seismic vibration control. The proposed control starategy is designed and then tested and validated in a simulated environment. The control strategy is validated by considering a more destructive seismic disturbance as input for the damper-structure system. The proposed geno-fuzzy hybrid controller offers improved performance and implementability for real-time applications.**

***Keywords:*** *semi-active control, fuzzy controller, magnetorheological fluid damper, seismic response, genetic algorithms, hybrid geno-fuzzy controller.*

## I. Introduction

Earthquake induced vibration of civil structures is a current topic of high interest. As buildings rise and materials are sought to be lighter and cheaper, the limitations of structural design are visible in buildings subjected to seismic and wind disturbance. A common approach is using additional structural vibration damping devices, be they passive, active, or semi-active. The technological advancements in computer and information technology make possible the real-time implementation of complex, advanced or non-linear control systems.

This article focuses on the use of magnetorheological (MR) dampers for semi-active seismic vibration control, by means of a hybrid geno-fuzzy non-linear controller. Using MR actuators for their dissipative properties is not a new idea. However, the applied control strategies vary in structure and performances. MR and ER (electrorheologic) bracing systems' analysis of seismic response with a linear controller based on ground acceleration is performed in [1], the authors showing showed that placing dampers near the base of a structure, as opposed to the upper levels, gives a better response reduction. Instead, in [2] a non-linear fuzzy control system is successfully employed for a base isolation MR damper.

Due to the non-linear intrinsic character of the MR dampers and of the fuzzy controllers, researchers have attempted evolutionary optimization of the fuzzy control systems for active and semi-active dampers. A base isolation system is designed in [3], combining a MR damper with a passive friction pendulum system. The authors have obtained a neuro-fuzzy model of the MR damper and have performed a genetic algorithm optimization of the fuzzy rules and the associated membership functions' parameters. A decrease in base displacements was observed, without increasing the acceleration, as seen in fully passive systems.

Another base isolation system was developed for a benchmark structure using MR dampers and a fuzzy controller, in [4]. Numerically simulated genetic algorithms were used to optimize the control system's performance. The genetic algorithm chromosomes have been used to code the membership functions' parameters, as well as a set of weighting factors for the fuzzy rules, the authors obtaining structural response reduction in both the base and the supra-structure. The evolutionary optimization of fuzzy controllers is also applied to an active tuned mass damper (ATMD) system in [5], where a genetic algorithm was used to optimize membership functions, rule weighting coefficients and three of the ATMD parameters.

In recent years, development of optimized fuzzy control systems for structural vibration control has taken a turn towards implementation of these algorithms. Thus, in [6], genetic algorithms are used to optimize model parameters of a benchmark building and a fuzzy model of a MR damper is obtained. Genetic algorithms are also used to optimize the fuzzy controller rules, that are considered to be described by membership functions and their parameters, reaching a chromosome length of 80 to 100 genes.

Computation time was still an issue in [7], where genetic algorithms and particle swarm optimization are used for the optimization of a fuzzy rule base and membership functions' parameters. The considered damping system was a semi-active MR actuator, obtaining a computing time between 2 and 60 hours for the tuning of the fuzzy controller.

Genetic algorithms also are used for determining the rule base of a fuzzy control system for seismic vibration control with an MR semi-active damper in [8]. In comparison with an adaptive controllers, the authors have obtained a better response reduction of the structural system from the optimized fuzzy controller.

This paper is organized as follows: in section 2, the authors present the models for the magnetorheological damper and

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

structure, along with the principle of semi-active vibration control. In section 3, the proposed control strategy is presented, while section 4 contains a case study along with its results. Finally, section 5 contains the conclusions.

## II. MAGNETORHEOLOGICAL SEMI-ACTIVE DAMPER

### *A. Magnetorheological Damper Model*

A magnetorheological damper is a hydraulic-class actuator used in seismic protection design [9]. This device is used to generate the necessary control forces using as an input a command current and the velocity of the story on which it is mounted. The damper is a hydraulic cylinder filled with MR fluid – a magnetically polarizable micron size suspension in oil or other fluids [2]. The damping coefficient of this device is controlled by varying a magnetic field, thus changing the fluid from viscous to semi-solid in milliseconds. In this specific case, the command signal is a current between *0-2 A*.

In order to obtain a satisfactory vibration control of a given structure, it is necessary that the actuators perform inside a set of strict performance criteria, such as response time and robustness versus uncertainties. The output force generated by these dampers is required to be maintained into specific limits, as not to induce instability into the structure. Therefore, a control loop for the actuator is required. In this paper, a magnetorheological damper (figure 1) is controlled via a geno-fuzzy hybrid controller.

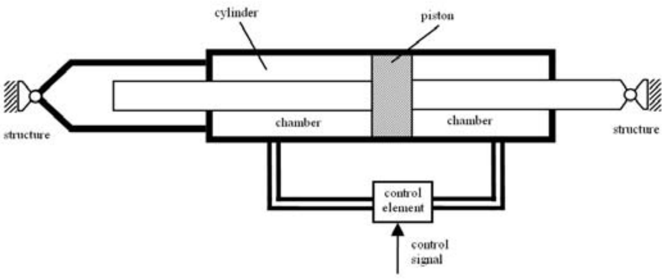

Figure 1. Magnetorheological damper.

A MR (magnetorheological) damper is analyzed. Due to uncertainties in modeling of the damper, a two velocity domain approximation is performed. The behavior of the semi-active MR damper used in this paper has is given by [10]:

$$\left\{\begin{array}{c} f = c_0\dot{x} + \alpha z \\ \dot{z} = -\gamma|\dot{x}||z||z|^{n\text{-}1} - \beta\dot{x}|z|^{n} + A\dot{x} \\ \alpha = \alpha_a + \alpha_b u \\ c_0 = c_{0a} + c_{0b}u \\ \dot{u} = -\eta(u - v) \end{array}\right. \tag{1}$$

where $f$ is the force generated by the damper, $u$ is the command signal and $v$ is the command voltage. The control element is modeled by the fourth equation with first order dynamic. This research makes use of the following parameter values [11]: $c_{0a}$ = 0.0064 Ns/cm, $c_{0b}$ = 0.0052 Ns/cmV, $a_a$ = 8.66 N/cm, $a_b$ = 8.86 N/cmV, $\gamma$ = 300cm$^{-2}$, $\beta$ = 300cm$^{-2}$, A = 120, n = 2 and $\eta$ = 80s$^{-1}$.

### *B. Structure Model*

The damper is considered to be mounted in the base of a building. Thus, the equation used to describe a structural system with a damper that is subject to earthquake disturbances is:

$$M\ddot{x} + C\dot{x} + Kx = F_d + F_u \tag{2}$$

where $x$ is a vector containing the displacements $x_i$ of each story, $F_d$ is the force induced by the earthquake and $F_u$ is a vector containing the control forces for each story. Due to physical connection of each damper, this vector consists of pairs of control forces, equal in value, but in opposing directions, each pair corresponding to one damper. *M*, *C* and *K* are mass, damping and stiffness matrices, respectively, as follows: *M* is a diagonal matrix that contains the stories' masses, *C* and *K* are tri-diagonal matrices describing the codependency between adjacent stories [12].

### *C. Semi-Active Vibration Control*

Semi-active vibration control allows the damping system behaves as a passive one while the structural vibration remains in specified constraints, otherwise the control is active. Advantages of these type of actuators show low costs and little need for auxiliary power sources. Semi-active dampers can efficiently respond with precision, to strong wind or damaging earthquakes. The necessary control forces are generated based on the information received from the sensor distribution throughout the structure. The performance levels are comparable to the ones offered by active control strategies, without their major drawbacks and with minimal risk to generate unstable behaviour. The principle of the semi-active control is presented in the figure 2. Earthquake induced ground motion information is submitted to a switch module which disables or enables the passive and active modes accordingly.

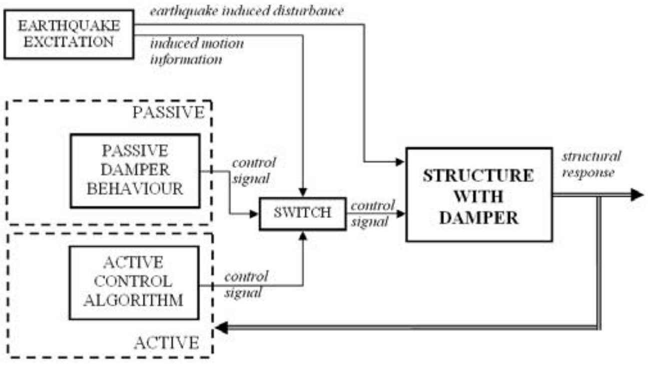

Figure 2. Semi-active control principle.

## III. PROPOSED CONTROL STRATEGY

Fuzzy sets are generally used to reflect vague information of the real world environment. Due to model nonlinearities and uncertainties, it is difficult to accurately describe the structural response or even the damper behavior. Nevertheless, fuzzy logic presents a viable solution, its main advantage being high performance when dealing with non-linear systems and vague information.

To this extent, the fuzzy controller implemented in this paper is constructed with a set of rules that would have been extracted from human experience. The authors propose an evolutionary learning strategy for the fuzzy controller. Because of the non-linear nature of these controllers, genetic algorithms (GAs) are used for tuning the existing "knowledge" of the fuzzy controller. The general strategy is presented in [13]. Figure 3 illustrates the control architecture proposed in this paper, where: $x$ is the displacement of the structure; $\dot{x}$ and $\ddot{x}$ are the velocity and acceleration of the structure, respectively; $F$ is the control force; $i$ is the command current, , $i_P$ is the passive command current, $i_A$ is the active command voltage; $I$ is the performance index for the genetic algorithm; $\Phi$ represents a vector containing the fuzzy controller parameters that are optimized via genetic algorithm; $a$ and $v$ are the earthquake induced ground acceleration and velocity, respectively.

The proposed strategy is structured on two levels. One level deals with damper control and building displacement reduction, while the other level deals with tuning the implemented fuzzy controller. The scheme functions online only through the first level, GA tuning being an offline procedure. The output is a generated control force. The main loop implements a hybrid geno-fuzzy controller.

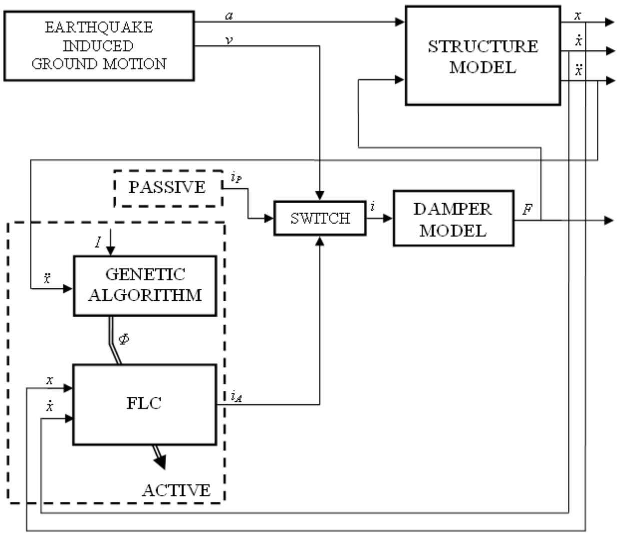

Figure 3. The proposed control architecture.

Fuzzy logic controllers (FLCs) make use of linguistic terms to describe process variables. The main characteristic of fuzzy systems is the use of vague notions instead of crisp numerical values. The linguistic information is represented through words like *small*, *medium*, *large* etc, and makes for a valuable tool in control systems design when the numerical information is incomplete. A FLC is comprised of a fuzzification module, a rule base, an inference mechanism, and a defuzzification module. The fuzzification module transforms the crisp variable into their vague counterparts, while the defuzzifier performs the inverse operation, allowing the controller to generate commands that are compatible with the real life plant. The inference mechanism retrieves the rules from the rule base according to the current inputs of the controller.

Genetic algorithms (GAs) are evolutionary optimization algorithms, also suited for searching problems, specifically when the solution pool is vast and the information is little. GAs are able to perform multi-dimensional searches, even in conditions of uncertainty, and impartial to the strictness of the constraints. The main steps of a GA [14] require first an initialization of the solution pool, knows as a population. Then, for each generation, each individual is evaluated based on a problem-specific fitness function and thus is either selected or eliminated from the current population, followed by a recombination of the selected individuals. The loop repeats until a termination condition is met, either considering a maximum number of generations, or a specified population fitness. The fitness function models the objective of the algorithm, its purpose being the rejection of unfit/unwanted solutions from the gene pool.

The genetic learning of fuzzy controllers is a fine tuning procedure for the parameters of the latter. The procedure requires two steps. First, an algebraic model (AM) for the fuzzy controller is obtained, by fitting a non-linear function over the fuzzy input-output dependency using GAs. Next, the AM's coefficients are tuned in closed loop in order to obtain a better system response, again by means of GAs. The structure of a hybrid geno-fuzzy controller is presented in figure 4, pointing out the inputs and outputs of the closed loop tuning genetic algorithm.

The algebraic model (AM) of the FLC has the following general structure:

$$\delta = \sum_{i=1}^{N} \frac{f_{i0} + f_{i1} \cdot \varepsilon + f_{i2} \cdot d\varepsilon}{f_{i3} + f_{i4} \cdot \varepsilon + f_{i5} \cdot d\varepsilon} \tag{3}$$

where $\delta$ is the controller output (command), $\varepsilon$ is the control deviation between the setpoint and the system's output, $d\varepsilon$ is the derivative of $\varepsilon$, and $N$ is the number of terms in the AM, dependant on the complexity of the designed FLC.

The parameters $f$ in the model represent the algebraic model coefficients. In order to find the AM coefficients, a GA was implemented that minimizes a performance index $I$ as the sum of the square errors between the AM output $\delta$ and the actual fuzzy controller output.

Further tuning of the AM is required, by means of GA. This time around, the GA searches the adjiacent space of the previously found solutions in order to obtain a better performance from the control system. Since the AM has numerical coefficients, the tuning procedure is much faster than if human operator would apply modifications to the fuzzy membership functions or rulebase.

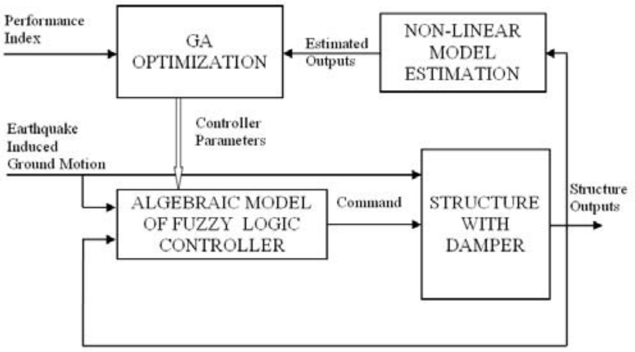

Figure 4. Geno-fuzzy controller.

## IV. CASE STUDY

The case study presented here implements the proposed control architecture and analyzes the hybrid geno-fuzzy controller's performance in conditions of model uncertainties and external disturbances. The authors considered a base mounting of the MR damper. Since the destructive effect of the earthquake is a result of its horizontal vibrational components, the vertical load on the ground story is not taken into account, and all spring and damper structural elements are considered in a horizontal direction. The masses cover both the floors and the associated walls.

This paper implements a geno-fuzzy control strategy for seismic vibration mitigation. Considering non-linearities and model uncertainties, the authors approached a hybrid geno-fuzzy controller, which was included in a semi-active control strategy. The fuzzy controller input variables are the displacement and velocity of the structure and the output is the command voltage used for the elecrohydraulic damper. The discourse universes for each input variable are normalized to [-1, 1], while the output is generated in the interval [0, 5]. The scaling factors used were obtained by analyzing the structure output. The input and output variables and the rulebase are presented in figure 5, in which all membership functions are triangular, with a 50% overlap. The linguistic terms are coded as follows: E - displacement (deviation from zero), D - velocity (derivative of first input), C - command (output), N - negative, P- positive, L - large, M - medium, S - small, Z - zero.

Figure 5. Rulebase of the fuzzy controller.

The control methods described above have been simulated together with a 3-story structure. For the design of the hybrid geno-fuzzy controller, the structure is modeled as a system which integrates the damper in its base (figure 6).

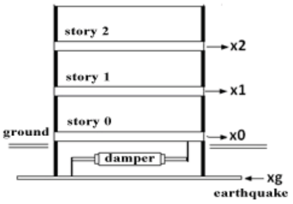

Figure 6. Base isolation of the structure.

The three story building has the following parameters:

$$\begin{cases} M = \begin{bmatrix} 98.3 & 0 & 0 \\ 0 & 98.3 & 0 \\ 0 & 0 & 98.3 \end{bmatrix} [kg] \\ C = \begin{bmatrix} 175 & -50 & 0 \\ -50 & 100 & -50 \\ 0 & -50 & 50 \end{bmatrix} [Ns/m] \\ K = 10^5 \begin{bmatrix} 12 & -6.84 & 0 \\ -6.84 & 13.7 & -6.84 \\ 0 & -6.84 & 6.84 \end{bmatrix} [N/m] \end{cases} \tag{4}$$

Details of this model are given in [15].

A set of evaluation criteria [8] has been chosen:

$$\begin{cases} J_1 = \dfrac{\max|x_i(t)|}{x_{open}} \\ J_2 = \dfrac{\max|d_i(t)|}{d_{open}} \\ J_3 = \dfrac{\max|\ddot{x}_i(t)|}{\ddot{x}_{open}} \end{cases} \tag{5}$$

where $x_i(t), \ddot{x}_i(t)$ are the relative displacement, acceleration of the *i*-th story, while $d_i(t)$ is the interstory drift and the notation *open* designates the overall maximum absolute displacements, accelerations and drifts of the uncontrolled structure.

The control system of the MR damper is simulated by means Matlab (Simulink). Figure 8 presents the response of the MR damper-structure system when excited with an earthquake input signal (Northridge 1994 - the earthquake accelerogram is presented in figure 7), controlled with the geno-fuzzy controller vs. the uncontrolled response of the ground story. The performance criteria is to reduce ground story movement.

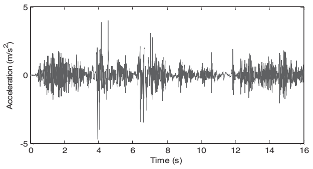

Figure 7. Northridge earthquake accelerogram.

For the fuzzy controller designed, the maximum controlled displacement and acceleration was observed to be 15.22% lower than for the open loop simulation.

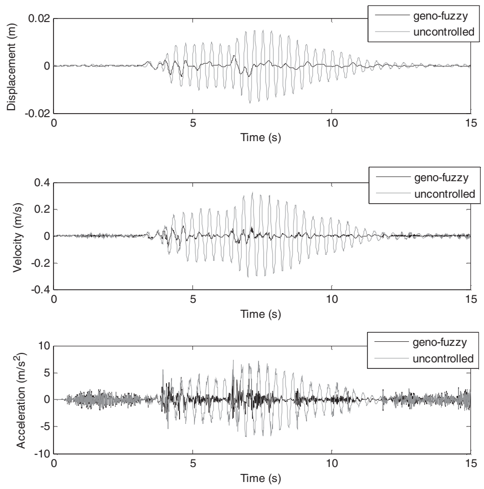

Figure 8. Comparative base structural responses: geno-fuzzy.

The fuzzy logic controller (FLC) designed in this paper has a set of rules, with a rule base created based on human experience. The AM obtained in this paper is:

$$\delta = \frac{0.113+0.415\cdot d+0.743\cdot v}{-0.4+0.843\cdot d+0.167\cdot v} + \frac{0.005+0.86\cdot d+0.434\cdot v}{0.02+0.054\cdot d+0.7\cdot v} + \frac{-0.88\cdot d\cdot v}{0.04-0.4\cdot d-0.9\cdot v} \quad (6)$$

where $v$ is the velocity, $\varepsilon$ is the deviation and $d\varepsilon$ is the difference of the deviation at two consecutive time samples as inputs of the controller, $\delta$ is the output, a current between 0 and 5 V, with a performance index $I = 0.0039$.

Equation (6) presents an approximate model for the FLC. Further tuning of the AM parameters is necessary. Using GA optimization once more, the model for the fuzzy controller is:

$$\delta_{tuned} = \frac{0.113-0.28\cdot d+0.74\cdot v}{-0.4+0.83\cdot d+0.167\cdot v} + \frac{0.764+0.4\cdot d+0.464\cdot v}{0.02+0.054\cdot d+0.7\cdot v} + \frac{0.75\cdot d\cdot v}{0.04-1.03\cdot d+0.02\cdot v} \quad (7)$$

with a performance index of $J = 0.0087$ ($J$ is computed as the normalized sum of square acceleration deviations in closed loop).

The responses of the system using both the AM and the tuned geno-fuzzy controllers, versus the uncontrolled structural responsem show an acceleration reduction of the ground story of 39.25% for the tuned controller relative to the uncontrolled system and 37.5% for the AM controller relative to the uncontrolled system.

Further validation of the hybrid geno-fuzzy controller has been obtained by using a different set of external disturbances: the Vrancea 1977 earthquake accelerogram is presented in figure 9.

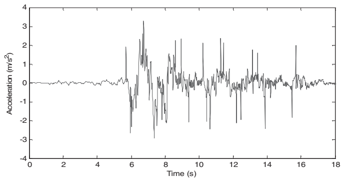

Figure 9. Vrancea earthquake accelerogram.

Results for each case are presented in Table I, for the following cases: using the fuzzy controller, using the algebraic model of the fuzzy controller and finally using the tuned geno-fuzzy controller. A comparative analysis of the proposed control strategy has been performed, using bang-bang and skyhook controllers [16]. Although these two controllers offer a good displacement reduction, their effect on the acceleration of the building is massive, adding up to 63% acceleration. In opposition, the geno-fuzzy controller reduces both acceleration and displacements, as well as inter-story drifts.

TABLE I. PERFORMANCE EVALUATION

| Disturbance | Controller | $J_1$ | $J_2$ | $J_3$ |
|---|---|---|---|---|
| Northridge | Fuzzy | 1.2419 | 1.2385 | 1.3227 |
| | AM | 0.9032 | 0.8979 | 1.0433 |
| | Geno-Fuzzy | 0.4729 | 0.4373 | 0.6317 |
| | Bang-bang | 0.1770 | 0.1570 | 1.5442 |
| | Skyhook | 0.7772 | 0.8101 | 1.6285 |
| Vrancea | Fuzzy | 1.3022 | 1.3541 | 1.2934 |
| | AM | 0.7802 | 0.7995 | 0.7563 |
| | Geno-Fuzzy | 0.5989 | 0.5959 | 0.7470 |
| | Bang-bang | 0.1760 | 0.1455 | 1.3737 |
| | Skyhook | 0.9076 | 0.9540 | 1.4363 |

For the Northridge earthquake, the tuned hybrid geno-fuzzy controller offers the best performances: 39.25% acceleration reduction, 75.32% velocity reduction and 70.1% displacement reduction. For the Vrancea earthquake, the hybrid geno-fuzzy controller offers the best performances: 12.6% acceleration reduction, 33.3% velocity reduction and 7.8% displacement reduction.

Figures 10 and 11 show the displacements, the inter-story drifts and the accelerations on each story, for the Northridge and Vrancea earthquakes, respectively. The designed geno-fuzzy controller offers a good performace for an earthquake with a maximum displacement amplitude approximately 4.5 times greater than the one it was originally designed for: maximum displacement for the Northridge earthquake is 27.9mm, while the maximum displacement for the Vrancea earthquake is 124.6mm. It was thus shown that the designed geno-fuzzy controller can still offer acceptable performances in conditions of high uncertainties regarding the seismic magnitude of the region for which the controller is meant to be implemented.

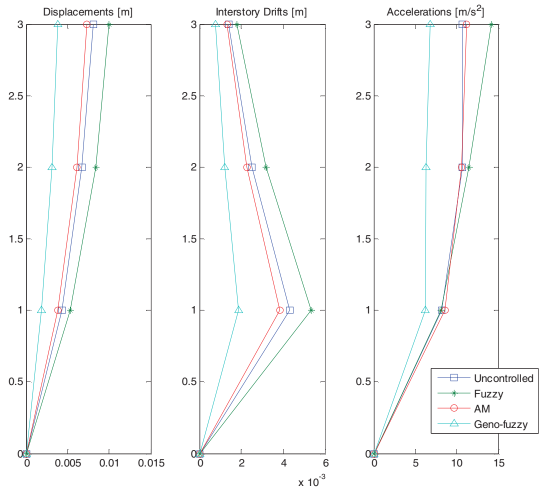

Figure 10. Maximum displacements, inter-story drifts and accelerations for the Northridge earthquake.

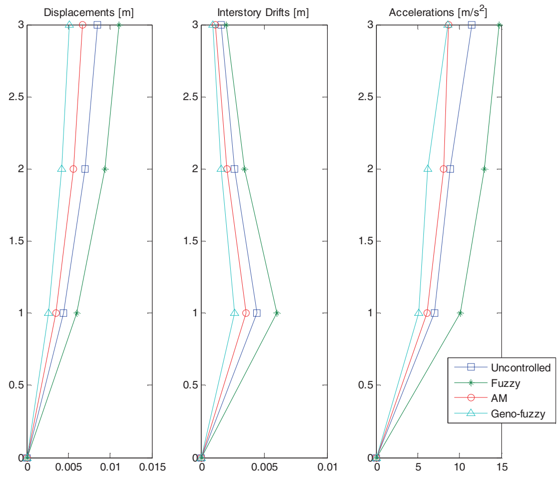

Figure 11. Maximum displacements, inter-story drifts and accelerations for the Vrancea earthquake.

The total computing time, including generating the algebraic model and the subsequent tuning procedure, is between 50 and 60 seconds, using an Intel Pentium Dual CPU 2.16 GHz processor. Through optimization of the GA code on a dedicated processor, the total computing time can be significantly reduced, thus making possible the real-time implementation of the geno-fuzzy tuning procedure.

## V. CONCLUSIONS

By means of genetic algorithms, the learning capabilities of a fuzzy logic controller have been enhanced. The designed hybrid geno-fuzzy controller offered better performance than the equivalent fuzzy controller.

Moreover, by changing the basic implementation form of the fuzzy controller from a heterogenic entity to an algebraic model, the computing time decreases exponentially, making the obtained geno-fuzzy controller easy to implement without removing its non-linear essence.

The proposed geno-fuzzy hybrid controller can offer improved performance and increased implementability in real life buildings.

*Abstract*— **In this paper, a finite-horizon optimal control scheme for a class of nonlinear systems with saturating actuator is proposed by an improved iterative adaptive dynamic programming (ADP) algorithm. The Hamilton-Jacobi-Bellman (HJB) equation corresponding to constrained control is formulated using a suitable nonquadratic function. Then mathematical analysis of the convergence is presented, by proving that the performance index function can reach the optimum using the adaptive iteration. Finally the finite-horizon optimal control law can be obtained by the ε-iterative adaptive algorithm. The examples are given to demonstrate the effectiveness of the above methods.**

***Keywords-Adaptive dynamic programming(ADP); Saturating actuators; nonlinear system; Finite time optimal control***

## I. INTRODUCTION

In a practical control system, the saturating actuators will reduce the system's dynamic performance, and even affect the stability of the system. Therefore seeking a better way to design control systems with saturating actuator has attached considerable attention by many researchers in recent years. The stability of discrete-time linear systems subject to actuator saturation was analyzed using a saturation-dependent Lyapunov function based on the solution of an LMI optimization problem[1]. Saberi (1996) and Sussmann(1994) proposed several processes to control saturation problems, but they did not consider non-linear systems and optimal problems (see [2],[3]). A gain-scheduled output control design for systems coping with nonlinear time-varying parameter dependent systems subject to saturated actuators was proposed in [4]. Pontryagin's Minimum Principle is a way to solve optimal control problem with Saturating Actuator. However, this needs to solve differential equations with boundary, and the result we get is an open-loop control by this way. Lyshevski designed an optimal control for a closed-loop feedback system using a non-quadratic performance index function problem to deal with the control constraints based on dynamic programming principle in [5], but the difficulty lies in the HJB equations.

Adaptive Dynamic Programming (ADP) is a powerful tool proposed by the idea of adaptive critic and reinforcement learning with dynamic programming[6]. It is solved by iterative algorithm to get an approximate solution of HJB equation, ADP has become an effective tool for optimal control problems and has achieved many results[7],[8-12]. A greedy iterative adaptive algorithm was proposed to solve the nonlinear discrete-time systems HJB equation in [8]. Iterative ADP was used to get an infinite horizon optimal control scheme for nonlinear systems with saturating actuator in [9].

However, for practical systems, a limited period of time is required to achieve control. Finite time optimal control problem could be backward solved by dynamic programming, when facing the multi-dimensional nonlinear characteristics of complex systems, the calculation will be very large, that is the problem of the "curse of dimensionality". ε-error bounds of adaptive algorithm was proposed to deal with finite time optimal control in [10],[11]. To the best of our knowledge, quite few research has been presented to deal with finite-horizon optimal control with saturating actuator. This motivates our research.

This paper aims to solve finite time optimal control problem for nonlinear systems with saturating actuator. It is organized as follows. In Section II, the problem is introduced and HJB equation corresponding to constrained control is presented. In Section III, the iterative ADP algorithm and its convergence for finite-horizon optimal control problem are derived. In Section IV, ε-optimal control algorithm is developed with the definition of finite iteration steps and ε-optimal control. In Section V, an example is given to demonstrate the effectiveness of the algorithm. In Section VI, the conclusion is drawn.

## II. HJB EQUATION CORRESPONDING TO CONSTRAINED CONTROL

### A. *Deal with saturated problem*

Consider the following class of discrete-time nonlinear systems

$$\boldsymbol{x}(k+1)=\boldsymbol{F}\left(\boldsymbol{x}(k),\boldsymbol{u}(k)\right) \qquad k=0,1,2,\ldots \tag{1}$$

Where $\boldsymbol{x}(k)\in\mathbb{R}^n$ is the state, assume the system $\boldsymbol{F}\left(\boldsymbol{x}(k),\boldsymbol{u}(k)\right)$ is Lipschitz continuous controllable on a set $\boldsymbol{\Omega}$

This work is supported by National Natural Science Foundation of China (60964002, 61034002)

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

containing the origin. The control $\boldsymbol{u}(k)\in\boldsymbol{\Omega}_{\boldsymbol{u}}$, and $\boldsymbol{\Omega}_{\boldsymbol{u}}=\left\{\boldsymbol{u}(k)=[u_1(k),u_2(k),\cdots,u_m(k)]^{\mathrm{T}}\in\mathbf{R}^{\mathrm{m}}:\left|u_i(k)\right|\le\bar{u}_i\right\}$, where $\overline{u}_i$ is the $i$-th execution controller saturation boundary, $i=1,\dots,m$. On the other hand, the constant diagonal matrix is $\mathbf{A}=diag\left[\bar{u}_1,\bar{u}_2,\cdots,\bar{u}_m\right],\mathbf{A}\in\mathbb{R}^{\mathrm{m\times m}}$ . $\boldsymbol{F}(\mathbf{0,0})=\mathbf{0}$, hence $\boldsymbol{x}=\mathbf{0}$ is an equilibrium state of system (1) under the control $\boldsymbol{u}=\mathbf{0}$.

For the initial state $\boldsymbol{x}(0)$, to minimize the performance index function defined in (2) with finite control sequences as $\underline{\boldsymbol{u}}_0^{N-1}=(\boldsymbol{u}(0),\boldsymbol{u}(1),\cdots,\boldsymbol{u}(N-1))$ .

$$\boldsymbol{J}\left(\boldsymbol{x}(0),\underline{\boldsymbol{u}}_0^{N-1}\right)=\sum_{k=0}^{N-1}\left\{\boldsymbol{x}(k)^{\mathrm{T}}Q\boldsymbol{x}(k)+\boldsymbol{W}(\boldsymbol{u}(k))\right\} \tag{2}$$

Where $\boldsymbol{W}(\boldsymbol{u}(k))=2\int_0^{\boldsymbol{u}(k)}(\mathbf{A}\tanh^{-1}(\boldsymbol{s}/\mathbf{A}))^{\mathrm{T}}\mathbf{R}d\boldsymbol{s}$. The length $N$ is determined with terminal time, this kind of optimal control problems has been called finite-horizon problems with unspecified terminal time [10].

If we set $\boldsymbol{W}(\boldsymbol{u}(k))=\boldsymbol{u}(k)^{\mathrm{T}}\boldsymbol{R}\boldsymbol{u}(k)$ in (2), the quadratic performance index function with unconstrained control is used to design the optimal control for control system with saturated actuator, however, this system could not ensure the optimal system performance, even may lead to system instability. According to [12], let

$$\boldsymbol{W}(\boldsymbol{u}(k))=2\int_0^{\boldsymbol{u}(k)}\mathbf{A}\boldsymbol{\phi}^{-T}({}^{\boldsymbol{s}}\!/\!_{\mathbf{A}})\mathbf{R}ds \tag{3}$$

Where

$$\boldsymbol{\phi}^{-1}(u(k))=[\phi^{-1}(u_1(k)),\phi^{-1}(u_2(k)),\cdots\phi^{-1}(u_m(k))]^T$$

$|\boldsymbol{u}|\le\mathbf{A}$, $\boldsymbol{s}\in\mathbb{R}^m$, $\boldsymbol{\phi}\in\mathbb{R}^m$, let $\boldsymbol{R}$ be a diagonal positive definite, $\phi(\bullet)$ is a bounded monotonically increasing odd function belongs to $\mathbb{C}^p(p\ge1)$ and $\boldsymbol{L}_2(\Omega)$ with $|\phi(\bullet)|\le1$ , the first derivative is a bounded constant $\boldsymbol{M}$ , such function as $\phi(\bullet)=\tanh(\bullet)$. Figure 1 shows a well approaching saturation when $|u|\le0.5$ with function $\boldsymbol{\phi}(\bullet)$. Therefore, we can guarantee the control output signal within the range of actuator saturation using the performance index function in (2).

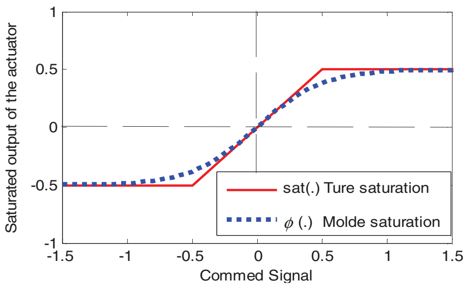

Figure 1. The model of saturation when $|u|\le0.5$

### B. HJB equation and solution

*Definition 1 :* The corresponding finite-horizon admissible control sequence of performance index function in (2) $\underline{\boldsymbol{u}}_k^{k+N-1}$ is defined as follows: For $\forall\boldsymbol{x}(k)\in\mathbb{R}^n$, there exists a control sequence $\underline{\boldsymbol{u}}_k^{k+N-1}$ satisfy $\boldsymbol{x}^f(\boldsymbol{x}(k),\underline{\boldsymbol{u}}_k^{k+N\text{-}1})=\boldsymbol{0}$ and $\boldsymbol{J}(\boldsymbol{x}(k),\underline{\boldsymbol{u}}_k^{N\text{-}1})$ is finite. Where $N>0$ is a positive integer, $\boldsymbol{x}^f(\boldsymbol{x}(k),\underline{\boldsymbol{u}}_k^{k+N\text{-}1})$ is the terminal state.

Let $\mathbf{C}_{\boldsymbol{x}_k}^N=\left\{\underline{\boldsymbol{u}}_k^{k+N-1}:\ \boldsymbol{x}^f(\boldsymbol{x}(k),\underline{\boldsymbol{u}}_k^{k+N\text{-}1})=\boldsymbol{0},\left|\underline{\boldsymbol{u}}_k^{k+N\text{-}1}\right|=N\right\}$ be all the admissible control sets with length $N$ .Assume a state $\boldsymbol{x}(k)$ is a finite-horizon admissible control. By Definition 1, the optimal performance index function at the finite-horizon admissible control could be written as

$$\boldsymbol{J}^*(\boldsymbol{x}(k))=\underset{\underline{\boldsymbol{u}}_k^{N\text{-}1}}{\boldsymbol{inf}}\left\{\boldsymbol{J}(\boldsymbol{x}(k),\underline{\boldsymbol{u}}_k^{N\text{-}1}):\underline{\boldsymbol{u}}_k^{N\text{-}1}\in\mathbf{C}_{\boldsymbol{x}_k}^N\right\} \tag{4}$$

According to the performance index function defined by equation (2) and Bellman principle of optimality, $\boldsymbol{J}^*(\boldsymbol{x}(k))$ under discrete time HJB equation can be written as

$$\boldsymbol{J}^*(\boldsymbol{x}(k))=\min_{\boldsymbol{u}(k)}\left\{\boldsymbol{x}(k)^{\mathrm{T}}Q\boldsymbol{x}(k)+\boldsymbol{W}(\boldsymbol{u}(k))+\boldsymbol{J}^*(\boldsymbol{F}(\boldsymbol{x}(k),\boldsymbol{u}(k)))\right\} \tag{5}$$

Define the optimal control sequence starting at $k$ with length of $N$ by

$$\underline{\boldsymbol{u}}_k^*(\boldsymbol{x}(k))=\underset{\underline{\boldsymbol{u}}_k^{k+N-1}}{\boldsymbol{inf}}\left\{\boldsymbol{J}(\boldsymbol{x}(k),\underline{\boldsymbol{u}}_k^{k+N-1}):\ \underline{\boldsymbol{u}}_k^{k+N-1}\in\mathbf{C}_{\boldsymbol{x}_k}^N\right\} \tag{6}$$

and define the one step optimal control vector by

$$\boldsymbol{u}^*(\boldsymbol{x}(k))=\mathbf{arg}\min_{\boldsymbol{u}(k)}\left\{\boldsymbol{x}(k)^{\mathrm{T}}Q\boldsymbol{x}(k)+\boldsymbol{W}(\boldsymbol{u}(k))+\boldsymbol{J}^*(\boldsymbol{F}(\boldsymbol{x}(k),\boldsymbol{u}(k)))\right\} \tag{7}$$

Dynamic programming is used to solving optimal control sequence in equation (6), while the first step is to determine $\boldsymbol{u}^*(\boldsymbol{x}(k+N-1))$ by equation(6) in terminal state $\boldsymbol{x}(k+N-1)$.

$$\boldsymbol{u}^*(\boldsymbol{x}(k+N-1))=\underset{\boldsymbol{u}(N\text{-}1)}{\mathbf{argmin}}\left\{\boldsymbol{x}(k+N-1)^{\mathrm{T}}Q\boldsymbol{x}(k+N-1)+\boldsymbol{W}(\boldsymbol{u}(k+N-1))\right\}$$
$$\boldsymbol{s.t.}\ \boldsymbol{F}(\boldsymbol{x}(k+N-1),\boldsymbol{u}(k+N-1))=\mathbf{0} \tag{8}$$

Putting $\boldsymbol{u}^*(\boldsymbol{x}(k+N-1))$ into (5), the optimal performance index function

$$\boldsymbol{J}^*(\boldsymbol{x}(k+N-1))=\boldsymbol{x}(k+N-1)^{\mathrm{T}}Q\boldsymbol{x}(k+N-1)+\boldsymbol{W}(\boldsymbol{u}^*(k+N-1)) \tag{9}$$

After $\boldsymbol{u}^*(\boldsymbol{x}(k+N-1))$ and $\boldsymbol{J}^*(\boldsymbol{x}(k+N-1))$ is obtained, $\boldsymbol{u}^*(\boldsymbol{x}(k+N-2))$ and $\boldsymbol{J}^*(\boldsymbol{x}(k+N-2))$,…, could be determined by equation (5) and (7), finally $\boldsymbol{u}^*(\boldsymbol{x}(k))$ and $\boldsymbol{J}^*(\boldsymbol{x}(k))$ is solved. Then solving $\boldsymbol{u}^*(k)=\boldsymbol{u}^*(\boldsymbol{x}(k))$ with $\boldsymbol{x}(k)$, and putting $\boldsymbol{u}^*(k)$ into equation (1) so as to get $\boldsymbol{x}(k+1)=\boldsymbol{F}(\boldsymbol{x}(k),\boldsymbol{u}^*(k))$. By the same way, solving $\boldsymbol{u}^*(k+1)$ by $\boldsymbol{x}(k+1)$ and $\boldsymbol{u}^*(\boldsymbol{x}(k+1))$ , putting $\boldsymbol{u}^*(\boldsymbol{x}(k+1))$ into equation (1) , then we can easily get $\boldsymbol{x}(k+2)=\boldsymbol{F}(\boldsymbol{x}(k+1),\boldsymbol{u}^*(k+1))$, repeating this process [9], the optimal control sequence will be obtained as $\underline{\boldsymbol{u}}_k^*(\bullet)=\{\boldsymbol{u}^*(k),\boldsymbol{u}^*(k+1),\dots,\boldsymbol{u}^*(k+N-1)\}$.

However, the performance index function in this paper is non- quadratic, and the system is non-linear. Therefore, it is hard to get an analytical solution of optimal control law by solving HJB equation. On the other hand, when dealing with discrete time dynamic programming by backward method, one has to calculate and save all $\boldsymbol{J}^*(\boldsymbol{x}(k))$ and $\boldsymbol{u}^*(\boldsymbol{x}(k))$ of the sequence. Hence, it will meet difficulties when calculating finite-horizon optimal control problems by dynamic programming.

## III. FINITE TIME ITERATIVE ADP ALGORITHM

### *A. Formula derived for iterative ADP*

For any state $\boldsymbol{x}(k)$, the performance index function $\{\boldsymbol{V}_i\}$ and control policy $\{\upsilon_i\}$ in the iterative ADP algorithm are updated by recursive iterations. The iterative starts with $i=0$ and the initial performance index function $\boldsymbol{V}_0(\boldsymbol{x}(k))=0$, the performance index function for $i=1$ is computed as

$$\begin{aligned}\boldsymbol{V}_1(\boldsymbol{x}(k)) &= \min_{\boldsymbol{u}(k)}\left\{\boldsymbol{x}(k)^{\mathrm{T}}Q\boldsymbol{x}(k)+\boldsymbol{W}(\boldsymbol{u}(k))+\boldsymbol{V}_0(\boldsymbol{F}(\boldsymbol{x}(k),\boldsymbol{u}(k)))\right\}\\ &\quad s.t.\ \boldsymbol{F}(\boldsymbol{x}(k),\boldsymbol{u}(k))=\boldsymbol{0}\\ &=\min_{\boldsymbol{u}(k)}\left\{\boldsymbol{x}(k)^{\mathrm{T}}Q\boldsymbol{x}(k)+\boldsymbol{W}(\boldsymbol{u}(k))\right\}\\ &\quad s.t.\ \boldsymbol{F}(\boldsymbol{x}(k),\boldsymbol{u}(k))=\boldsymbol{0}\\ &=\boldsymbol{x}(k)^{\mathrm{T}}Q\boldsymbol{x}(k)+\boldsymbol{W}(\boldsymbol{u}^*(\boldsymbol{x}(k)))\end{aligned} \tag{10}$$

Where $\boldsymbol{F}\left(\boldsymbol{x}(k),\boldsymbol{u}^*(k)\right)=\boldsymbol{0}$, let $\boldsymbol{u}^*(k)=\upsilon_1(\boldsymbol{x}(k))$, then (10) can be written as

$$\begin{aligned}\boldsymbol{V}_1(\boldsymbol{x}(k)) &= \min_{\boldsymbol{u}(k)}\left\{\boldsymbol{x}(k)^{\mathrm{T}}Q\boldsymbol{x}(k)+\boldsymbol{W}(\boldsymbol{u}(k))+\boldsymbol{V}_0(\boldsymbol{F}(\boldsymbol{x}(k),\boldsymbol{u}(k)))\right\}\\ &\quad s.t.\ \boldsymbol{F}(\boldsymbol{x}(k),\boldsymbol{u}(k))=\boldsymbol{0}\\ &=\boldsymbol{x}(k)^{\mathrm{T}}Q\boldsymbol{x}(k)+\boldsymbol{W}(\upsilon_1(\boldsymbol{x}(k)))\end{aligned} \tag{11}$$

where

$$\begin{aligned}\upsilon_1(\boldsymbol{x}(k)) &= \mathbf{arg}\min_{\boldsymbol{u}(k)}\{\boldsymbol{x}(k)^{\mathrm{T}}Q\boldsymbol{x}(k)+\boldsymbol{W}(\boldsymbol{u}(k))\}\\ &\quad s.t.\ \boldsymbol{F}(\boldsymbol{x}(k),\boldsymbol{u}(k))=\boldsymbol{0}\end{aligned} \tag{12}$$

For $i=2,3,4\ldots$, the iterative ADP algorithm is updated as follows

$$\begin{aligned}\boldsymbol{V}_i(\boldsymbol{x}(k)) &= \min_{\boldsymbol{u}(k)}\left\{\boldsymbol{x}(k)^{\mathrm{T}}Q\boldsymbol{x}(k)+\boldsymbol{W}(\boldsymbol{u}(k))+\boldsymbol{V}_{i-1}(\boldsymbol{F}(\boldsymbol{x}(k),\boldsymbol{u}(k)))\right\}\\ &=\boldsymbol{x}(k)^{\mathrm{T}}Q\boldsymbol{x}(k)+\boldsymbol{W}(\upsilon_i(\boldsymbol{x}(k)))+\boldsymbol{V}_{i-1}(\boldsymbol{F}(\boldsymbol{x}(k),\upsilon_i(\boldsymbol{x}(k))))\end{aligned} \tag{13}$$

where

$$\upsilon_i(\boldsymbol{x}(k))=\mathbf{arg}\min_{\boldsymbol{u}(k)}\{\boldsymbol{x}(k)^{\mathrm{T}}Q\boldsymbol{x}(k)+\boldsymbol{W}(\boldsymbol{u}(k))+\boldsymbol{V}_{i-1}(\boldsymbol{F}(\boldsymbol{x}(k),\boldsymbol{u}(k)))\} \tag{14}$$

After $i$ steps iteration, the performance index function sequence is obtained as $\{\boldsymbol{V}_i\}=(\boldsymbol{V}_i,\boldsymbol{V}_{i-1},\cdots,\boldsymbol{V}_1)$ and control policy sequence as $\{\upsilon_i\}=(\upsilon_i,\upsilon_{i-1},\cdots\upsilon_1)$. Note that in this case, each control sequence $\boldsymbol{u}(\cdot)$ will obey with different control policy, that is, for $i=0,1,\cdots N-1$, control sequence $\boldsymbol{u}(i)$ is obtained by $\upsilon_i$ respectively. However, one could prove that $\boldsymbol{V}_i(\boldsymbol{x}(k))$ is limit to $\boldsymbol{J}^*(\boldsymbol{x}(k))$ when $i\to\infty$. Therefore, the performance index function $\boldsymbol{J}^*(\boldsymbol{x}(k))$ in HJB equation will be replaced by the iterative performance index function $\boldsymbol{V}_i(\boldsymbol{x}(k))$ while control policy $\boldsymbol{u}(\boldsymbol{x})$ will be replaced by the iterative control policy.

### *B. Convergence of iteration ADP*

*Remark 1:* According to (2) and (13), we have

$$\boldsymbol{V}_{i+1}(\boldsymbol{x}(k))=\min_{\underline{\boldsymbol{u}}_k^{k+i}}\{\boldsymbol{J}(\boldsymbol{x}(k),\underline{\boldsymbol{u}}_k^{k+i}):\underline{\boldsymbol{u}}_k^{k+i}\in\mathbf{C}_{\boldsymbol{x}_k}^{(i+1)}\} \tag{15}$$

*Prove:* According to (13), we have

$$\begin{aligned}\boldsymbol{V}_i(\boldsymbol{x}(k+i)) &= \min_{\boldsymbol{u}(k+i)}\{\boldsymbol{x}(k+i)^{\mathrm{T}}Q\boldsymbol{x}(k+i)\ +\boldsymbol{W}(\boldsymbol{u}(k+i)))\}\\ &\quad \boldsymbol{s.t.}\ \boldsymbol{F}(\boldsymbol{x}(k+i),\boldsymbol{u}(k+i))=\boldsymbol{0}\end{aligned} \tag{16}$$

Thus,

$$\begin{aligned}\boldsymbol{V}_{i+1}(\boldsymbol{x}(k)) &= \min_{\boldsymbol{u}(k)}\{\boldsymbol{x}(k)^{\mathrm{T}}Q\boldsymbol{x}(k)+\boldsymbol{W}(\boldsymbol{u}(k))+\boldsymbol{V}_i(\boldsymbol{x}(\mathrm{k}+1)\}\\ &=\min_{\boldsymbol{u}(k)}\left\{\ \boldsymbol{x}(k)^{\mathrm{T}}\mathrm{Q}\boldsymbol{x}(k)+\boldsymbol{W}(\boldsymbol{u}(k))\right.\\ &\quad+\min_{\boldsymbol{u}(k+1)}\left\{\ \{\boldsymbol{x}(k+1)^{\mathrm{T}}Q\boldsymbol{x}(k+1)+\boldsymbol{W}(\boldsymbol{u}(k+1))\right.\\ &\quad+\min_{\boldsymbol{u}(k+2)}\{\ \boldsymbol{x}(k+2)^{\mathrm{T}}Q\boldsymbol{x}(k+2)+\boldsymbol{W}(\boldsymbol{u}(k+2))+\cdots\\ &\quad+\min_{\boldsymbol{u}(k+i-1)}\{\boldsymbol{x}(k+i\text{-}1)^{\mathrm{T}}Q\boldsymbol{x}(k+i\text{-}1)+\boldsymbol{W}(\boldsymbol{u}(k+i\text{-}1))\\ &\quad\left.\left.+\boldsymbol{V}_1(\boldsymbol{x}(k+i))\}\cdots\ \}\ \right\}\ \right\}\end{aligned} \tag{17}$$

Then (17) could be written as

$$\begin{aligned}\boldsymbol{V}_{i+1}(\boldsymbol{x}(k)) &= \min_{\underline{\boldsymbol{u}}_k^{k+i}}\{\boldsymbol{x}(k)^{\mathrm{T}}Q\boldsymbol{x}(k)+\boldsymbol{W}(\boldsymbol{u}(k))\\ &\quad+\boldsymbol{x}(k+1)^{\mathrm{T}}Q\boldsymbol{x}(k+1)\ +\boldsymbol{W}(\boldsymbol{u}(k+1))+\cdots\\ &\quad+\boldsymbol{x}(k+i)^{\mathrm{T}}Q\boldsymbol{x}(k+i)+\boldsymbol{W}(\boldsymbol{u}(k+i))\}\\ &\quad\boldsymbol{s.t.}\ \boldsymbol{F}(\boldsymbol{x}(k+i),\boldsymbol{u}(k+i))=\boldsymbol{0}\\ &=\min_{\underline{\boldsymbol{u}}_k^{k+i}}\{\boldsymbol{J}(\boldsymbol{x}(k),\underline{\boldsymbol{u}}_k^{k+i}):\underline{\boldsymbol{u}}_k^{k+i}\in\mathbf{C}_{\boldsymbol{x}_k}^{(i+1)}\}\end{aligned} \tag{18}$$

Thus (15) holds.

Three theorems as well as a corollary are given in the following. For the proof in detail, see [10],[11].

*Theorem 1:* Giving an arbitrary state vector $\boldsymbol{x}(k)$, assume there exist an integral $i$ such that $\mathbf{C}_{\boldsymbol{x}_k}^{(i)}\neq\varnothing$, then $\mathbf{C}_{\boldsymbol{x}_k}^{(i+1)}\neq\varnothing$, the performance index function $\boldsymbol{V}_i(\boldsymbol{x}(k))$ is a monotonically nonincreasing sequence. i.e. $\forall i\geq 1$, $\boldsymbol{V}_{i+1}(\boldsymbol{x}(k))\leq\boldsymbol{V}_i(\boldsymbol{x}(k))$.

*Theorem 2:* Giving an arbitrary state vector $\boldsymbol{x}(k)$,Define the performance index function $\boldsymbol{V}_\infty(\boldsymbol{x}(k))$ as the limit of the iterative function $V_i(\boldsymbol{x}(k))$, i.e.,

$$\boldsymbol{V}_\infty(\boldsymbol{x}(k)) = \lim_{i\to\infty} \boldsymbol{V}_i(\boldsymbol{x}(k)) \tag{19}$$

Thus,

$$V_\infty(\boldsymbol{x}(k)) = \min_{\boldsymbol{u}(k)} \{\boldsymbol{x}(k)^{\mathrm{T}} Q\boldsymbol{x}(k) + \boldsymbol{W}(\boldsymbol{u}(k)) + V_\infty(\boldsymbol{x}(k+1))\} \tag{20}$$

*Theorem 3:* Define the performance index function $\boldsymbol{V}_\infty(\boldsymbol{x}(k))$ as (13), assume the state $\boldsymbol{x}(k)$ is controllable, then the performance index function $\boldsymbol{V}_\infty(\boldsymbol{x}(k))$ equals the optimal performance index function $\boldsymbol{J}^*(\boldsymbol{x}(k))$, i.e.

$$\lim_{i\to\infty} \boldsymbol{V}_i(\boldsymbol{x}(k)) = \boldsymbol{J}^*(\boldsymbol{x}(k)) \tag{21}$$

*Corollary 1:* Assume the system state $\boldsymbol{x}(k)$ is admissible controllable and the performance index function is defined in (13), and Theorem 3 holds, then the iterative control law $\upsilon_i(\boldsymbol{x}(k))$ converges to the optimal control law $\boldsymbol{u}^*(\boldsymbol{x}(k))$.

## IV. ε-Optimal Control Algorithm

### *A. ε-Optimal Control*

In order to get the limit of the performance index function $\boldsymbol{V}_i(\boldsymbol{x}(k))$, iterative ADP algorithm (10) is need to perform, optimal control law $\boldsymbol{u}^*(\boldsymbol{x}(k))$ won't obtain until $i \to \infty$. However, $i$ is usually numbered in practical, $\boldsymbol{J}^*(\boldsymbol{x}(k)) = \boldsymbol{V}_i(\boldsymbol{x}(k))$ could not hold for any finite $i$. Therefore, error bound ε is introduced for $\boldsymbol{V}_i(\boldsymbol{x}(k))$ and $\boldsymbol{J}^*(\boldsymbol{x}(k))$ in iterative ADP algorithm, so that the performance index function $\boldsymbol{V}_i(\boldsymbol{x}(k))$ approximates to the optimal performance index function $\boldsymbol{J}^*(\boldsymbol{x}(k))$ in finite number of steps.

*Definition 2:* let $\boldsymbol{\Gamma}_\infty$ be a controllable state set, $\boldsymbol{x}(k) \in \boldsymbol{\Gamma}_\infty, \varepsilon > 0$, then the number of iteration steps $K_{\boldsymbol{\varepsilon}}(\boldsymbol{x}(k))$ for optimal control is defined as

$$K_{\boldsymbol{\varepsilon}}(\boldsymbol{x}(k)) = \min\left\{ i : \left| \boldsymbol{V}_i(\boldsymbol{x}(k)) - \boldsymbol{J}^*(\boldsymbol{x}(k)) \right| \le \boldsymbol{\varepsilon} \right\} \tag{22}$$

$K_{\boldsymbol{\varepsilon}}(\boldsymbol{x}(k))$ refers to the length of control sequence reaching equilibrium point from $\boldsymbol{x}(k)$, since $\boldsymbol{x}(k) \in \boldsymbol{\Gamma}_\infty$, thus $\lim_{i\to\infty} \boldsymbol{V}_i(\boldsymbol{x}(k)) = \boldsymbol{J}^*(\boldsymbol{x}(k))$. Therefore, there exists a finite $i$ such that

$$\left| \boldsymbol{V}_i(\boldsymbol{x}(k)) - \boldsymbol{J}^*(\boldsymbol{x}(k)) \right| \le \boldsymbol{\varepsilon} \tag{23}$$

holds. Thus $\left\{ i : \left| \boldsymbol{V}_i(\boldsymbol{x}(k)) - \boldsymbol{J}^*(\boldsymbol{x}(k)) \right| \le \boldsymbol{\varepsilon} \right\} \ne \varnothing$, so that $K_{\boldsymbol{\varepsilon}}(\boldsymbol{x}(k))$ is defined.

*Definition 3:* let $\boldsymbol{x}(k) \in \boldsymbol{\Gamma}_\infty$ be a controllable state vector, for any $\boldsymbol{\varepsilon} > 0$, if $\left| \boldsymbol{V}_i(\boldsymbol{x}(k)) - \boldsymbol{J}^*(\boldsymbol{x}(k)) \right| \le \boldsymbol{\varepsilon}$ holds for the iterative control law $\upsilon_i(\boldsymbol{x}(k))$, then the $\upsilon_i(\boldsymbol{x}(k))$ is defined as a ε-Optimal Control $\boldsymbol{\mu}_\varepsilon^*(\boldsymbol{x}(k))$, i.e.

$$\boldsymbol{\mu}_\varepsilon^*(\boldsymbol{x}(k)) = \upsilon_i(\boldsymbol{x}(k)) = \arg\min_{\boldsymbol{u}(k)} \left\{ \begin{array}{l} \boldsymbol{x}(k)^{\mathrm{T}} Q\boldsymbol{x}(k) + \boldsymbol{W}(\boldsymbol{u}(k)) \\ + \boldsymbol{V}_{i-1}(\boldsymbol{F}(\boldsymbol{x}(k), \boldsymbol{u}(\boldsymbol{x}(k)))) \end{array} \right\} \tag{24}$$

### *B. Summary of the ε -Optimal Control Algorithm*

Step A1. Giving an initial state $\boldsymbol{x}(k)$ and an error bound ε .

Step A2. Set $i = 0$, $V_0(\boldsymbol{x}(k)) = 0$ and $K_{\boldsymbol{\varepsilon}}(\boldsymbol{x}(k)) = 0$.

Step A3. Calculate $\upsilon_1(\boldsymbol{x}(k)) = \boldsymbol{u}^*(k)$ by (12).

Step A4. For $i = 1$, calculate $\boldsymbol{V}_1(\boldsymbol{x}(k))$ by (11).

Step A5. Set $i = i + 1$ and $K_{\boldsymbol{\varepsilon}}(\boldsymbol{x}(k)) = i$

Step A6. For $i = 2, 3, \cdots$, calculate $\upsilon_i(\boldsymbol{x}(k))$ by (14), calculate $\boldsymbol{V}_i(\boldsymbol{x}(k))$ by (13).

Step A7. If $\left| \boldsymbol{V}_{i+1}(\boldsymbol{x}(k)) - \boldsymbol{V}_i(\boldsymbol{x}(k)) \right| \le \boldsymbol{\varepsilon}$, go to step A8; then $K_{\boldsymbol{\varepsilon}}(\boldsymbol{x}(k)) = i$ is the number of optimal control steps, ε-optimal control law is $\boldsymbol{\mu}_\varepsilon^*(\boldsymbol{x}(k)) = \upsilon_i(\boldsymbol{x}(k))$ .otherwise, go to step A5.

Step A8. Stop.

## V. Simulation Study

### *A. ε-Iterative ADP Algorithm for Saturating Actuator*

Consider the following nonlinear system

$$\boldsymbol{x}(k+1) = f(\boldsymbol{x}(k)) + g(\boldsymbol{x}(k))\boldsymbol{u}(k) \tag{25}$$

where

$$f(\boldsymbol{x}(k)) = \begin{bmatrix} -0.5x_2(k) \\ sin(0.8x_1(k) - x_2(k)) + 1.8x_2(k) \end{bmatrix}$$

$$g(\boldsymbol{x}(k)) = \begin{bmatrix} -0.1x_1(k) & 0 \\ 0 & -0.8x_2(k) \end{bmatrix}, \mathbf{A} = \begin{bmatrix} \bar{u}_1 & 0 \\ 0 & \bar{u}_2 \end{bmatrix} = \begin{bmatrix} 0.5 & 0 \\ 0 & 1 \end{bmatrix}, \boldsymbol{Q} = \boldsymbol{R} = \boldsymbol{I}_{2\times 2},$$

The performance index function is

$$\boldsymbol{J}\left(\boldsymbol{x}(k), \boldsymbol{u}(\cdot)\right) = \sum_{i=k}^{k+N-1} \left\{ \boldsymbol{x}(i)^{\mathrm{T}} Q\boldsymbol{x}(i) + \boldsymbol{W}(\boldsymbol{u}(i)) \right\} \tag{26}$$

Neural networks are used to implement the iterative ADP algorithm in [7],[9],[10] with its good function approximating characteristics. The structure diagram of the iterative ADP algorithm using Neural-Network approximate function is shown in figure 2. In the diagram, critic neural network is used to approximate function $\boldsymbol{V}_i(\boldsymbol{x})$, action neural network is used to control law $\upsilon_i(\boldsymbol{x}(k))$, gradient descent algorithm is used to adjust the weight by neural network training rule, the approximate proof and formula derivation can be checked in [7],[9],[12]. The critic network and the action network are chosen as three-layer back-propagation (BP) neural networks with the structures of 2–10–1 and 2–10–2. According to ε-optimal control algorithm, let $\boldsymbol{\varepsilon} = 10^{-3}$, the initial state is chosen as $\boldsymbol{x}(k) = [1, -1]^{\mathrm{T}}$, learning rate $\alpha = 0.05$ . For each iterative step, the critic network and the action network are trained for 100 iteration steps so as to guarantee the neural network training error is less than $10^{-6}$.

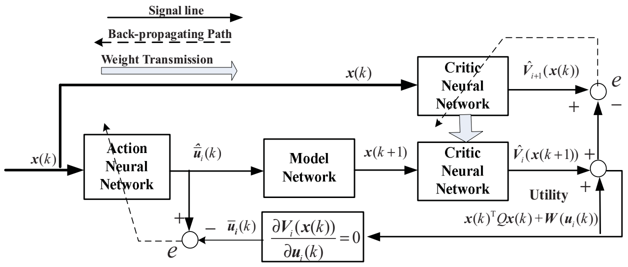

Figure 2. The structure diagram of the iterative ADP algorithm using Neural-Network approximate $V_i(x)$ and $\upsilon_i(x)$

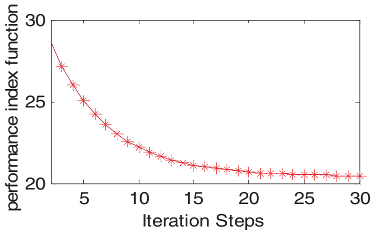

Figure 3. The convergence process of the cost function

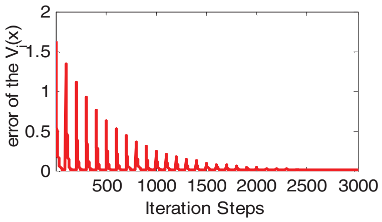

Figure 4. The error of neural-network approximate cost function

Simulation result in Figure 3 shows the iteration convergence process of the cost function $V_i(x(k))$. When $i=30$, $|V_i(x(k))-J^*(x(k))|\le\varepsilon$ holds, thus ε−optimal control law $\mu_\varepsilon^*$ is obtained in finite step $K_\varepsilon(x(k))=i=30$. Besides, Figure 3 also shows that $V_i(x(k))$ satisfy the monotonically nonincreasing and constringency property in Theorem 1 since $V_{i+1}(x(k))\le V_i(x(k))$. Figure 4 shows the error of neural-network approximate cost function. In order to verify the control law $\mu_\varepsilon^*$ obtained by ε-iteration algorithm, the state trajectories and the optimal control trajectories are shows in Figure 5 and Figure 6 for the state $x(k)=[1,-1]^{\mathrm{T}}$, Figure 7 shows the state trajectories in 3d space performance. Notice that the state has been control in stable within finite step $T_f=30$ showed in Figure 6, which satisfies the theory, on the other hand, the control output $|u_1|\le\bar{u}_1=0.5$, $|u_2|\le\bar{u}_2=1$ in Figure 6 shows that control output signal actuator keeps under the constraints $|u|\le\mathbf{A}$.

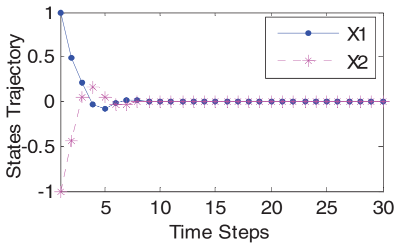

Figure 5. The state trajectories

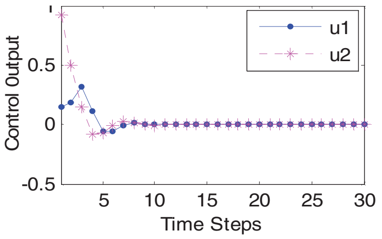

Figure 6. The optimal control trajectories

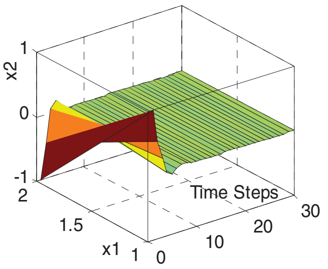

Figure 7. The state trajectories in 3d space performance

## *B. Comparison of simulation*

In order to contrast with the controller with saturating actuator, the state trajectories without actuators saturation is showed in Figure 8 and the optimal control trajectories without actuators saturation is showed in Figure 9. In Figure 9, control output satisfy $|u_1|\ge 0.5$, $|u_2|\ge 1$, thus the control signal will be distorted with saturating actuator, while it keeps under the constraints in Figure 6. Comparing results with Figure 6 and Figure 9, result shows that ε-Iterative adaptive dynamic programming works effective for finite-horizon optimal control scheme for nonlinear systems with saturating actuator.

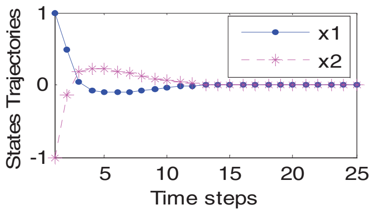

Figure 8. The state trajectories without actuators saturation

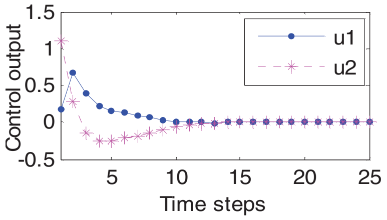

Figure 9. The optimal control trajectories without actuators saturation

## VI. CONCLUSION

In this paper, a functional performance index function was used to deal with saturating actuator control with constraints effectively. Furthermore, discrete HJB equation of nonlinear systems was derived. Finite horizon iteration ADP algorithm for control with saturation was developed via mathematical analysis. Finally the finite-horizon optimal control was obtained by the ε−iterative adaptive algorithm.

*Abstract* - **This paper presents a method for actively controlling torsional vibrations in rotating machines caused by angle-dependent parameters. The work is motivated by rotating machines with crank or cam gear mechanisms that cause fluctuations in the angular speed when the machine is driven by a constant load torque or when the speed is controlled with conventional controllers. A very general model for such a system is introduced and used to derive a control law by feedback linearization. With this control law, the speed fluctuations are completely eliminated and desired linear dynamics can be prescribed for the system. The method is tested in a simulation study with a model of a real industrial machine. Although the proposed method works well, the study is preliminary in the sense that the method has not been applied experimentally and its robustness has not been assessed.**

***Active vibration control; Feedback linearization; Nonlinear control; Speed control; Torsional vibrations***

## I. Motivation

There are different causes for torsional vibrations in drives. These vibrations can be the result of eccentric masses [1] or be excited by the propulsion itself, e.g. a combustion engine [2, 3, 4] or an electric drive [5, 6]. Another commonly occurring cause is the transformation of the rotational motion of the propulsion into a translational motion. This typically happens in a cam gear or a crank assembly and causes a periodically varying load torque.

As an example, a simple crank assembly, which only includes a single oscillating mass, is shown in Fig. 1. The torque equilibrium for this example leads to the equation of motion given as

$$\begin{aligned} T &= m\cdot\ddot{s}(\varphi)\frac{\mathrm{d}s}{\mathrm{d}\varphi} \\ &= m\left(\frac{\mathrm{d}^2s}{\mathrm{d}\varphi^2}\dot{\varphi}^2\cdot+\frac{\mathrm{d}s}{\mathrm{d}\varphi}\cdot\ddot{\varphi}\right)\frac{\mathrm{d}s}{\mathrm{d}\varphi} \qquad (1)\\ &= m\frac{\mathrm{d}^2s}{\mathrm{d}\varphi^2}\frac{\mathrm{d}s}{\mathrm{d}\varphi}\dot{\varphi}^2+m\left(\frac{\mathrm{d}s}{\mathrm{d}\varphi}\right)^2\ddot{\varphi}\ , \end{aligned}$$

where $T$ is the driving torque and all the other variables are as shown in Fig. 1. The displacement $s$ depends on the rotation angles $\alpha$ and $\varphi$ and is given as

$$\begin{aligned} s &= l\left(1-\cos\alpha\right)+r\left(1-\cos\varphi\right) \\ &= l\left(1-\sqrt{1-\frac{r^2}{l^2}\sin^2\varphi}\right)+r\left(1-\cos\varphi\right)=s\left(\varphi\right). \qquad (2) \end{aligned}$$

The introduction of $m\cdot\left(\mathrm{d}s/\mathrm{d}\varphi\right)^2$ as an angle depended parameter $J(\varphi)$ (which could be seen as an apparent, angle-dependent, moment of inertia) leads to

$$T=\frac{1}{2}\frac{\mathrm{d}J(\varphi)}{\mathrm{d}\varphi}\dot{\varphi}^2+J(\varphi)\ddot{\varphi}\,. \qquad (3)$$

Even if a constant driving torque is applied to the system, the internal dynamics lead to nonlinear vibrations. This is due to the dependency of the parameters in the model describing the system on the rotational angle.

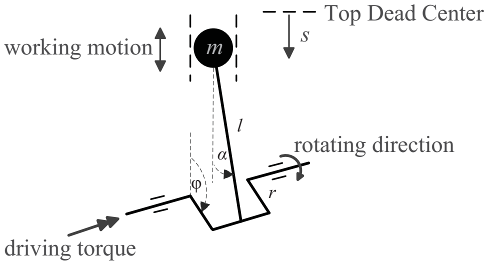

Fig. 1 Schematic diagram of the crankshaft

Such torsional vibrations are a well-known problem in industrial drives like rolling mill systems [7, 8], paper machines [9, 10] or turbo generators [11] and also in vehicles [2]. They lead to product quality problems like damage of machinery and a shorter lifecycle of the plant.

Possible approaches for the attenuation of these vibrations are to change the inertia or to use damping elements, but this often has a negative effect on the dynamics of the machines. Because of these disadvantages several active control approaches to attenuate torsional vibrations have been proposed. In [12], a damping filter is implemented and in [13] a digital PI/PID controller is used to achieve active damping of the vibrations. In [14], an adaptive sliding neuro-fuzzy approach is suggested and in [15] sliding mode and force dynamics are considered. Active damping based on learning control is presented in [16]. In [4] the main target is to reduce the torsional vibrations of a crankshaft by adjusting the fuel injection duration by minimizing a cost function.

Another way to control the dynamic system and attenuate the nonlinear behavior and prescribe linear system dynamics is to use the method of feedback linearization. In [17] and [18], feedback linearization control is used for improved fuel consumption in combustion engines by using feedback linearization, but the afore-mentioned dynamical connections are only regarded marginally. In other fields, vibration control is the main aspect as in [19] where feedback linearization is used for active vehicle suspension control to reduce the vibrations. To the best of the authors' knowledge, however, no applications of feedback linearization to the problem considered in this paper have been reported in the literature to date.

As mentioned above, the torsional vibrations can result from angle-dependent parameters in the system dynamics. The angle itself is also a state of the system. In order to make the method presented in this paper applicable to a wide range of systems, a very universal system description is introduced for systems with state-dependent parameters. The resulting description is very compact. With this description, it is very easy to derive a control law (which is given here only for systems with a relative degree of two, but can easily be extended).

The remainder of this paper is organized as follows. The system description is introduced in Sec. II. The control law is derived in Sec. III. The control approach has been tested in simulation studies for a model that corresponds to an industrial machine that is operated by an industrial partner with whom this study has been conducted. The obtained results are shown in Sec. IV. Some conclusions are given in Sec. V.

## II. System Description

Real industrial drives are more complex systems than the simple example discussed in the introduction. Often, they are composed of more than one crank assembly or cam gear or even combine both types. Furthermore, elasticity, damping and gear ratios have to be taken into account.

Nevertheless, the final system description of such systems will still contain constant and angle-dependent parameters. Due to the rotational mode of operation, the angle-dependent parameters are periodic in the rotational angle (see for example, the parameter $J_\alpha$ for the example considered in Sec. IV shown in Fig. 2).

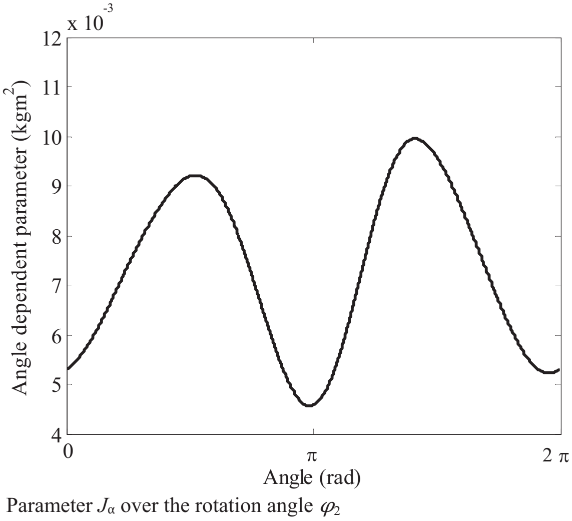

Fig. 2 Parameter $J_\alpha$ over the rotation angle $\varphi_2$

These angle-dependent parameters can then be expanded into a Fourier series. Here, the exponential Fourier series is used for an easier handling of the derivatives. Expanding system parameters into Fourier systems is quite common for describing rotational systems (see, for example, [2], [4] and [20]).

The system dynamics are described by the nonlinear state-space model

$$\dot{\boldsymbol{x}} = \boldsymbol{A}(\boldsymbol{x})\,\boldsymbol{x} + \boldsymbol{B}u\,, \tag{4}$$

where $\boldsymbol{x}$ is the state vector, $u$ the input of the system and $y$ the output. The "system matrix" $\boldsymbol{A}(\boldsymbol{x})$ is assumed to depend on linear combinations of the state vectors according to

$$\boldsymbol{A}(\boldsymbol{x}) = \boldsymbol{A}_0 + \bar{\boldsymbol{A}}\left(\boldsymbol{v}_1^{\mathrm{T}}\boldsymbol{x},\dots,\boldsymbol{v}_N^{\mathrm{T}}\boldsymbol{x}\right) + \tilde{\boldsymbol{A}}\left(\boldsymbol{v}_1^{\mathrm{T}}\boldsymbol{x},\dots,\boldsymbol{v}_N^{\mathrm{T}}\boldsymbol{x}\right). \tag{5}$$

The matrix $\boldsymbol{A}_0$ is constant (and therefore, corresponds to the "linear part" of the system dynamics), the matrix $\bar{\boldsymbol{A}}$ depends periodically on linear combinations of the state vector and the matrix $\tilde{\boldsymbol{A}}$ depends periodically and linearly on the linear combinations of the state vector.

The matrices $\bar{\boldsymbol{A}}(\boldsymbol{x})$ and $\tilde{\boldsymbol{A}}(\boldsymbol{x})$ in the model are expressed as

$$\begin{aligned}\bar{\boldsymbol{A}}(\boldsymbol{x}) &= \bar{\boldsymbol{A}}\left(\boldsymbol{v}_1^{\mathrm{T}}\boldsymbol{x},\dots,\boldsymbol{v}_N^{\mathrm{T}}\,\boldsymbol{x}\right)\\ &= \sum_{l=1}^{N}\sum_{\mu=-L}^{L}\bar{\boldsymbol{M}}_{l,\mu}\,\mathrm{e}^{\,\mathrm{j}\mu\,\boldsymbol{v}_l^{\mathrm{T}}\boldsymbol{x}}\\ &= \sum_{l=1}^{N}\left[\bar{\boldsymbol{M}}_{l,-L}\;\cdots\;\bar{\boldsymbol{M}}_{l,L}\right]\left(\begin{bmatrix}\mathrm{e}^{\left(-L\,\mathrm{j}\boldsymbol{v}_l^{\mathrm{T}}\boldsymbol{x}\right)}\\ \vdots\\ \mathrm{e}^{\left(L\mathrm{j}\boldsymbol{v}_l^{\mathrm{T}}\boldsymbol{x}\right)}\end{bmatrix}\otimes\mathbf{I}_n\right)\end{aligned} \tag{6}$$

and

$$\begin{aligned}&\tilde{\boldsymbol{A}}(\boldsymbol{x}) =\\ &= \tilde{\boldsymbol{A}}\left(\boldsymbol{v}_1^{\mathrm{T}}\boldsymbol{x},\dots,\boldsymbol{v}_N^{\mathrm{T}}\boldsymbol{x}\right)\\ &= \sum_{h=1}^{N}\sum_{l=1}^{N}\sum_{\mu=-L}^{L}\tilde{\boldsymbol{M}}_{h,l,\mu}\;\mathrm{e}^{\,\mathrm{j}\mu\,\boldsymbol{v}_l^{\mathrm{T}}\boldsymbol{x}}\;\boldsymbol{v}_h^{\mathrm{T}}\boldsymbol{x}\\ &= \sum_{h=1}^{N}\sum_{l=1}^{N}\left[\tilde{\boldsymbol{M}}_{h,l,-L}\;\cdots\;\tilde{\boldsymbol{M}}_{h,l,L}\right]\left(\begin{bmatrix}\mathrm{e}^{\left(-L\mathrm{j}\boldsymbol{v}_l^{\mathrm{T}}\boldsymbol{x}\right)}\\ \vdots\\ \mathrm{e}^{\left(L\mathrm{j}\boldsymbol{v}_l^{\mathrm{T}}\boldsymbol{x}\right)}\end{bmatrix}\otimes\left(\boldsymbol{v}_h^{\mathrm{T}}\boldsymbol{x}\mathbf{I}_n\right)\right).\end{aligned} \tag{7}$$

Here, $\otimes$ stands for the Kronecker product [21], $L$ is the order of the Fourier series and $N$ the number of the linear combinations of the state vector that the matrices depend upon. The linear combinations are expressed as $\boldsymbol{v}_p^{\mathrm{T}}\boldsymbol{x}$ with $p = 1,\dots,N$.

The matrices $\bar{\boldsymbol{M}}_{l,\mu}$ and $\tilde{\boldsymbol{M}}_{h,l,\mu}$ result from expanding the periodic system parameters into Fourier series. Since the exponential Fourier series representation is used, it holds that

$$\operatorname{Re}\bar{\boldsymbol{M}}_{l,\mu} = \operatorname{Re}\bar{\boldsymbol{M}}_{l,-\mu}\,,\ \operatorname{Re}\tilde{\boldsymbol{M}}_{h,l,\mu} = \operatorname{Re}\tilde{\boldsymbol{M}}_{h,l,-\mu} \tag{8}$$

$$\operatorname{Im}\bar{\boldsymbol{M}}_{l,\mu} = -\operatorname{Im}\bar{\boldsymbol{M}}_{l,-\mu}\,,\ \operatorname{Im}\bar{\boldsymbol{M}}_{h,l,\mu} = -\operatorname{Im}\bar{\boldsymbol{M}}_{h,l,-\mu} \tag{9}$$

and

$$\operatorname{Im}\bar{\boldsymbol{M}}_{l,0} = \boldsymbol{0}\,,\ \operatorname{Im}\bar{\boldsymbol{M}}_{h,l,0} = \boldsymbol{0}\,. \tag{10}$$

## III. Derivation of the Control Law

Consider a completely controllable SISO system of the form already introduced above, namely

$$\dot{\boldsymbol{x}} = \boldsymbol{A}(\boldsymbol{x})\,\boldsymbol{x} + \boldsymbol{B}u \tag{11}$$

with the output equation

$$y = \boldsymbol{C}\boldsymbol{x}\,. \tag{12}$$

The first step in the derivation of the control law in feedback linearization consists of differentiating the output $y$ until the input signal $u$ shows up in the derivative. The amount of times the output has to be differentiated is known as the relative degree. In the following, it is assumed that the relative degree is two.
The first derivative of $y$ with respect to the time $t$ is

$$\dot{y} = \boldsymbol{C}\,\dot{\boldsymbol{x}} = \boldsymbol{C}\boldsymbol{A}(\boldsymbol{x})\boldsymbol{x} + \boldsymbol{C}\boldsymbol{B}u\,. \tag{13}$$

Since the relative degree is two, it holds that

$$\boldsymbol{C}\boldsymbol{B} = 0\,. \tag{14}$$

The second derivative is then given by

$$\begin{aligned}\ddot{y} &= \boldsymbol{C}\boldsymbol{A}(\boldsymbol{x})\dot{\boldsymbol{x}} + \boldsymbol{C}\dot{\boldsymbol{A}}(\boldsymbol{x})\boldsymbol{x} \\ &= \boldsymbol{C}\boldsymbol{A}(\boldsymbol{x})\big(\boldsymbol{A}(\boldsymbol{x})\boldsymbol{x} + \boldsymbol{B}u\big) + \boldsymbol{C}\dot{\boldsymbol{A}}(\boldsymbol{x})\boldsymbol{x}.\end{aligned} \tag{15}$$

To obtain the second derivative of $y$, the derivative of $\boldsymbol{A}$ with respect to the time $t$ is needed. Using standard rules from matrix differential calculus [21], the time derivative of $\boldsymbol{A}$ follows as

$$\begin{aligned}\dot{\boldsymbol{A}}(\boldsymbol{x}) &= \frac{\partial \boldsymbol{A}(\boldsymbol{x})}{\partial \boldsymbol{x}^{\mathrm{T}}}\frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}t} = \frac{\partial \boldsymbol{A}(\boldsymbol{x})}{\partial \boldsymbol{x}^{\mathrm{T}}}\big(\dot{\boldsymbol{x}} \otimes \mathbf{I}_n\big) \\ &= \frac{\partial \boldsymbol{A}(\boldsymbol{x})}{\partial \boldsymbol{x}^{\mathrm{T}}}\big(\boldsymbol{A}(\boldsymbol{x})\boldsymbol{x} \otimes \mathbf{I}_n + \boldsymbol{B}u \otimes \mathbf{I}_n\big).\end{aligned} \tag{16}$$

From the system description (5), the derivative of $\boldsymbol{A}$ with respect to the transposed state vector $\boldsymbol{x}$ follows as

$$\frac{\partial \boldsymbol{A}(\boldsymbol{x})}{\partial \boldsymbol{x}^{\mathrm{T}}} = \frac{\partial \boldsymbol{A}_0}{\partial \boldsymbol{x}^{\mathrm{T}}} + \frac{\partial \bar{\boldsymbol{A}}(\boldsymbol{x})}{\partial \boldsymbol{x}^{\mathrm{T}}} + \frac{\partial \tilde{\boldsymbol{A}}(\boldsymbol{x})}{\partial \boldsymbol{x}^{\mathrm{T}}}\,. \tag{17}$$

Since $\boldsymbol{A}_0$ is constant, it follows that

$$\frac{\partial \boldsymbol{A}_0}{\partial \boldsymbol{x}^{\mathrm{T}}} = \boldsymbol{0}\,. \tag{18}$$

Using the matrix chain rule and the matrix product rule [21], the second and the third term on the right hand side of (13) become

$$\begin{aligned}\frac{\partial \bar{\boldsymbol{A}}(\boldsymbol{x})}{\partial \boldsymbol{x}^{\mathrm{T}}} &= \sum_{p=1}^{N} \frac{\partial \bar{\boldsymbol{A}}(\boldsymbol{x})}{\partial \boldsymbol{v}_p^{\mathrm{T}}\boldsymbol{x}} \frac{\mathrm{d}\,\boldsymbol{v}_p^{\mathrm{T}}\boldsymbol{x}}{\mathrm{d}\,\boldsymbol{x}^{\mathrm{T}}} \\ &= \sum_{p=1}^{N} \frac{\partial \bar{\boldsymbol{A}}(\boldsymbol{x})}{\partial \boldsymbol{v}_p^{\mathrm{T}}\boldsymbol{x}} (\boldsymbol{v}_p^{\mathrm{T}} \otimes \mathbf{I}_n)\end{aligned} \tag{19}$$

and

$$\begin{aligned}\frac{\partial \tilde{\boldsymbol{A}}(\boldsymbol{x})}{\partial \boldsymbol{x}^{\mathrm{T}}} &= \sum_{p=1}^{N} \frac{\partial \tilde{\boldsymbol{A}}(\boldsymbol{x})}{\partial \boldsymbol{v}_p^{\mathrm{T}}\boldsymbol{x}} \frac{\mathrm{d}\,\boldsymbol{v}_p^{\mathrm{T}}\boldsymbol{x}}{\mathrm{d}\,\boldsymbol{x}^{\mathrm{T}}} \\ &= \sum_{p=1}^{N} \frac{\partial \tilde{\boldsymbol{A}}(\boldsymbol{x})}{\partial \boldsymbol{v}_p^{\mathrm{T}}\boldsymbol{x}} (\boldsymbol{v}_p^{\mathrm{T}} \otimes \mathbf{I}_n)\,.\end{aligned} \tag{20}$$

To calculate these derivatives, the derivatives of the matrices $\bar{\boldsymbol{A}}(\boldsymbol{x})$ and $\tilde{\boldsymbol{A}}(\boldsymbol{x})$ with respect to $\boldsymbol{v}_p^{\mathrm{T}}\boldsymbol{x}$ are required. These derivatives can be easily calculated from (6) and (7) and are given as

$$\begin{aligned}\frac{\partial \bar{\boldsymbol{A}}(\boldsymbol{x})}{\partial \boldsymbol{v}_p^{\mathrm{T}}\boldsymbol{x}} &= \sum_{\mu=-L}^{L} \bar{\boldsymbol{M}}_{p,\mu}\; \mathrm{j}\mu\; \mathrm{e}^{\,\mathrm{j}\mu\, \boldsymbol{v}_p^{\mathrm{T}}\boldsymbol{x}} \\ &= \begin{bmatrix} \bar{\boldsymbol{M}}_{p,-L} & \cdots & \bar{\boldsymbol{M}}_{p,L} \end{bmatrix} \left( \begin{bmatrix} -L\mathrm{j}\cdot \mathrm{e}^{\left(-L\,\mathrm{j}\boldsymbol{v}_p^{\mathrm{T}}\boldsymbol{x}\right)} \\ \vdots \\ L\mathrm{j}\cdot \mathrm{e}^{\left(L\,\mathrm{j}\boldsymbol{v}_p^{\mathrm{T}}\boldsymbol{x}\right)} \end{bmatrix} \otimes \mathbf{I}_n \right)\end{aligned} \tag{21}$$

and

$$\begin{aligned}&\frac{\partial \tilde{\boldsymbol{A}}(\boldsymbol{x})}{\partial \boldsymbol{v}_p^{\mathrm{T}}\boldsymbol{x}} = \\ &= \sum_{h=1}^{N}\sum_{l=1}^{N}\sum_{\mu=-L}^{L} \tilde{\boldsymbol{M}}_{h,l,\mu} \left( \mathrm{e}^{\,\mathrm{j}\mu\, \boldsymbol{v}_l^{\mathrm{T}}\boldsymbol{x}} \frac{\partial\, \boldsymbol{v}_h^{\mathrm{T}}\boldsymbol{x}}{\partial\, \boldsymbol{v}_p^{\mathrm{T}}\boldsymbol{x}} + \frac{\partial\, \mathrm{e}^{\,\mathrm{j}\mu\, \boldsymbol{v}_l^{\mathrm{T}}\boldsymbol{x}}}{\partial\, \boldsymbol{v}_p^{\mathrm{T}}\boldsymbol{x}}\, \boldsymbol{v}_h^{\mathrm{T}}\boldsymbol{x} \right) \\ &= \sum_{l=1}^{N}\sum_{\mu=-L}^{L} \tilde{\boldsymbol{M}}_{p,l,\mu}\, \mathrm{e}^{\,\mathrm{j}\mu\, \boldsymbol{v}_l^{\mathrm{T}}\boldsymbol{x}} + \sum_{h=1}^{N}\sum_{\mu=-L}^{L} \tilde{\boldsymbol{M}}_{h,i,\mu}\, \mathrm{j}\mu\, \mathrm{e}^{\,\mathrm{j}\mu\, \boldsymbol{v}_p^{\mathrm{T}}\boldsymbol{x}}\; \boldsymbol{v}_h^{\mathrm{T}}\boldsymbol{x} \\ &= \sum_{l=1}^{N} \begin{bmatrix} \tilde{\boldsymbol{M}}_{p,l,-L} & \cdots & \tilde{\boldsymbol{M}}_{p,\,l,L} \end{bmatrix} \left( \begin{bmatrix} \mathrm{e}^{-\mathrm{j}\,L\boldsymbol{v}_l^{\mathrm{T}}\boldsymbol{x}} \\ \vdots \\ \mathrm{e}^{\,\mathrm{j}\,L\boldsymbol{v}_l^{\mathrm{T}}\boldsymbol{x}} \end{bmatrix} \otimes \mathbf{I}_n \right) + \\ &+ \sum_{h=1}^{N} \begin{bmatrix} \tilde{\boldsymbol{M}}_{h,\,p,-L} & \cdots & \tilde{\boldsymbol{M}}_{h,\,p,L} \end{bmatrix} \cdot \\ &\qquad\cdot \left( \begin{bmatrix} -\mathrm{j}L\,\mathrm{e}^{-\mathrm{j}\,L\boldsymbol{v}_p^{\mathrm{T}}\boldsymbol{x}} \\ \vdots \\ \mathrm{j}L\,\mathrm{e}^{\,\mathrm{j}\,L\boldsymbol{v}_p^{\mathrm{T}}\boldsymbol{x}} \end{bmatrix} \otimes \left(\boldsymbol{v}_h^{\mathrm{T}}\boldsymbol{x}\,\mathbf{I}_n\right) \right).\end{aligned} \tag{22}$$

From (21) and (22) the advantage of the description in the introduced matrix notation becomes obvious because the matrices remain unchanged since their elements are constant. Only the vectors including the exponential functions of the Fourier series and the second factor of the Kronecker product change due to the differentiation.

With (16) to (22) all necessary expressions are given to compute the control law

$$\begin{aligned}u = &\frac{-\boldsymbol{C}\left(\dfrac{\partial \boldsymbol{A}(\boldsymbol{x})}{\partial \boldsymbol{x}^{\mathrm{T}}}\big(\boldsymbol{A}(\boldsymbol{x})\boldsymbol{x} \otimes \boldsymbol{I}_n\big) + \boldsymbol{A}^2(\boldsymbol{x})\right)\boldsymbol{x}}{\boldsymbol{C}\left(\dfrac{\partial \boldsymbol{A}(\boldsymbol{x})}{\partial \boldsymbol{x}^{\mathrm{T}}}\big(\boldsymbol{B} \otimes \boldsymbol{I}_n\big)\boldsymbol{x} + \boldsymbol{A}(\boldsymbol{x})\boldsymbol{B}\right)} + \\ &+ \frac{-\gamma_1 \boldsymbol{C}\boldsymbol{A}(\boldsymbol{x})\boldsymbol{x} - \gamma_0 \boldsymbol{C}\boldsymbol{x} + \beta w}{\boldsymbol{C}\left(\dfrac{\partial \boldsymbol{A}(\boldsymbol{x})}{\partial \boldsymbol{x}^{\mathrm{T}}}\big(\boldsymbol{B} \otimes \boldsymbol{I}_n\big)\boldsymbol{x} + \boldsymbol{A}(\boldsymbol{x})\boldsymbol{B}\right)},\end{aligned} \tag{23}$$

which can be calculated from (15). Applying the control law (23) leads to the resulting closed loop dynamics described by

$$\ddot{y} = -\gamma_1\dot{y} - \gamma_0 y + \beta w \tag{24}$$

As mentioned above, the derivation shown here is for systems with a relative degree of two. An extension to systems with a higher relative degree is fairly straightforward.

## IV. Simulation Studies

The control design described in the previous section is applied to an industrial machine in a simulation study. A schematic diagram of the model is shown in Fig. 3.

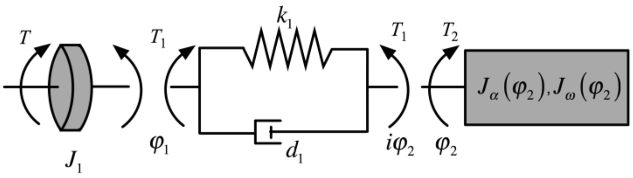

Fig. 3 Schematic diagram of the industrial machine (belt not shown)

The dynamics of this model are described by

$$J_1 \ddot{\varphi}_1 = T - T_1 , \tag{25}$$

$$J_\alpha(\varphi_2)\ddot{\varphi}_2 + J_\omega(\varphi_2)\dot{\varphi}_2^2 = T_2 \tag{26}$$

with

$$T_1 = k_1(\varphi_1 - i\varphi_2) + d_1(\dot{\varphi}_1 - i\dot{\varphi}_2), \tag{27}$$

and

$$T_2 = iT_1 \ . \tag{28}$$

In this model, $T$ is the driving torque generated from an electrical machine (not included in the model) and $T_1$ and $T_2$ are inner torques that are transmitted through a belt drive (not shown in the diagram) with gear ratio $i$; $\varphi_1$ and $\varphi_2$ are the rotation angles of the drive side and the load side; $J_1$ is the moment of inertia at the driving end, $k_1$ is the stiffness and $d_1$ the damping of the system; $J_\alpha$ and $J_\omega$ are angle-dependent parameters that can be calculated from the construction data of the machine and were provided by an industrial partner that manufactures this type of machine. The variations of the parameters $J_\alpha$ over the angle $\varphi_2$ and $J_\omega$ over the angle $\varphi_2$ are shown in Fig. 2 and Fig. 4, respectively.

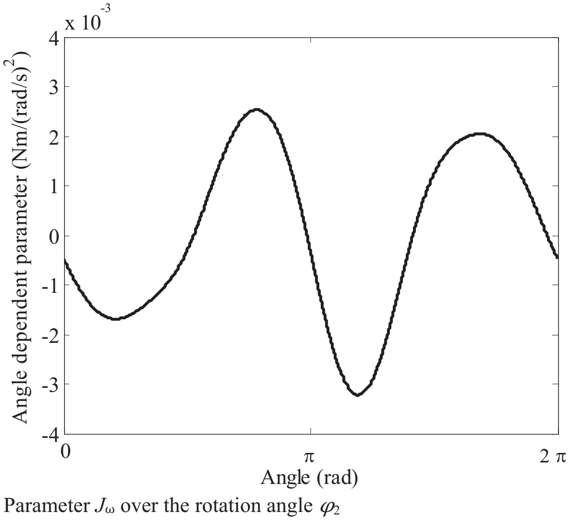

Fig. 4 Parameter $J_\omega$ over the rotation angle $\varphi_2$

If the system is driven by a constant input torque, the resulting angular speed fluctuates around a mean value. This undesirable behavior is shown in Fig. 5. The potential of standard cascaded PID/PI speed control for reducing these oscillations is limited. The tuning of PID/PI control for such systems is difficult since certain settings of the controller parameters can even amplify the oscillations in certain operating conditions.

The system equations can be written as the state space model given by (11) and (12) with

$$\boldsymbol{x} = \begin{bmatrix} \varphi_1 & \dot{\varphi}_1 & \varphi_2 & \dot{\varphi}_2 \end{bmatrix}^{\mathrm{T}}, \tag{29}$$

$$\boldsymbol{A}(\boldsymbol{x}) = \begin{bmatrix} 0 & 1 & 0 & 0 \\ \frac{-k_1}{J_1} & \frac{-d_1}{J_1} & \frac{ik_1}{J_1} & \frac{id_1}{J_1} \\ 0 & 0 & 0 & 1 \\ \frac{ik_1}{J_\alpha(x_3)} & \frac{id_1}{J_\alpha(x_3)} & -\frac{i^2 k_1}{J_\alpha(x_3)} & -\frac{i^2 d_1 + J_\omega(x_3) x_4}{J_\alpha(x_3)} \end{bmatrix}, \tag{30}$$

$$\boldsymbol{B} = \begin{bmatrix} 0 & 1/J_1 & 0 & 0 \end{bmatrix}^{\mathrm{T}}, \tag{31}$$

and

$$\boldsymbol{C} = \begin{bmatrix} 0 & 0 & 0 & 1 \end{bmatrix}. \tag{32}$$

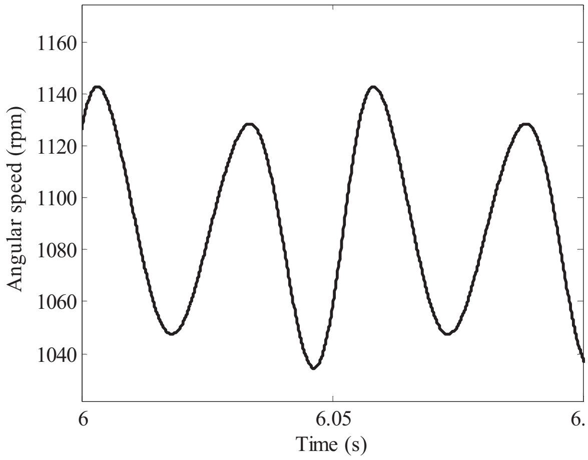

Fig. 5 Angular speed $\dot{\varphi}_2$ if the system is driven by constant torque

From (30) it can be seen that the behavior of the considered system depends on the rotation angle $\varphi_2$ which corresponds to the state $x_3$ and its derivative $\dot{\varphi}_2$ which corresponds to the state $x_4$.

For this system the state space representation of the form introduced in Sec. II becomes

$$\dot{\boldsymbol{x}} = \left(\boldsymbol{A}_0 + \bar{\boldsymbol{A}}(\boldsymbol{v}_1^{\mathrm{T}}\boldsymbol{x}, \boldsymbol{v}_2^{\mathrm{T}}\boldsymbol{x}) + \tilde{\boldsymbol{A}}(\boldsymbol{v}_1^{\mathrm{T}}\boldsymbol{x}, \boldsymbol{v}_2^{\mathrm{T}}\boldsymbol{x})\right)\boldsymbol{x} + \boldsymbol{B}u \tag{33}$$

$$y = \boldsymbol{C}\boldsymbol{x}, \tag{34}$$

with the vectors

$$\mathbf{v}_1 = \begin{bmatrix} 0 & 0 & 1 & 0 \end{bmatrix}^{\mathrm{T}} \tag{35}$$

and

$$\mathbf{v}_2 = \begin{bmatrix} 0 & 0 & 0 & 1 \end{bmatrix}^{\mathrm{T}} \tag{36}$$

the relevant states $x_3$ and $x_4$ can be selected. Thus, $N = 2$ .

From the system matrix in (30) the linear part of the system matrix can be read off directly and gives

$$\boldsymbol{A}_0 = \begin{bmatrix} 0 & 1 & 0 & 0 \\ -k_1/J_1 & -d_1/J_1 & ik_1/J_1 & id_1/J_1 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{bmatrix}. \tag{37}$$

As introduced in (5), the nonlinear parts of (30) are divided into a part $\bar{\boldsymbol{A}}$ with a harmonic dependence on the states and $\tilde{\boldsymbol{A}}$ with a harmonic and a linear dependence on the states. These nonlinear parts can be represented by a Fourier series.

The matrix coefficients $\bar{\boldsymbol{M}}_{l,\mu}$ for the matrix $\bar{\boldsymbol{A}}$ in (6) are obtained as

$$\bar{\boldsymbol{M}}_{1,\mu} = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ ik_1\bar{m}_\mu & id_1\bar{m}_\mu & -i^2k_1\bar{m}_\mu & -d_1i^2\bar{m}_\mu \end{bmatrix} \tag{38}$$

and

$$\bar{\boldsymbol{M}}_{2,\mu} = \boldsymbol{0}\,, \tag{39}$$

where the scalars $\bar{m}_\mu$ are the coefficients of the Fourier expansion of $J_\alpha^{-1}$. Similarly, the matrix coefficients for $\tilde{\boldsymbol{A}}$ in (7) are obtained as

$$\tilde{\boldsymbol{M}}_{2,1,\mu} = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & \tilde{m}_\mu \end{bmatrix}, \tag{40}$$

$$\tilde{\boldsymbol{M}}_{1,1,\mu} = \tilde{\boldsymbol{M}}_{1,2,\mu} = \tilde{\boldsymbol{M}}_{2,2,\mu} = \boldsymbol{0}\,, \tag{41}$$

where the scalars $\tilde{m}_\mu$ are the coefficients of the Fourier expansion of $J_\omega / J_\alpha$. Fourier series of eight order are used, that is, $L = 8$ .

The simulated control result for the model of the industrial machine is shown in Fig. 6. The effects of the nonlinearities are attenuated by the calculated control law with feedback linearization. Also the desired linear behavior as a second order system is achieved.

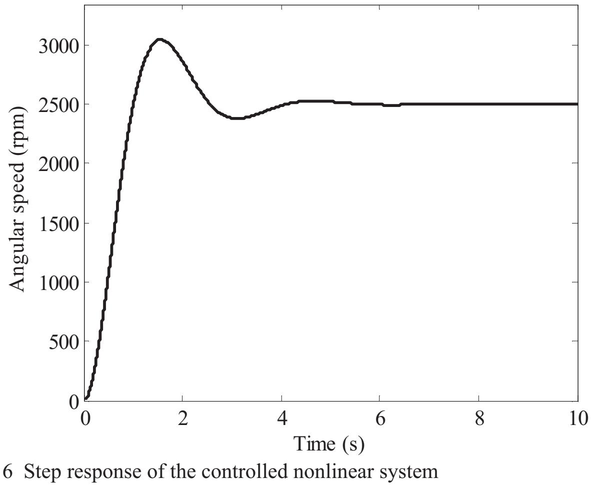

Fig. 6 Step response of the controlled nonlinear system

In Fig. 7 it can be seen that the angular speed at the drive side is still fluctuating while the angular speed at the load side is constant.

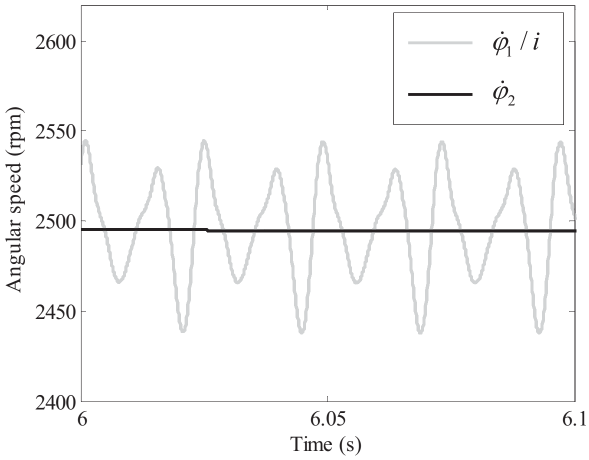

Fig. 7 Fluctuating angular speed $\dot{\varphi}_1$ at the drive side (related to the load side by including the gear ratio *i*) and constant angular speed $\dot{\varphi}_2$ at the load side

The control signal for the considered system to achieve the desired behavior is shown in Fig. 8. No calculations are needed to obtain the derivatives and the control law since the matrix coefficients can be simply plugged into the corresponding equations and the control law is readily obtained.

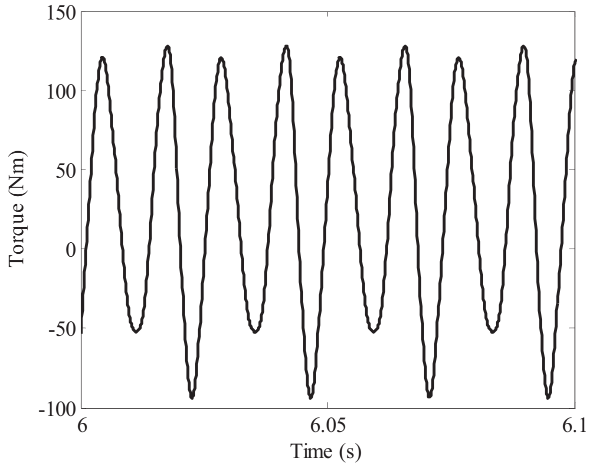

Fig. 8 Control signal to achieve the desired behavior on the output

## V. Summary and Conclusion

In this paper, the active control of speed fluctuations in rotating machines has been considered. After a simple motivating example, a very general state-space description of the considered systems was introduced. With this system description, it is very easy to derive a control law that eliminates the speed fluctuations and results in a second-order linear dynamics for the controlled system. The proposed control law has been applied to a model that represents the behavior of an industrial machine that shows undesired speed fluctuations. To the best of the authors knowledge, this is the first time that feedback linearization has been used for active vibration control for such systems.

The steps that need to be carried out in the control design process consist of transforming the model equations into the general form. This involves reading off entries from the model equations and expanding periodic model parameters into Fourier series. This can be easily done using the standard discrete Fourier transform.

Although the simulation results show that the approach works well (as predicted by theory), it is stressed that this is a preliminary study. The setup considered here corresponds to an ideal case (noise free measurements, no actuator and sensor dynamics included, all system parameters exactly known, all states available for feedback, continuous-time control possible). The applicability of this approach in more realistic cases will be investigated in future studies, where robustness issues (sensitivity to noise and model inaccuracies), implementation issues (discretization of the control algorithm) and extensions (including actuator and sensor dynamics, using an observer to reconstruct unmeasured state variables) will be investigated. The main contribution of this paper is the idea of using feedback linearization for the active control of torsional vibrations.

# An adaptive sliding mode approach to decentralized control of uncertain systems

Zheng Huang, Ron J Patton
Department of Engineering
University of Hull
Hull, UK
Z.Huang@2009.hull.ac.uk; r.j.patton@hull.ac.uk

*Abstract*—**This paper proposes a systematic adaptive sliding mode controller design for the decentralized system with nonlinear interactions and unmatched uncertainties. An adaptive tuning approach is developed to deal with unknown but bounded uncertainties/interactions. The sliding surface is designed which obviates the use of regular transformation, by solving a simple LMI-based optimization problem. The feasibility of the LMIs is also discussed in this paper. Finally, a numerical example is used to illustrate this method.**

***Keywords-Decentralized control, sliding mode, unmatched unccertainties/interactions, adaptive control***

## I. Introduction

Decentralized control has gained considerable attention in the literature for two decades. [1]-[9]. The main idea of decentralized control is to use only local information at the level of each subsystem in the controller for large-scale interconnected systems. This feature can overcome the limitations of the traditional centralized control or partial decentralized control [10] that requires large communication bandwidth to exchange information between subsystems and controller. The decentralized control has much simpler control structure and more practical approach than centralized controller.

On the other hand, sliding mode control (SMC), as a powerful robust control method, has been widely researched,[11], [12]. When using sliding mode, there are two steps i). sliding surface design and ii). control law design. The system states will be driven to the sliding surface and be maintained on it. Once the system is running in the sliding surface, the system is insensitive to the matched perturbations (perturbations coming from input channels). Edwards and Spurgeon [11] develop their approach to the classical sliding mode control design algorithm by introducing a so called *"regular form"* to set up a decomposition comprising matched/unmatched state space components. This approach can be considered too complex for a single SMC system and this motivates the use of an alternative approach obviating a need for transformations, whilst still satisfying matching condition properties.

Choi [12],[13] proposed another SMC approach in which the sliding surface can be designed by solving a simple LMI problem. Although no transformations are used Choi's work is focused on SMC of single rather than decentralized control systems. The proposal here is to further develop Choi's approach with application to uncertain decentralized systems.

When applying sliding mode in the decentralized system, researchers consider the interactions as perturbations and try to eliminate or at least attenuate these perturbations. [9], [14]-[15]. However, the sliding mode can only deal with matched perturbations and the upper bound of perturbations should also be known. In this case, researchers start trying to combine the sliding mode with other robust control methods to overcome the unmatched problem limitation [9]. Šiljak [3] proposes a feedback control using an LMI approach that can deal with the interactions no matter whether or not they are matched. Also the assumption of unknown interactions in [3] is more general which includes both linear and non-linear types of interactions. Kalsi [5], [6] uses the control method of [3] to develop a sliding approach to observer-based control. Although a lot of research has been done in this area [9], [14]-[16], the main contribution of this paper is to use the LMI-based work of Choi [12], [13] to construct a simpler and more general approach to decentralized control. This will also provide an efficient strategy for accounting for modeling uncertainty and subsystem interactions. Also the known upper bound limitation is removed by an adaptive mechanism in our work. Although this paper focuses on the state feedback strategy, output feedback control can be easily formulated as an extension based on the proposed method. Moreover, other robust improvements can be extended based on this approach.

This paper is organized as follows. The basic assumptions are given and the design objective is proposed in Section II. Then the main results are given in Section III, where both the sliding surface and control law designs are represented. Also in Section III, the feasibility of LMIs is discussed and more constraints are proposed to improve the methods. A numerical example is given in Section V which demonstrates the efficacy of the techniques developed in this paper. Finally, the concluding remarks and further work are given in Section V.

## II. System description and Problem formation

Consider a class of perturbed large-scale systems which are comprise N-linked subsystems with uncertainties in the interactions. The dynamic equation of each subsystem is represented as:

Zhen Huang's research study at the University of Hull [2009-2012] is supported by the China Scholarship Council (CSC) and the Hull-China scholarship.

$$\dot{x}_i(t) = A_i x_i(t) + B_i(u_i(x_i,t) + f_i(x_i,t)) + h_i(x,t),$$
$$i = 1,2,\dots,N \qquad (1)$$

where $x_i(t) \in R^{n_i}$ is the state variable of the *i*-th subsystem, $u_i(x_i,t) \in R^{m_i}$ is the control input vector of the *i*-th subsystem, the matrix $A_i \in R^{n\times n}$ is the system characteristic matrix, and the matrix $B_i \in R^{n\times m}$ is the input matrix with full rank $m < n$. And $f_i(x,t)$ is any uncertainty or disturbance in the input channel. The term $h_i(x,t)$ reflects the interaction of the *i*-th subsystem with other subsystems and the uncertainty dynamics associated with the *i*-th subsystem itself.

We also assume the followings to be valid:

*1)* All the pair $(A_i, B_i), i = 1,2,\dots,N$ are controllable.

*2)* All the state variables $x_i$, $i = 1,2,\dots,N$ are locally available for measurement for all time.

*3)* The subsystem interactions are globally bounded, that is, $\|h_i(x,t)\| < \beta_i < \infty$ for some unknown constant $\beta_i > 0$. The interactions satisfy the same quadratic constraint as, for example [3],[5]-[7] , that is:

$$h_i^T(x,t)h_i(x,t) \le \alpha_i^2 x H_i^T H_i x \qquad (2)$$

*4)* The external disturbance $f_i(t)$ is bounded by a known constant $\varepsilon_i$, i.e. $\|f_i(x,t)\| < \varepsilon_i$

The overall interconnected system can be rewritten in a compact form as:

$$\dot{x}(t) = Ax(t) + B\big(u(x,t) + f(t)\big) + h(x,t) \qquad (3)$$

where $A = diag(A_1,\dots,A_N)$, $B = diag(B_1,\dots,B_N)$, $f(t) = [f_1^T(t),\dots,f_N^T(t)]^{\mathrm{T}}$ and $h(x,t) = [h_1^T(x,t),\dots,h_N^T(x,t)]^{\mathrm{T}}$, and with the third assumption, the interconnections $h(x,t)$ are bounded as follows:

$$h^T(x,t)h(x,t) \le x\left(\sum_{i=1}^{N} \alpha_i^2 H_i^T H_i\right)x = xH^T Hx$$

where $\alpha_i$ is a bounding constant.

Because all of the subsystems are stabilizable, it is easy to verify that the overall system is controllable.

The objective is to design a totally decentralized sliding mode controller that robustly regulates the state of the overall system without any information exchange between the subsystems. And with this type of controllers, the overall system is robust to all the uncertainties and matched perturbations.

## III. Main result

It is well known that in SMC design, there are two steps: a). Sliding surface design and b) control law design. In this Section, the sliding surface is designed by an LMI and an adaptive control law is realised.

### *A. Sliding surface design*

Define $\Gamma$ as any basis of the null space of $B^T$, i.e. $\Gamma$ is an orthogonal complement of $B$.

Consider the following LMIs:

Minimize $\gamma_i$, subject to $X > 0$,

$$\begin{bmatrix} \Gamma^T(XA^T + AX + I)\Gamma & \Gamma^T XH_1^T & \cdots & \Gamma^T XH_N^T \\ H_1X\Gamma & -\gamma_1 I & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ H_N X\Gamma & 0 & \cdots & -\gamma_N I \end{bmatrix} < 0$$
$$(4)$$

Assume that the sliding surface $\sigma$ is given by

$$\sigma(x,t) = B^T X^{-1} x(t) \qquad (5)$$

where $X$ is a solution to the LMIs (4). This sliding surface is proposed in [12]

***Remark 1***: we should note that $X = diag(X_1,\dots,X_N)$ because that the LMIs (4) is based on the overall system (3). Also the sliding surface $\sigma(x,t) = [\sigma_1^T(x_1,t),\dots,\sigma_N^T(x_N,t)]^T$. The $\sigma_i(x_i,t)$ represents the sliding surface for the *i*-th subsystem.

***Theorem 1:*** Suppose the LMIs (4) have a solution $X$ and the sliding surface is given by Eq. (5). Then once the sliding surface (5) is reached and maintained thereafter, i.e. $\sigma(x,t) = 0$ and $\dot{\sigma}(\mathrm{x,t}) = 0$ and hence the overall system is stable.

***Proof:*** Define a transformation matrix and its inverse matrix as described in [12] as

$$T = \begin{bmatrix} \Gamma^T \\ S \end{bmatrix}, T^{-1} = [X\Gamma(\Gamma^T X\Gamma)^{-1} \quad B(SB)^{-1}] \qquad (6)$$

And the associated vector $z$ is given as

$$z(t) = \begin{bmatrix} z_1(\mathrm{t}) \\ z_2(\mathrm{t}) \end{bmatrix} = \begin{bmatrix} z_1(\mathrm{t}) \\ \sigma(t) \end{bmatrix} = Tx(t) \qquad (7)$$

where $z_1 \in \mathrm{R}^{\mathrm{n-m}}$ and $z_2 \in \mathrm{R}^{\mathrm{m}}$. And with the transformation (6), we can obtain a new state equation as:

$$\dot{z}(\mathrm{t}) = TAT^{-1}z(t) + TB(u(t) + f(x,t)) + Th(x,t) \quad (8)$$

where,

$$TAT^{-1} = \begin{bmatrix} \Gamma^T AX\Gamma(\Gamma^T X\Gamma)^{-1} & \Gamma^T AB(SB)^{-1} \\ \mathrm{S}A\Gamma(\Gamma^T X\Gamma)^{-1} & \mathrm{S}AB(SB)^{-1} \end{bmatrix}$$

$$TB = \begin{bmatrix} 0 \\ SB \end{bmatrix}$$

And note that once the system is on the sliding surface and maintained there, $\sigma(t) = 0$, $\dot{\sigma}(\mathrm{t}) = 0$. In this case, the system is insensitive to all the matched uncertainties or disturbances $f(x,t)$. The state equation (8) then becomes:

$$\dot{z}_1(\mathrm{t}) = \Gamma^T AX\Gamma(\Gamma^T X\Gamma)^{-1} z_1(t) + \Gamma^T h(x,t) \tag{9}$$

Now define a Lyapunov function for the system (9):

$$V(z_1) = z_1^T P z_1 \tag{10}$$

where P is a symmetric and positive definite (s.p.d) matrix.

The time derivative of $V(z_1)$ along the trajectories of Eq. (9) is given by:

$$\begin{aligned}\dot{V}(z_1) = z_1^T((\Gamma^T AX\Gamma(\Gamma^T X\Gamma)^{-1})^T P + P\Gamma^T AX\Gamma(\Gamma^T X\Gamma)^{-1})z_1 \\ +\mathrm{z}_1^{\mathrm{T}}\mathrm{P}\Gamma^T\mathrm{h} + \mathrm{h}^{\mathrm{T}}\Gamma P z_1\end{aligned} \tag{11}$$

To obtain a quadratic form of (11), we use the following result in [16]:

$$X^T Y + Y^T X \leq X^T X + Y^T Y$$

for any matrices (or vectors) $X$ and $Y$ with appropriate dimension.

It follows that:

$$z_1^T P\Gamma^T h + h^T \Gamma P z_1 \leq z_1^T P\Gamma^T \Gamma P z_1 + h^T h \tag{12}$$

Also, from the Assumption 3), the interactions satisfy the quadratic form:

$$h^T(x,t)h(x,t) \leq xH^T Hx = z^T (T^{-1})^T H^T H T^{-1} z \tag{13}$$

Because the system is in the sliding surface, $z_2 = \sigma = 0$. We can simplify the above inequality of interactions (13) as

$$h^T(x,t)h(x,t) \leq z_1^T(\Gamma^T X\Gamma)^{-1}\Gamma^T \mathrm{X} H^T HX\Gamma(\Gamma^T X\Gamma)^{-1} z_1 \tag{14}$$

Substitute the inequalities (12) and (14) into (11), we have a quadratic form of the derivative of the Lyapunov function as

$$\begin{aligned}\dot{V}(z_1) = z_1^T((\Gamma^T \mathrm{A}X\Gamma(\Gamma^T X\Gamma)^{-1})^{\mathrm{T}} P + P\Gamma^T \mathrm{A}X\Gamma(\Gamma^T X\Gamma)^{-1} + \\ P\Gamma^T \Gamma P + (\Gamma^T X\Gamma)^{-1}\Gamma^T \mathrm{X} H^T HX\Gamma(\Gamma^T X\Gamma)^{-1})z_1\end{aligned} \tag{15}$$

The stabilization of system (9) requires that:

$$\dot{V}(z_1) < 0 \tag{16}$$

for all $z_1 \neq 0$.

The development of (16) leads to

$$\begin{aligned}(\Gamma^T \mathrm{A}X\Gamma(\Gamma^T X\Gamma)^{-1})^{\mathrm{T}} P + P\Gamma^T \mathrm{A}X\Gamma(\Gamma^T X\Gamma)^{-1} + P\Gamma^T \Gamma P + \\ (\Gamma^T X\Gamma)^{-1}\Gamma^T \mathrm{X} H^T HX\Gamma(\Gamma^T X\Gamma)^{-1} < 0\end{aligned} \tag{17}$$

In this case, the problem is to find an s.p.d matrix $P$ such that the inequality (17) is satisfied. By pre-multiplying and post-multiplying the inverse matrix of $P$, we can simplify the inequality (17).

Define $Y = P^{-1}$, we have:

$$\begin{aligned}\mathrm{Y}(\Gamma^T \mathrm{A}X\Gamma(\Gamma^T X\Gamma)^{-1})^{\mathrm{T}} + \Gamma^T \mathrm{A}X\Gamma(\Gamma^T X\Gamma)^{-1}\mathrm{Y} + \Gamma^T \Gamma \\ + \mathrm{Y}(\Gamma^T X\Gamma)^{-1}\Gamma^T \mathrm{X} H^T HX\Gamma(\Gamma^T X\Gamma)^{-1} Y < 0\end{aligned}$$

We can easily find a matrix $\mathrm{Y} = \Gamma^T X\Gamma$ which satisfies the s.p.d condition so that the above inequality becomes:

$$\Gamma^T(\mathrm{A}X + XA^T + I + XH^T HX)\Gamma < 0 \tag{18}$$

With Assumption 3), we rewrite the inequality (18) as:

$$\Gamma^T\left(\mathrm{A}X + XA^T + I + \sum_{i=1}^{N}(\alpha_i^2 X H_i^T H_i X)\right)\Gamma < 0$$

By defining $\gamma_i = \frac{1}{\alpha_i^2}$ and using the Schur complement, the above inequality can be rewritten as the form of LMIs (4). □

After solving the LMIs (4), we have the s.p.d matrix $X$ which has the structure of $X = diag(X_1, \ldots, X_N)$. In this case, for each subsystem, the local sliding surface could be given by

$$\sigma_i(x_i,t) = S_i x_i(t) = B_i^T X_i^{-1} x_i(t) \tag{19}$$

*B. Adaptive Control law design*

It has proved above that once the system reaches the sliding surface and is maintained on it thereafter, the control objective is achieved. In the following a sliding control law is designed to drive the system to the sliding surface.

Introducing the control strategy for each subsystem:

$$u_i(x_i,t) = \begin{cases} -(S_i B_i)^{-1} A_i x_i(t) + \Psi_{\mathrm{i}} \frac{\sigma_i}{\|\sigma_i\|}, & \|\sigma_i\| \neq 0 \\ -(S_i B_i)^{-1} A_i x_i(t), & \|\sigma_i\| = 0 \end{cases} \tag{20}$$

where,

$$\Psi_{\mathrm{i}} = -\eta_{\mathrm{i}} - \|(\mathrm{SB})^{-1}\mathrm{S}\|\hat{\beta}_{\mathrm{i}}(\mathrm{t}),\ \dot{\hat{\beta}}_{\mathrm{i}}(\mathrm{t}) = \|\sigma_i\| \tag{21}$$

where, $\eta_{\mathrm{i}} > \varepsilon_{\mathrm{i}}$ is a positive constant. $\hat{\beta}_{\mathrm{i}}$ is the estimation of the upper bound of the interaction of *i*-th subsystem.

***Theorem 2***: For each subsystem of the form (1) and the sliding surface (19), by applying the control law (20) and (21) to each subsystem, the overall system trajectory converges to the sliding surface $\sigma_i(x_i,t) = 0$ in finite time and is maintained on the surface, i.e. $\dot{\sigma}_i(x_i,t) = 0$. Meanwhile, the system is insensitive to all the matched disturbances.

***Proof:*** To prove the reachability, we define the Lyapunov function with respect to the sliding surface as:

$$V = \sum_{i=1}^{N} \frac{1}{2}\left[\sigma_i^T (S_i B_i)^{-1}\sigma_i + \|(S_i B_i)^{-1} S\|\bar{\beta}_i^{\,2}\right] \tag{22}$$

The matrix $(S_i B_i)^{-1}$ satisfies the s.p.d condition since that $X_i^{-1}$is a s.p.d matrix and $(S_i B_i)^{-1} = (B_i^T X_i^{-1} B_i)^{-1} > 0$.

Moreover, we define the estimation error $\bar{\beta}_i(t) = \hat{\beta}(t) - \beta_i$.

Since $\beta_i$ is a constant, $\dot{\bar{\beta}}_i(t) = \dot{\hat{\beta}}_i(t) = \|\sigma_i\|$.

Differentiating (19) with respect to time yields:

$$\dot{\sigma}_i(x_i,t) = S_iA_ix_i(t) + S_iB_i(u_i(x_i,t) + f_i(t)) + S_ih_i(x,t)$$

Then taking the derivative of the Lyapunov function (22) we have:

$$\begin{aligned}\dot{V} &= \sum_{i=1}^{N}\left\{\sigma_i^T\left[\Psi_{\mathrm{i}}\frac{\sigma_i}{\|\sigma_i\|} + f_i(t) + (S_iB_i)^{-1}Sh_i(x,t)\right]\right.\\ &\qquad\left. + \|(S_iB_i)^{-1}S\|\bar{\beta}_i\dot{\bar{\beta}}_i\right\}\\ &\le \sum_{i=1}^{N}\left\{\sigma_i^T\left[\Psi_{\mathrm{i}}\frac{\sigma_i}{\|\sigma_i\|} + \varepsilon_i + (S_iB_i)^{-1}Sh_i(x,t)\right]\right.\\ &\qquad\left. + \|(S_iB_i)^{-1}S\|\bar{\beta}_i\|\sigma_{\mathrm{i}}\|\right\}\end{aligned} \tag{23}$$

We can easily verify that $\sigma_i^T\Psi_{\mathrm{i}}\frac{\sigma_i}{\|\sigma_i\|} = \Psi_{\mathrm{i}}\|\sigma_i\|$ , and on substituting (21) into (23), we have:

$$\begin{aligned}\dot{V} &\le \sum_{i=1}^{N}\{\Psi_{\mathrm{i}}\|\sigma_i\| + \|\sigma_i\|\varepsilon_{\mathrm{i}} + \|\sigma_i\|\|(S_iB_i)^{-1}S\|\beta_{\mathrm{i}}\\ &\qquad + \|(S_iB_i)^{-1}S\|\big(\hat{\beta}(t) - \beta_i\big)\|\sigma_{\mathrm{i}}\|\}\\ &\le \sum_{i=1}^{N}\{-\eta_{\mathrm{i}}\|\sigma_i\| - \|\sigma_i\|\|(\mathrm{SB})^{-1}\mathrm{S}\|\hat{\beta}_{\mathrm{i}}(\mathrm{t}) + \|\sigma_i\|\varepsilon_{\mathrm{i}}\\ &\qquad + \|(S_iB_i)^{-1}S\|\beta_{\mathrm{i}}\\ &\qquad + \|(S_iB_i)^{-1}S\|\big(\hat{\beta}(t) - \beta_i\big)\|\sigma_{\mathrm{i}}\|\}\\ &\le \sum_{i=1}^{N}(-(\eta_{\mathrm{i}} - \varepsilon_{\mathrm{i}})\|\sigma_i\|) < 0\end{aligned} \tag{24}$$

which implies that the overall system will reach the sliding surface in finite time [11] and be maintained on it.

***Remark 2:*** Following [15], with the adaptive mechanism, we do not need to know the upper bound of the interaction. It is worthwhile noting that for the purpose of reducing the "chattering" around the switching surface, a commonly used approach is to substitute $\frac{\sigma_i}{\|\sigma_i\|+\theta_{\mathrm{i}}}$ in the SMC for $\frac{\sigma_i}{\|\sigma_i\|}$, where $\theta_{\mathrm{i}}$ is a small positive constant (the so called boundary layer) [11]. However, if we use the boundary layer method here, $\hat{\beta}_{\mathrm{i}}(\mathrm{t})$ may keep growing in magnitude during sliding and the chattering will not be reduced since $\dot{\hat{\beta}}_{\mathrm{i}}(\mathrm{t}) \neq 0$. In this case, we should modify our controller (20) to:

$$u_i(x_i,t) = \begin{cases}-(S_iB_i)^{-1}A_ix_i(t) + \Psi_{\mathrm{i}}\frac{\sigma_i}{\|\sigma_i\|+\theta_{\mathrm{i}}}, & \|\sigma_i\| > \theta_{\mathrm{i}}\\ -(S_iB_i)^{-1}A_ix_i(t), & \|\sigma_i\| < \theta_{\mathrm{i}}\end{cases} \tag{25}$$

### *C. Feasibility of LMIs and improvement*

A lot of literature only describe the LMIs and do not prove the feasibility of the LMIs. It is always reasonable to prove the feasibility when raising an LMI problem. To prove the LMIs (4), we should introduce a preliminary Lemma:

***Lemma 1*** [13]: Given a symmetric matrix $G \in R^{n\times n}$ and two matrices $U \in R^{p\times n}$ and $V \in R^{n\times m}$ where $p,m < n$ . Consider the problem of finding some matrix *K* such that:

$$G + UKV^T + VK^TU^T < 0$$

Denote by $\tilde{U}$ and $\tilde{V}$ the orthogonal complements of $U$ and $V$. Then the above inequality is solvable for *K* if and only if

$$\tilde{U}^TG\tilde{U} < 0, \tilde{V}^TG\tilde{V} < 0$$

And the feasibility of the LMIs (4) is given by the following Lemma 2.

***Lemma 2:*** The optimization problem given by LMIs (4) is feasible if the pairs $(A_i, B_i)$ are controllable for all the subsystems.

***Proof:*** Because the LMIs (4) are based on the overall system equation (3), we first need to prove the controllability of the overall system (3) It then follows that the overall system is controllable as all of the overall system eigenvalues are changeable by the local inputs, i.e. there are no fixed modes in this decentralized system. [1] Assume there is no actuator disturbance or no interactions in the overall state equation (3). In this case, there exists a control law $u = Kx$ if and only if there exist an s.p.d matrix *X* such that:

$$XA^T + AX + \mathrm{X}K^TB + BKX < 0 \tag{26}$$

As a consequence of the system controllability, we can always find a gain matrix *K* and an s.p.d matrix *X* satisfying (25), Moreover, we can restrict (26) to:

$$XA^T + AX + \mathrm{I} + XK^TB + BKX < 0 \tag{27}$$

There also still exists a *K* and an s.p.d matrix *X* satisfying (27). Then by using *Lemma 1*, the following inequality is feasible:

$$\Gamma^T(XA^T + AX + \mathrm{I})\Gamma < 0 \tag{28}$$

Using the Schur complement in the LMIs (4):

$$\Gamma^T(XA^T + AX + \mathrm{I})\Gamma + \Gamma^T\textstyle\sum_{i=1}^{N}(\frac{1}{\gamma_i}XH_i^TH_iX)\,\Gamma < 0 \tag{29}$$

Therefore, from (28) and (29), the solution of the LMIs (4) are guaranteed by the existence of a set of large enough $\gamma_i$ □

The LMI optimization problem given by (4) does not pose any restriction on the size of the matrix *X*. Consequently, the results of these two optimization problems may yield inappropriate results. For example, very small $\gamma_i$ and *X* result in very large *S* values. In this case, we can restrict *X* by posing a further constraint on $\gamma_i$ as:

$$\gamma_i > \frac{1}{\bar{\alpha}_{\mathrm{i}}^2}, \bar{\alpha}_i > 0 \tag{30}$$

$\bar{\alpha}_i$ are given constants for $i = 1,2,\ldots,N$. Or equivalently:

$$X > \Lambda \tag{31}$$

where, $\Lambda = \mathrm{diag}(\kappa_1 I_{n_1}, \ldots, \kappa_N I_{n_N})$ , $\kappa_i > 0, i = 1,\ldots,N$ are given constants. The upper bound of the parameters could also be defined in the same way.

*Remark 3:* We should note that if the constants $\alpha_i, i = 1,\ldots,N$ are known, the optimization problem (4) becomes feasibility problem. By substituting $\gamma_i = 1/\alpha_i^2$ into (4), the solution of the LMIs is equivalent to finding a feasible solution *X*. However, the use of an optimization algorithm could still be appropriate to find a solution capable of dealing with potentially stronger interactions.

For the purpose of improving the performance, here we introduce a modification to the LMIs in (4). By adding a $\mu$-stability constraint, the system satisfies $lim_{t\to\infty} e^{\mu t}\|x(t)\| = 0$ for all solution trajectories *x*. Therefore, we can ensure a minimum positive decay rate $\mu$ >after arriving sliding surface. Moreover, the larger the rate is, the earlier the sliding surface could be reached. Hence, the Eq. (4) could be rewritten as:

Minimize $\gamma_i$, subject to $X > 0$,

$$\begin{bmatrix} \Gamma^T(X\bar{A}^T + \bar{A}X + I)\Gamma & \Gamma^T X H_1^T & \cdots & \Gamma^T X H_N^T \\ H_1 X\Gamma & -\gamma_1 I & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ H_N X\Gamma & 0 & \cdots & -\gamma_N I \end{bmatrix} < 0 \tag{32}$$

where, $\bar{A} = A + \mu I$. Other improvement of robust performance for the system (e.g. $H_\infty$, $H_2$, etc.) could also be constructed based on this LMI approach.

## IV. NUMERICAL EXAMPLE

In this Section, we illustrate the performance of the proposed decentralized controller with an example similar to the one used in [7]. This non-linear interconnected system model consists of three subsystems. The first subsystem is a second-order system and the others are third-order systems. Disturbance signals are also added to each subsystem.

The dynamic subsystems are given by:

$$\dot{x}_1 = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix} x_1 + \begin{bmatrix} 0 \\ 1 \end{bmatrix} (u_1 + f_1(x_1,t)) + h_1(x,t)$$

$$\dot{x}_2 = \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{bmatrix} x_2 + \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix} (u_2 + f_2(x_2,t)) + h_2(x,t)$$

$$\dot{x}_3 = \begin{bmatrix} -3 & 0 & 1 \\ 1 & 2 & 0 \\ 0 & 1 & -2 \end{bmatrix} x_2 + \begin{bmatrix} 0 \\ 1 \\ 0 \end{bmatrix} (u_3 + f_3(x_2,t)) + h_3(x,t)$$

where, $x_1 = [x_{11} \quad x_{12}]^T$ , $x_2 = [x_{21} \quad x_{22} \quad x_{23}]^T$ , $x_3 = [x_{31} \quad x_{32} \quad x_{33}]^T$

$$f_1(x_1,t) = 0.4\sin(\mathrm{x}_{11}) + 0.5\sin(10\mathrm{t}),$$

$$f_2(x_1,t) = 0.3\cos(\mathrm{x}_{22}) + 0.6\sin(5\mathrm{t}),$$

$$f_3(x_1,t) = 0.5\cos(\mathrm{x}_{33}) + 0.6\sin(7\mathrm{t})$$

$$h_1(x,t) = \alpha_1\, cos(x_{22})\, H_1 x,$$

$$h_2(x,t) = \alpha_2\, cos(x_{32})\, H_2 x,$$

$$h_3(x,t) = \alpha_3\, cos(x_{11})\, H_3 x$$

$$\alpha_1 = \alpha_2 = \alpha_3 = 0.1,$$

$$H_1 = \frac{1}{\sqrt{10}}\begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \end{bmatrix}$$

$$H_2 = \frac{1}{\sqrt{15}}\begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \end{bmatrix}$$

$$H_3 = \frac{1}{\sqrt{13}}\begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \end{bmatrix}$$

Choosing $\bar{\alpha}_1 = \bar{\alpha}_2 = 0.2$ and solving the optimization problem (4) and (29) results in

$$X_1 = \begin{bmatrix} 0.515 & -0.5 \\ -0.5 & 0.515 \end{bmatrix} X_2 = \begin{bmatrix} 1.454 & -0.515 & -0.722 \\ -0.515 & 0.738 & -0.514 \\ -0.722 & -0.514 & 1.451 \end{bmatrix}$$

$$X_3 = \begin{bmatrix} 0.221 & -0.112 & -0.013 \\ -0.112 & 0.184 & -0.138 \\ -0.013 & -0.138 & 0.228 \end{bmatrix}$$

with this solution, we have the sliding surface matrices for each of the subsystems:

$$S_1 = [32.94 \quad 33.94]$$
$$S_2 = [36.143 \quad 50.744 \quad 36.627]$$
$$S_3 = [15.772 \quad 28.942 \quad 18.459]$$

Using the control law (25) and choosing $\theta_i = 0.01$ and $\eta_i = 5$ for $i = 1,2$ . The initial conditions $x_1(0) = [0.5 \quad 0.5]^T$ , $x_2 = [0.5 \quad 0.5 \quad 0.5]^T$. $x_3 = [0.5 \quad 0.5 \quad 0.5]^T$

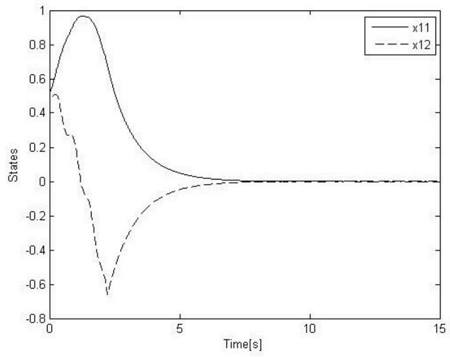

Figure 1. State responses for subsystem 1

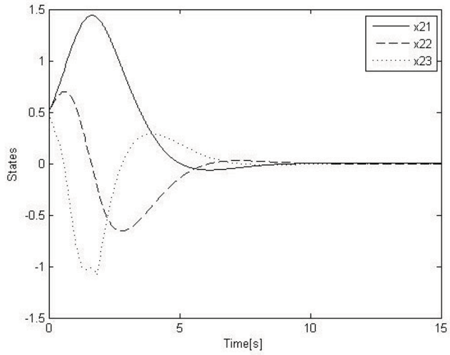

Figure 2. State responses for subsystem 2

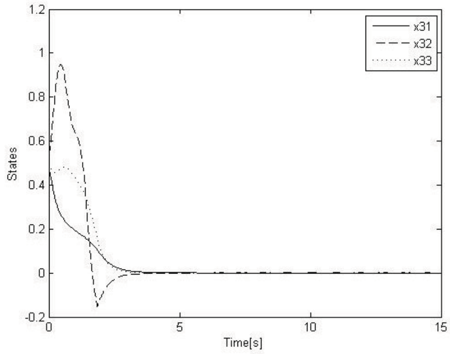

Figure 3. State responses for subsystem 3

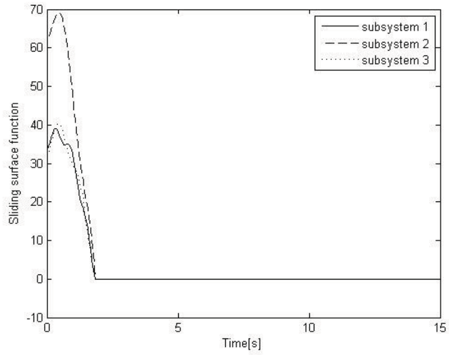

Figure 4. Sliding surface function for both subsystems

Figures 1-2 show the state responses for the system. From Figure 4, the sliding surface is reached in finite time. Moreover, combine with Figure 3, we note that after reaching the sliding surface, the system is stable and insensitive to the disturbances. However, in the reaching phase, the system is sensitive to the disturbances. This is also one of the main disadvantages of sliding mode theory.

## V. CONCLUSION

This paper proposes a simple and easy way to design a decentralized sliding mode system. The difference between the proposed approach and other decentralized sliding mode methods is that, this method requires the solution of only one LMI optimization problem in the sliding surface design, without a requirement for any unmatched and matched separation analysis. The mismatched uncertainties and interactions are handled well by the LMI approach. Meanwhile, all of the matched uncertainties and external disturbances are rejected by the SMC. The upper bound limitation of the uncertainties/interaction in the classical sliding mode design is removed by the adaptive mechanism. Other robust control methods could be easily extended based on this LMI approach.

***Abstract*—This paper presents a novel decoupling method for multivariable systems with disturbances. In this method, the undesirable coupling parts in each loop are treated as the output disturbances. These disturbances, as well as the external disturbances, can be actively rejected by the equivalent-input-disturbance (EID) approach. The parameters of the controller in each loop can be designed independent of each other. A typical example demonstrates the simplicity in parameters design and good performance in decoupling control and disturbance rejection.**

## I. Introduction

Multiple-inputs and multiple-outputs (MIMO) processes are often encountered in industry, such as chemical reactor, continuous stirred tank reactor, *et. al*. Because of the interaction between each control loop, the controller design for MIMO system becomes a complex problem and the common single-input single-output (SISO) control theories are not effective for MIMO systems. However, the practical control engineers are always accustomed to deal with the MIMO system loop by loop, which requires the common SISO control methods, such as PID control, optimal control. To solve such a problem, one of the control strategies is trying to eliminate the interactions between control loops, which is known as decoupling control.

The decoupling control theory has been well developed and established for several decades. To measure the interaction of the MIMO systems, Bristol [1] introduced relative gain array method for the input-output pairings and controller design. For linear systems, an effective approach to the internal model design [2] is proposed for decoupling stable square multivariable process with delays. A transfer function matrix decoupling approach is presented for the MIMO Smith Scheme [3]. Although many significant results have been proposed, the decoupling performance is still desired to be improved and some key problems, such as robustness, disturbance rejection, and other practical concerns [4] continue to pose serious challenges.

It is well known that the disturbance is of a primary concern for control system design, and is even the ultimate objective. This problem, in conjunction with decoupling control, has attracted many researchers. Feedback control [5] may be effective for reducing the disturbance and making disturbance rejection tuning independent of the controller design, if the disturbance is measurable. Due to the difficulties in obtaining exact model or disturbance, decoupling control schemes are often constructed to estimate the cross-couplings and disturbance at the same time; and a number of observer-based methods are making progress. Such as the disturbance observer based method (DOB) [6], the perturbation observer approach (POB) [7], disturbance decoupling control [8] based on the active disturbance rejection control (ADRC) [9] and so on. However, DOB requires the inverse dynamics model and POB needs the accurate model of the plant. The ADRC based decoupling method overcomes some drawbacks of the existing methods. However, the parameters in the resulting controller are usually very complicated.

In an MIMO system, the output of one loop is always the sum of all inputs actions. The actions of other loops are the resource of the interactions and bring bad effect on the stability and performance, which is just like output disturbances occurring in this loop. Intuitionally, we may think that if such ”output disturbances” can be fully overcame or compensated, the output of one loop is only determined by the relevant input, and then the MIMO system can be well decoupled. One of the novelties of this paper is that, we treat the undesirable coupling parts of each loop as its output disturbances, and compensate them together with the external disturbance. The equivalent-input-disturbance (EID) approach [10], [11] is a relatively new disturbance rejection method. It can reject more than one disturbance simultaneously and compensate any kind of disturbance effectively without knowing prior information. These important features motivated us to design the decoupling controller using the EID-based method.

This paper first constructs a configuration of the decoupling control based on the EID approach. Then, the controller parameters for each loop are designed independently. Finally, simulation results are shown for validating the proposed method.

## II. Configuration of the dynamic decoupling control

Consider a linear time-invariant MIMO system. Let $r_i$ and $u_i$, $i = 1, 2, \cdots, n$ denote the reference inputs and the control inputs, respectively. Suppose that the open loop transfer function matrix of the process is described by

$$G(s) = [g_{ij}(s)]_{n\times n} \tag{1}$$

Then for the *i*-th loop, the output is given by

$$y_i = \sum_{j=1}^{n} g_{ij}(s)u_j, \quad i = 1, 2, \cdots, n \tag{2}$$

We divide it into two parts:

$$y_i = g_{ii}(s)u_i + \sum_{j=1, j\neq i}^{n} g_{ij}(s)u_j \tag{3}$$

where $g_{ii}(s)$ is regarded as the transfer function of the plant in the *i*-th loop, the second term in the right hand side is treated as a disturbance signal. So that it becomes an SISO system with disturbances for each loop.

For clarity, we take a two-input two-output (TITO) system as an example, as shown in Fig.1. For the plant $g_{11}$, we only need to design a controller $c_1$ to reject the signal through $g_{12}$, as well as the disturbance $d_1$. Similarly, one designs controller $c_2$. Due to this process, we can also notice that only the diagonal elements of the transfer function are needed in the compensation instead of the whole information.

For convenience, the processes are formulated in state-space forms. Then the plant in the *i*-th loop is given by

$$\begin{cases} \dot{x}_i(t) = A_i x_i(t) + B_i u_i(t) + D_i d_i(t) \\ y_i(t) = C_i x_i(t) + \Phi_i \varphi_i(t) \end{cases} \tag{4}$$

where $A_i$, $B_i$ and $C_i$ are matrices obtained by the transfer function $g_{ii}(s)$, $i = 1, 2, \cdots, n$, $\Phi_i\varphi_i(t)$ denotes the signal $\sum\limits_{j=1, j\neq i}^{n} g_{ij}(s)u_j$, which need not to be known exactly, and $D_i d_i(t)$ is the external disturbance.

Now, a transformation is required. For the output $y_i(t)$, there must exist a matrix $\Psi_i$ such that

$$y_i(t) = C_i[x_i(t) + \Psi_i\varphi_i(t)] \tag{5}$$

Let

$$\tilde{x}_i(t) = x_i(t) + \Psi_i\varphi_i(t) \tag{6}$$

Combing (5) and (6), the state equation (4) is derived as

$$\begin{cases} \dot{\tilde{x}}_i(t) = A_i\tilde{x}_i(t) + B_i u_i(t) + [D_i d_i(t) - A_i\Psi_i\varphi_i(t)] \\ y_i(t) = C_i\tilde{x}_i(t) \end{cases} \tag{7}$$

where $D_i d_i(t) - A_i\Psi_i\varphi_i(t)$ is regarded as whole disturbances imposed on this loop.

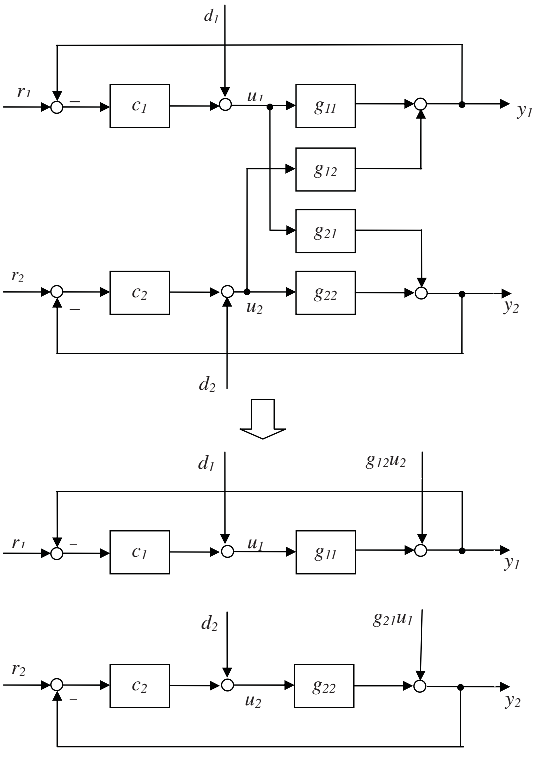

Fig. 1. Configuration of TITO decoupling control system

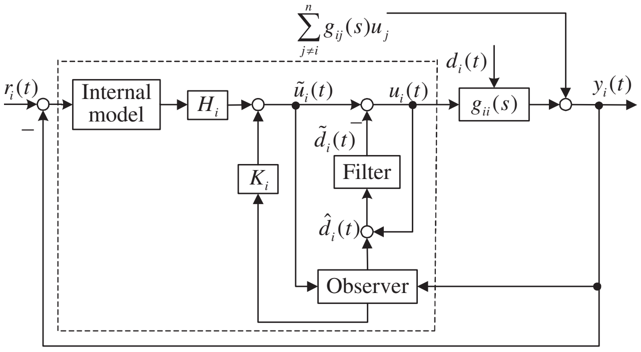

Fig. 2. Configuration of the EID method

An EID of the plant is defined to be a signal on the control input channel that produces the same effect on the output as disturbances do for all $t \geq 0$. The EID of the disturbance must exist under the condition that the plant does not have any zeros on the imaginary axis [10]. Suppose that a disturbance $de_i(t)$ is imposed on the control input channel of the *i*-th plant, then (7) can be described as the following equivalent model

$$\begin{cases} \dot{\tilde{x}}_i(t) = A_i\tilde{x}_i(t) + B_i[u_i(t) + de_i(t)] \\ y_i(t) = C_i\tilde{x}_i(t) \end{cases} \tag{8}$$

Note that the same variable $\tilde{x}_i$ is used for both the state of plant (7) and (8). This should not make confusion.

The configuration of the EID-based control system is shown in Fig. 2. The controller $c_i$ in Fig. 1 is just designed using the parts within the dashed line in Fig. 2. In this figure, the internal model

$$\dot{\bar{x}}_i(t) = \bar{A}_i\bar{x}_i(t) + \bar{B}_i[r_i(t) - y_i(t)] \tag{9}$$

is employed to improve the tracking precision, in which the parameters are determined by the reference input $r_i(t)$. The Luenberger observer

$$\left\{ \begin{array}{l} \dot{\hat{x}}_i(t) = A_i\hat{x}_i(t) + B_i\tilde{u}_i(t) + L_i(y_i(t) - \hat{y}_i(t)) \\ \hat{y}_i(t) = C_i\hat{x}_i(t) \end{array} \right. \tag{10}$$

plays a key role in the disturbance estimation.

Let

$$\Delta x_i(t) = \tilde{x}_i(t) - \hat{x}_i(t). \tag{11}$$

[10] gives us the expression of the estimation value

$$\hat{d}_i(t) = B_i^{+} L_i C_i \Delta x_i(t) + u_i(t) - \tilde{u}_i(t) \tag{12}$$

where $B_i^{+} = (B_i^T B_i)^{-1} B_i^T$.

Then, a low-pass filter is used to select the frequency band of the signal, *e.i.*,

$$\mathscr{L}[\tilde{d}_i(t)] = F(s)\mathscr{L}[\hat{d}_i(t)] \tag{13}$$

where $\mathscr{L}(\cdot)$ is the Laplace transform and $F_i(s)$ satisfies

$$|F_i(j\omega)| \approx 1 \tag{14}$$

for all $\omega \in \Omega$, where $\Omega$ is the chosen frequency band. Note that each loop becomes an SISO system in the design, a first-order filter

$$F_i(s) = 1/(T_i s + 1) \tag{15}$$

can work well.

Thus, $\tilde{d}_i(t)$ is just the estimated compensation of the whole disturbances in the *i*-th loop. So that the control law is given by

$$u_i(t) = \tilde{u}_i(t) - \tilde{d}_i(t) \tag{16}$$

where the state feedback control law is

$$\tilde{u}_i(t) = H_i\bar{x}_i(t) + K_i\hat{x}_i(t) \tag{17}$$

## III. Stability analysis and parameters design

Since the plant we considered in each loop may be influenced by any of the reference input, we set

$$r_i(t) = 0, i = 1, 2, \cdots, n, \ d_i(t) = 0 \tag{18}$$

for the *i*-th loop to guarantee that all the external inputs be zero.

Then combining (4), (10), (11) and (18) yields

$$\Delta\dot{x}_i(t) = -(A_i - L_iC_i)\Delta x_i(t) + B_i\tilde{d}_i(t) \tag{19}$$

and

$$\hat{d}_i(t) = B_i^{+} L_i C_i \Delta x_i(t) + \tilde{d}_i(t) \tag{20}$$

So the transfer function from $\tilde{d}_i(t)$ to $\hat{d}_i(t)$ can be derived as

$$G_i(s) = B_i^{+}(sI - A_i)[sI - (A_i - L_iC_i)]^{-1}B_i \tag{21}$$

In the EID-based control system, the state feedback design does not influence the stability of the whole system. Therefore, we have the following theorem.

*Theorem 1:* [10] For suitably designed $H_i$ and $K_i$, the control law (16) guarantees the stability of the *i*-th loop, if $A_i - L_iC_i$ is stable and

$$\|G_i(s)F_i(s)\|_\infty < 1 \tag{22}$$

where $||\cdot||_\infty$ denotes the upper bound of the maximum singular value of the function.

Since the plant in each loop is controllable and observable, the state feedback gains and the observer can be designed independently [14]. This brings us great convenience for parameters design.

As for the state feedback gains, the following augmented system including the original plant and the internal model is considered

$$\delta\dot{x}_i(t) = \tilde{A}_i\delta x_i(t) + \tilde{B}_iu_i(t) \tag{23}$$

where

$$\delta x_i(t) = \left[ \begin{array}{c} \tilde{x}_i(t) \\ \bar{x}_i(t) \end{array} \right], \ \tilde{A}_i = \left[ \begin{array}{cc} A_i & 0 \\ -\bar{B}_iC_i & \bar{A}_i \end{array} \right], \ \tilde{B}_i = \left[ \begin{array}{c} B_i \\ 0 \end{array} \right] \tag{24}$$

$H_i$ and $K_i$ can be optimized by using a well-known linear quadratic regulation (LQR) method [15]. The optimal state-feedback control law is given by

$$u_i^*(t) = -R_i^{-1}\tilde{B}_i^TP_i\delta x_i(t) \tag{25}$$

where $P_i = \left[ \begin{array}{cc} K_i & H_i \end{array} \right]$ is a solution of the Riccati equation

$$P_i\tilde{A}_i + \tilde{A}_i^TP_i + Q_i - P_i\tilde{B}_iR_i^{-1}\tilde{B}_i^TP_i = 0 \tag{26}$$

$Q_i > 0$ and $R_i > 0$ are diagonal matrices to be determined by the coefficient matrices of the augmented system.

The Luenberger observer has an important function that enables the coupling parts and disturbances to be compensated for. It will achieve good performance and be easily operated for a well designed gain $L_i$. We use the well-known pole-placement theory in this study instead of the perfect regulation method in [10], no matter if the plant is stable. First, we need to select a time parameter $T_i$ that satisfies (14) for the low-pass filter. Then $L_i$ can be obtained by the following procedure.

*Observer gain design algorithm*

Step 1: [14] For a prescribed $\zeta$, $0 \le \zeta \le 1$, the expected poles for the observer is chosen to be

$$\begin{aligned} \lambda_{1,2} &= -\zeta\sigma \pm j\sqrt{1-\zeta^2}\sigma, \\ \lambda_k &= -a_k\zeta\sigma, \ a_k \ge 5, \ k = 3, \cdots, m \end{aligned} \tag{27}$$

Step 2: Choose $\sigma$ in (27) and calculate the transfer function $G_i(s)$ in (21), such that (22) holds.

Step 3: Calculate the observer gain $L_i$ such that

$$\lambda_k(A_i - L_iC_i) = \lambda_k, \ k = 1, \cdots, m \tag{28}$$

*Remark 1:* Only if the plant is observable, the expected poles of the observer can be arbitrarily placed by the feedback matrix $L_i$. It is well known that the performance of the observer is determined by the dominant poles $\lambda_{1,2}$. In addition, the following part proves that there must exist a large enough $\sigma$ such that (22) holds.

It follows from (21) that

$$1/\left\|G_i(s)\right\|_\infty = \left\|\tilde{G}_i(s)\right\|_\infty \tag{29}$$

where

$$\tilde{G}_i(s) = B_i^{+}[sI - (A_i - L_iC_i)](sI - A_i)^{-1}B_i$$

Since $\lim\limits_{\sigma\to\infty} |\lambda_i| = \infty$ $(i = 1, \cdots, m)$, from (28), we have $\lim\limits_{\sigma\to\infty} \left\|A_i - L_iC_i\right\|_\infty = \infty$. For any fixed $\omega$, the matrices $j\omega I$ and $(j\omega I - A_i)^{-1}$ are constant matrices with finite norms, respectively. So,

$$\lim_{\sigma\to\infty} \left\|\tilde{G}_i\right\|_\infty = \infty. \tag{30}$$

Then, for a large enough $\sigma$, (22) holds. In view of the modeling uncertainties, $\sigma$ can be chosen a little large to handle the uncertainties and guarantee the stability of the system.

*Remark 2:* In the design of the proposed method, the coupling parts in each loop are treated as disturbances. In this case, even if strong multivariable interactions occur, the stability of the system will not be destroyed.

The controllers are designed loop by loop based on the analysis above. Although every loop needs a controller as discussed above, the parameters can be designed similarly among all loops and be independent of each other.

## IV. Numerical example

The Wood-Berry model of a pilot-scale distillation column [16] has been studied extensively. This section considers this multivariable system with delay set to zero, which is shown as

$$\begin{bmatrix} y_1(s) \\ y_2(s) \end{bmatrix} = \begin{bmatrix} \frac{12.8}{16.7s+1} & \frac{-18.9}{21s+1} \\ \frac{6.6}{10.9s+1} & \frac{-19.4}{14.4s+1} \end{bmatrix} \begin{bmatrix} u_1(s) \\ u_2(s) \end{bmatrix} \tag{31}$$

Let the reference inputs be $r_1 = 1$ and $r_2 = 1$, which were imposed at $t = 0$ s and $t = 20$ s, respectively. Then a disturbance $d_1(t) = 0.4$ was imposed on the first plant at $t = 40$ s.

The proposed method is applied to this model. Since the reference inputs are step signals, the parameters of the internal models are chosen to be

$$\bar{A}_1 = \bar{A}_2 = 0, \ \bar{B}_1 = \bar{B}_2 = 1 \tag{32}$$

As for the time constant $T_1$ and $T_2$, 0.01 will be suitable for both of the filters.

For the first loop, let

$$Q_1 = diag\left\{ \begin{array}{cc} 1 & 1 \end{array} \right\}, \ R_1 = 1 \tag{33}$$

Using LQR method yields

$$K_1 = -1.0, \ H_1 = 1.8233 \tag{34}$$

Set $\zeta = 1$ in (27) and choose $\sigma = 20$ in Step 2 of the observer gain design algorithm. So that they satisfy (22). Then

$$\lambda_1 = -20 \tag{35}$$

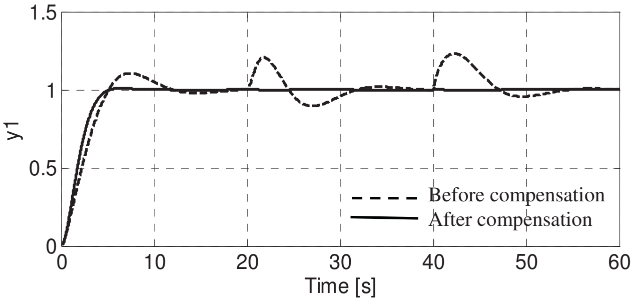

Fig. 3. The output responses for loop 1

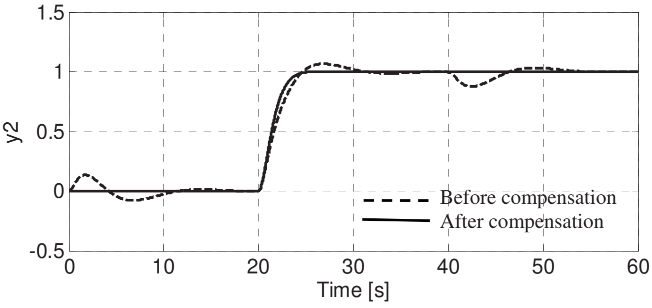

Fig. 4. The output responses for loop 2

Calculating the observer gain according to (28), yields

$$L_1 = 19.9401. \tag{36}$$

Similarly, for the second loop, choosing

$$Q_2 = diag\left\{ \begin{array}{cc} 1 & 1 \end{array} \right\}, \ R_2 = 1 \tag{37}$$

and

$$\lambda_2 = -20 \tag{38}$$

yields

$$K_2 = 1.0, \ H_2 = -1.5255 \tag{39}$$

and

$$L_2 = 19.9306. \tag{40}$$

The simulation results are shown in Fig.3 and Fig.4, respectively. In Fig.3, after the second step input and the disturbance being imposed, the peak to peak value (PPV) of the response in loop 1 is still less than 0.01. It occurs in loop 2 similarly; even the PPV at the beginning is only less than 0.01. It can be seen clearly that the proposed method achieves satisfactory performance in both decoupling control and disturbance rejection.

## V. Conclusion

A dynamic decoupling control method has been presented for MIMO systems with disturbances. The undesirable coupling parts and external disturbances in each loop are treated as ”disturbances”, respectively. So that these disturbances can be effectively compensated by using the EID-based approach. The decoupling control and disturbance rejection can be carried out simultaneity without knowing the prior information of all the treated disturbances. Although every loop needs a controller, the parameters design is still very simple and can be independent of each other. Simulation results demonstrated the good performance of the proposed method.

## ACKNOWLEDGMENT

The authors are grateful for the support of the National Natural Science Foundation of China (Grant No. 60974045). The authors would also like to thank the anonymous reviewers for their suggestions that help improve the manuscript.

*Abstract*— **The problem of robust decentralization of uncertain inter-connected systems is concerned with the goal of de-coupling a Lipschitz non-linear systems into individual "decentralized" subsystems satisfying security and fault-tolerance objectives. This work proposes a new strategy for robust decentralized control in which each subsystem uses an observer-based state estimate structure invoking an approach to *separation principle recovery*, based on Integral Sliding Model Control (ISMC) with careful consideration of both matched and unmatched uncertainties arising from inter-connections and disturbances. The proposed design strategy for the linear observer and uncertainty de-coupling designs involves a single LMI. An example of 3 unstable inter-connected non-linear systems is used to illustrate the power of the approach.**

Keywords Decentralized control, Integral sliding mode control

## I. Introduction

The study of control of non-linear inter-connected systems has received considerable interest in recent years [1], [2], [3]. Some research focuses on interconnected systems with uncertainties, e.g. unknown nonlinear interconnections and disturbances, presenting robustness design challenges involving control specifications for each subsystem. These systems are particularly difficult to design when faced with limitations arising from uncertainty matching conditions and lack of available state information [4].

In most cases the design of robust decentralized systems focuses on state feedback problems. However, in reality only output information is available and this adds a further challenge to the robust design problem. It is often the case that the controller designs must depend to a degree on estimated states, and hence it is common practice in the literature to investigate the observer based feedback control approach with state estimates based on local information [5], [6]. In fact, the derivation of robust output feedback for decentralized control systems with uncertain inter-connection remains a difficult challenge in the literature [7].

Observer-based strategies represent a commonly used way of dealing with output feedback design and there are two observer-based control paradigms for decentralized systems. Firstly, a separate "decentralized" observer is designed for each subsystem, taking account of local information. The second approach involves the use of "inter-connected observers" [8] in which each observer measurement and input information is shared with observers from other local subsystems.

In many branches of control systems there is a need to compensate robustly for effects of system uncertainties or effects of input disturbances or even faults, to maintain required closed-loop performance and stability. One such approach is the use of sliding mode control (SMC) in which the system dynamic behavior can be forced to be independent of inputs, and certain disturbances and modeling uncertainties, once the so-called sliding regime has been reached. Several studies of inter-connected decentralized systems have focused on the use of SMC as a basis for solving robustness [9]. However, the classical approach to SMC requires (i) a reachability condition to guarantee that the SMC sliding or switching motion in state space can be reached from arbitrary initial conditions, and (ii) that two separate controllers be designed to achieve reachability and satisfy the sliding mode design objectives [10]. In the case of ISMC the requirements for both (i) & (ii) above are obviated, since the sliding motion is reached from initial time, making the use of ISMC very attractive for robust control of decentralized systems [11].

This paper focuses on the use of ISMC for decentralized control, based on state estimate feedback. It is assumed that the local system states are not measurable and hence the *decentralized observer* approach outlined above is used as a part of a state-estimate feedback design problem. Decentralized observers are used as a part of the strategy to de-couple the effects of inter-connections between subsystems. Although, each observer has linear feedback structure the observer-based control is formulated using a single LMI procedure to satisfy both *Lyapunov stability* and performance of the augmented state space form of the observer-controller state space system. This relates to the classical Separation Principle only in the sense that objective for each subsystem is to provide effective recovery of the Separation Principle and hence also effective decentralization. This is achieved through the use of the single LMI approach involving the feedback designs for each observer and controller [12]. The system description involves both matched and unmatched uncertainty components (arising from inter-connections and disturbance) and the paper deals with both forms of uncertainty.

The paper is structured as follows. Section II describes the problem formulation. Then section III considered the proposed control approach that includes output integral sliding mode

[1] *Eshag Larbah acknowledges funding support for his PhD scholarship from the ministry of education of Libya.*

control (OISLMC) in the first part and LMI observer–based control design in the second part. Section IV describes a numerical example with three interconnected systems to illustrate the design approach and simulation performance. Section V gives some conclusions.

## II. PROBLEM FORMULATION

Consider an interconnected system comprising subsystems described by:

$$\dot{x}_i(t) = A_i x_i(t) + B_i u_i(t) + Z_i(x_i,t) + W_i(x_i,t) + E_i d_i(t) + B_i f_i(t)$$
$$y_i(t) = c_i x_i(t) \qquad i = 1,2,□,n \qquad (1)$$

where $x_i(t) \in \mathbb{R}^n$is the state vector, $u_i(t) \in \mathbb{R}^m$ are the control inputs and $y_i(t) \in \mathbb{R}^p$ is the vector of system outputs. $A_i, B_i, C_i$ and $E_\mathrm{i}$ are known matrices of appropriate dimension. $Z_i(x_i,t) \in \mathbb{R}^n$ represent the unknown time-varying interactions between the subsystems, containing matched and unmatched components. Hence, $Z_i = Z_{mi} + Z_{ui}$ where $Z_{mi}$ is a matched component of $Z_i$and $Z_{ui}$ is the unmatched components [13].

Dropping the subscripts in $Z_i(x_i,t)$ and using the identity $I_n = BB^+ + B^\perp B^{\perp +}$ where $B^+ = (B^T B)^{-1} B^T$, $Z_i = B_i B_i{}^+ Z_i + B_i{}^\perp B_i{}^{\perp +} Z_i$ and $B^T B^\perp = 0$, then $Z_i = B_i B_i{}^+ Z_i + \zeta_i$ where $\zeta_i = B_i{}^\perp B_i{}^{\perp +} Z_i$ contains the unmatched uncertainty components.

$W_i(x_i,t)$ represents the subsystem unknown modeling uncertainties that satisfies the matching condition $W_i(x_i,t) = B_i Q_i(x_i,t)$ are unknown, $d_i(t)$ is an unknown bounded process disturbance, $f_i(t) \in \mathbb{R}^k$ denotes the actuator faults, where $f_i(t) = -K(t)u_i$ and $K(t) = diag(K_i)$ with $0 \leq K_i \leq 1$, $K_i = 0$ means that the actuator is working perfectly and if $K_i = 1$ the actuator has failed completely otherwise the fault is present.

***Assumptions*:**

- **A1**-The pair $(A_i, B_i)$ is controllable and $(C_i, A_i)$ is an observable pair.
- **A2**-$B_i$ has full rank $m_i$.
- **A3**-The initial state $x_i(t_o)$ is bounded.
- **A4**- The $Z_i(x_i,t)$ are Euclidean bounded norms as: $\|Z_i(x_i,t)\| \leq \beta_i(x_i,t)$ where $\beta_i(x_i,t)$ is a known nonlinear function [14].
- **A5**- The $Q_i(x_i,t)$ are bounded as: $\|Q_i(x_i)\| \leq \kappa_i \|x_i\|$ where $\kappa_\mathrm{i} > 0$ are known Lipschitz constants [15].
- **A6**- The $d_i(t)$ are Euclidean bounded norms as: $\|d_i(t)\| \leq \gamma_i \|x_i\|$ where $\gamma_i > 0$ are known constants.
- **A7**- $f_i(t)$ are Euclidean bounded norms as: $\|f_i(t)\| \leq \eta_i \|x_i\|$ where $\eta_i > 0$ are known Lipschitz constants.

All these assumptions are applicable for real control system problems, since all designs are made off-line.

Following the assumptions above Eq. (1) becomes:

$$\dot{x}_i(t) = A_i x_i(t) + B_i u_i(t) + B_i B_i^+ Z_i(t) + \zeta_i(t) + B_i Q_i(x_i,t) + E_i d_i(t) + B_i f_i(t)$$
$$y_i(t) = c_i x_i(t) \qquad i = 1,2,\ldots\ldots,n \qquad (2)$$

The control signal contains *two* components:

$$u_i(t) = u_i^{OBC}(t) + u_i^{ISM}(t) \qquad (3)$$

where $u_i^{OBC}$ is responsible for stabilizing the system and affects the desired performance and decreases the affect of unmatched components where the state is not available. $u_i^{ISM}$ is a discontinuous control responsible for rejecting the effects of matched components (uncertainties and actuator faults).

## III. CONTROL DESIGN

As described in (3) the subsystem control signal includes two parts with each part designed using a different method where (i) $u_i^{ISM}(t)$ is designed by output integral sliding mode control OISMC where the state is not available and only the estimated state is obtainable, and (ii) $u_i^{OBC}(t)$ depends on the estimated state as shown in Fig. 1.

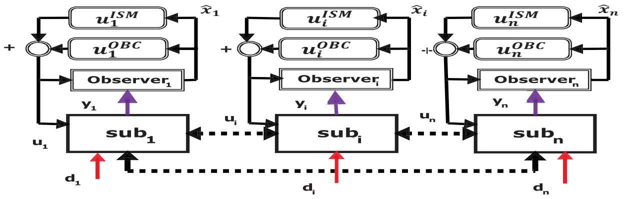

Figure 1 output control of interconnected systems via LMI+ISMC

### A. OUTPUT INTEGRAL SLIDING MODE CONTROL (OISLMC)

As outlined in Section 1 the integral sliding control can be used to remove the reachability problem. The output feedback case of integral sliding mode control can be developed by defining the following integral sliding switching surface:

$$\sigma_i(y_i, \hat{x}_i, t) =$$
$$G_i[y_i(t) - y_i(t_o) - \int_{t_o}^{t} (C_i A_i \hat{x}_i(t) + C_i B_i u_i^{LMI}(t)) dt] \qquad (4)$$

where $G_i \in \mathbb{R}^{mxp}$ is a design freedom matrix that must satisfy the invertibility of $G_i C_i B_i$ .

The two ISMC design steps are as:

1- Sliding surface design that satisfies the system performance and ensures that the system has required performance when the state trajectory is on the sliding surface.

2- Appropriate discontinuous control to maintain the system trajectory close to or on the sliding surface.

In the ISMC the design freedom of the integral action can be used to design a control law that satisfies the prescribed closed-loop performance.

The equivalent control $u_{eqi}(t)$ can be maintained on the sliding surface by forcing the time derivative of $\sigma_i(y_i, \hat{x}_i, t)$ in (4) to be zero-valued [16], i.e.:

$$\dot{\sigma}_i(y_i, \hat{x}_i, t) = G_i \dot{y}_i(t) - G_i C_i A_i \hat{x}_i(t) - G_i C_i B_i u_i^{OBC}(t) = 0 \qquad (5)$$

Then substituting (2) and (3) into (5) yields:

$$G_i C_i A_i x_i(t) + G_i C_i B_i u_i^{OBC} + G_i C_i B_i u_i^{ISM} + G_i C_i B_i B_i^+ Z_i(t) + G_i C_i \zeta_i(t) + G_i C_i B_i Q_i(x_i,t) + G_i C_i E_i d_i(t) + G_i C_i B_i f_i(t) - G_i C_i A_i \hat{x}_i(t) - G_i C_i B_i u_i^{OBC} = 0 \qquad (6)$$

Hence, the so-called *equivalent control* for the output feedback case is:

$$u_{eqi}(t) = u_i^{ISM} = -(G_iC_iB_i)^{-1}G_iC_iA_i(x_i(t) - \hat{x}_i(t)) - B_i^+Z_i(t) - (G_iC_iB_i)^{-1}G_iC_i\zeta_i(t) - Q_i(x_i,t) - (G_iC_iB_i)^{-1}G_iC_iE_id_i(t) - f_i(t) \quad (7)$$

Substituting (7) into (2) gives the $i^{\text{th}}$ subsystem state equation as:

$$\dot{x}_i(t) = A_ix_i(t) + B_iu_i^{OBC}(t) + [I_i - B_i(G_iC_iB_i)^{-1}G_iC_i]\zeta_i(t) + [I_i - B_i(G_iC_iB_i)^{-1}G_iC_i]E_id_i(t) - (G_iC_iB_i)^{-1}G_iC_iA_i(x_i(t) - \hat{x}_i(t) \quad (8)$$

From (8) the unknown matched uncertainties and actuator faults are completely nulled but the dynamics on the sliding surface contains the unknown unmatched uncertainties, disturbance and the state error. The unknown unmatched uncertainties and disturbances are multiplied by a matrix:

$$\Psi_i = [I_i - B_i(G_iC_iB_i)^{-1}G_iC_i]$$

To simplify the notation Eq. (10) can now be re-written as:

$$\dot{x}_i(t) = A_ix_i(t) + B_iu_i^{OBC}(t) + \Psi_i\zeta_i(t) + \Psi_iE_id_i(t) - M_ie_i(t) \quad (9)$$

where $M_i = (G_iC_iB_i)^{-1}G_iC_iA_i$ and $e_i(t) = x_i(t) - \hat{x}_i(t) \in \mathbb{R}^n$is the estimation error. The proposed discontinuous control is:

$$u_i^{ISM}(t) = -\mu_i \frac{\sigma_i(y_i,\hat{x}_i,t)}{\|\sigma_i(y_i,\hat{x}_i,t)\| + \mathfrak{z}_i} \quad (10)$$

The parameters $\mathfrak{z}_i > 0$ are chosen to reduce the amount of "chattering" of the motion around the sliding surface [15]. To satisfy subsystem stability the positive scalar $\mu_i$ is chosen according to the following derivation:

$$\mu_i > (G_iC_iB_i)^{-1}G_iC_i\beta_i(x_i,t) + \kappa_i\|x_i\| + (G_iC_iB_i)^{-1}G_iC_iE_i\gamma_i\,\|x_i\| + \eta_i\,\|x_i\| + (G_iC_iB_i)^{-1}G_iC_iA_i\|e_i(t)\| \quad (11)$$

To ensure sliding motion let $\sigma_i(y_i,\hat{x}_i,t) = 0$. Furthermore, the stability of the inter-connected system (1) is considered in terms of a positive definite summation of individual Lyapunov subsystems components as:

$$\textstyle\sum_{i=1}^n V_i\,(\sigma_i(y_i,\hat{x}_i,t)) = \sum_{i=1}^n\|\sigma_i(y_i,\hat{x}_i,t)\| > 0:$$

The derivative of the subsystem Lyapunov functions are:

$$\dot{V}_i(\sigma_i(y_i,\hat{x}_i,t)) = \frac{\sigma_i(y_i,\hat{x}_i,t)^T\dot{\sigma}_i(y_i,\hat{x}_i,t)}{\|\sigma_i(y_i,\hat{x}_i,t)\|} \quad (12)$$

Hence, from (4), (5) & (12) it can be shown that:

$$\textstyle\sum_{i=1}^n \dot{V}_i\left(\sigma_i(y_i,\hat{x}_i,t)\right) = \sum_{i=1}^n[-G_iC_iB_i\mu_i + \frac{\sigma_i(y_i,\hat{x}_i,t)}{\|\sigma_i(y_i,\hat{x}_i,t)\|}\,G_iC_iZ_i(t) + \frac{\sigma_i(y_i,\hat{x}_i,t)}{\|\sigma_i(y_i,\hat{x}_i,t)\|}\,G_iC_iB_iQ_i(x_i,t) + \frac{\sigma_i(y_i,\hat{x}_i,t)}{\|\sigma_i(y_i,\hat{x}_i,t)\|}G_iC_iE_id_i(t) + \frac{\sigma_i(y_i,\hat{x}_i,t)}{\|\sigma_i(y_i,\hat{x}_i,t)\|}\,G_iC_iB_if_i(t) + \frac{\sigma_i(y_i,\hat{x}_i,t)}{\|\sigma_i(y_i,\hat{x}_i,t)\|}G_iC_iA_ie_i(t)] \quad (13)$$

which can be re-written as:

$$\textstyle\sum_{i=1}^n \dot{V}_i\left(\sigma_i(y_i,\hat{x}_i,t)\right) \le \sum_{i=1}^n[-(G_iC_iB)[\mu_i - (G_iC_iB_i)^{-1}G_iC_i\|Z_i\| - \|Q_i\| - (G_iC_iB_i)^{-1}G_iC_iE_i\|d_i\| - \|f_i\| + (G_iC_iB_i)^{-1}G_iC_iA_i\|e_i(t)\|] \quad (14)$$

Then, according to A4, A5, A6 & A7:

$$\textstyle\sum_{i=1}^n \dot{V}_i\left(\sigma_i(y_i,\hat{x}_i,t)\right) \le \sum_{i=1}^n[-(G_iC_iB)[\mu_i - (G_iC_iB_i)^{-1}G_iC_i\beta_i(x_i,t) - \kappa_i\|x_i\| - (G_iC_iB_i)^{-1}G_iC_iE_i\gamma_i\,\|x_i\| - \eta_i\,\|x_i\| + (G_iC_iB_i)^{-1}G_iC_iA_i\|e_i(t)\|] \quad (15)$$

By suitable choice of $\mu_i$ in (11) then $\sum_{i=1}^n \dot{V}_i\left(\sigma_i(x_i,t)\right) \le 0$.

To minimize of norms $\|\Psi_i\zeta_i(t)\|$ and $\|\Psi_iE_id_i(t)\|$ corresponding to the unmatched uncertainty and disturbances, respectively, the matrix $G_i$ must be carefully chosen [13]. One choice is $G_i = B_i^TC_i^+$ which if substituted into (8) leads to the following:

**(i)** The term: $[I_i - B_i(B_i^+B_i)^{-1}B_i^+]B_i^\perp B_i^{\perp+}Z_i(t)$, with $B_i^TB_i^\perp = 0$, i.e.:

$$[I_i - B_i(B_i^+B_i)^{-1}B_i^+]B_i^\perp B_i^{\perp+}Z_i(t) = B_i^\perp B_i^{\perp+}Z_i(t) \quad (16)$$

**(ii)** The term:

$$[I_i - B_i(B_i^+B_i)^{-1}B_i^+]E_id_i(t) = [I_i - B_iB_i^+]E_id_i(t) \quad (17)$$

Substituting (16) & (17) into (8) yields the subsystem dynamics during sliding:

$$\dot{x}_i(t) = A_ix_i(t) + B_iu_i^{OBC}(t) + T_iZ_i(t) + H_id_i(t) - M_ie_i(t) \quad (18)$$

where $T_i = B_i^\perp B_i^{\perp+}$and $H_i = [I_i - B_iB_i^+]E_i$.

From (18) it can be observed that the unknown unmatched uncertainties and disturbances $T_iZ_i(t)\,, H_id_i(t)$ have not been minimized. Hence, another method must be found to minimize these terms and to limit their influence on the subsystem dynamics.

### B. *LMI OBSERVER-BASED CONTROL DESIGN*

After designing the ISMC, the subsystem sliding dynamics are:

$$\dot{x}_i(t) = A_ix_i(t) + B_iu_i^{OBC}(t) + \Gamma_iJ_i(t) - M_ie_i(t) \quad (19)$$

where $\Gamma_i = [T_i \quad H_i]$ and $J_i(t) = \begin{bmatrix} Z_i(t) \\ d_i(t) \end{bmatrix}$

The aggregated system dynamics are given by:

$$\dot{X}(t) = A_dX(t) + B_dU^{OBC}(t) + \Gamma_dJ(t) - M_de(t) \quad (20)$$

where: $X(t) = [x_1, x_2, \dots\dots, x_n]U^{OBC}(t) = [u_1, u_2, \dots\dots, u_n]$, $e(t) = [e_1, e_2, \dots\dots, e_n]$, $A_d = diag(A_i), B_d = diag(B_i)$, $\Gamma_d = diag(\Gamma_i)$ and $J(t) = [J_1, J_2, \dots\dots, J_n]$ , where "$diag$" represents the block diagonal matrix.

To develop a robust control law for the aggregate system consider a state estimate feedback of the form:

$$U^{OBC}(t) = K\hat{X}(t) = KX(t) - Ke(t) \quad (21)$$

where $K = diag(k_i)$ is the decentralized system gain that stabilizes the system under a specific performance objective. The design objective is to choose the gain $K$ to minimize the effect of $J(t)$ on the system. Suppose further that $J(t)$ is the unknown input disturbance which satisfies the quadratic inequality:

$$J^T(t)J(t) \le \alpha^2X^T(t)X(t) \quad (22)$$

where $\alpha > 0$ a positive constant. A suitable observer can estimate the aggregate system state $\hat{X}(t)$ any suitable observer can be used. However, the observer subsystems are given by:

$$\dot{\hat{x}}_i(t) = A_i\hat{x}_i(t) + B_i u_i^{OBC}(t) + L_i(y_i(t) - C_i\hat{x}_i(t)) \qquad (23)$$

where $L_i$ is the subsystem observer gain. The aggregate observer dynamics are thus:

$$\dot{\hat{X}}(t) = A_d\hat{X}(t) + B_d U^{OBC}(t) + L_d(Y(t) - C_d\hat{X}(t)) \qquad (24)$$

where $Y(t) = [y_1, y_2, \dots \dots, y_n]$ , $L_d = diag(L_i)$ and $C_d = diag(C_i)$

Subtracting (20) from (24) yields the state estimation error:

$$\dot{e}(t) = (A_d - L_d C_d)e(t) + \Gamma_d J(t) - M_d e(t) \qquad (25)$$

To check the stability of the observer-based closed-loop system the following candidate Lyapunov function is used:

$V(X,t) = X^T(t)PX(t) + e^T(t)Fe(t)$ where $P > 0$ & $F > 0$.

The time derivative of $V(X,t)$ is thus:

$$\dot{V}(X,t) = \dot{X}^T(t)PX(t) + X^T(t)P\dot{X}(t) + \dot{e}^T(t)Fe(t) + e^T(t)F\dot{e}(t) \qquad (26)$$

Substituting (21) and (20) into (26) and substituting (25) into (26):

$$\dot{V}(X,t) = X^T(t)[{A_d}^T P + K^T {B_d}^T P + PB_d K]X(t) - e^T[K^T {B_d}^T P - {M_d}^T P]X(t) + J^T(t){\Gamma_d}^T PX(t) + -X^T(t)[PB_d K - (t)PM_d]e(t) + X^T(t)P\Gamma_d J(t) + e^T(t)[{A_d}^T F - {C_d}^T {L_d}^T F - {M_d}^T F + FA_d - FL_d C_d - FM_d]e(t) + J^T(t){\Gamma_d}^T Fe(t) + e^T(t)F\Gamma_d J(t) \qquad (27)$$

The stability of subsystem (27) requires that $\dot{V}(X,t) < 0$ $\forall\, X(t) \neq 0$. Equation (27) can then be re-written as:

$$\mathcal{Z}^T\mathcal{D}\mathcal{Z} < 0 \qquad (28)$$

where: $\mathcal{Z} = \begin{bmatrix} X(t) \\ e(t) \\ J(t) \end{bmatrix}$ and

$$\mathcal{D} = \begin{bmatrix} {A_d}^T P + PA_d + K^T {B_d}^T P + PB_d K & -PB_d K - PM_d & P\Gamma_d \\ -K^T {B_d}^T P - {M_d}^T P & {A_d}^T F + FA_d + {C_d}^T {L_d}^T F + FL_d C_d - FM_d - {M_d}^T F & F\Gamma_d \\ {\Gamma_d}^T P & {\Gamma_d}^T F & 0 \end{bmatrix} \qquad (29)$$

To guarantee stability of the system (28) the matrix $\mathcal{D}$ must be negative-definite.

Furthermore, Eq (23) can be rewritten as:

$$\mathcal{Z}^T\mathcal{O}\mathcal{Z} \leq 0 \qquad (30)$$

where: $\mathcal{Z}_i = \begin{bmatrix} X(t) \\ e(t) \\ J(t) \end{bmatrix}$ and $\mathcal{O} = \begin{bmatrix} -\alpha^2 I & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & I \end{bmatrix}$.

To combine (28) & (30) into a single inequality the so-called S-procedure is now used [14].

If $\mathcal{D}$ and $\mathcal{O}$ can be considered as symmetric matrices then $\mathcal{Z}^T\mathcal{D}\mathcal{Z} < 0$ and $\mathcal{Z}^T\mathcal{O}\mathcal{Z} \leq 0$ . Hence, there is a number $\tau > 0$ where $-\tau\mathcal{O} < 0$ and it follows that:

$$\mathcal{D} - \tau\mathcal{O} = \begin{bmatrix} {A_d}^T P + PA_d + K^T {B_d}^T P + PB_d K + \tau\alpha^2 I & -PB_d K - PM_d & P\Gamma_d \\ -K^T {B_d}^T P - {M_d}^T P & {A_d}^T F + FA_d + {C_d}^T {L_d}^T F + FL_d C_d - FM_d - {M_d}^T F & F\Gamma_d \\ {\Gamma_d}^T P & {\Gamma_d}^T F & -\tau I \end{bmatrix} < 0 \qquad (31)$$

Substituting $\mathcal{Y} = \frac{P}{\tau}$ and $\Finv = \frac{F}{\tau}$ into (31) yields:

$$\Pi = \begin{bmatrix} {A_d}^T\mathcal{Y} + \mathcal{Y}A_d + K^T {B_d}^T\mathcal{Y} + \mathcal{Y}B_d K + \tau\alpha^2 I & -\mathcal{Y}B_d K - \mathcal{Y}M_d & \mathcal{Y}\Gamma_d \\ -K^T {B_d}^T\mathcal{Y} - {M_d}^T\mathcal{Y} & {A_d}^T\Finv + \Finv A_d + {C_d}^T {L_d}^T\Finv + \Finv L_d C_d - \Finv M_d - {M_d}^T\Finv & \Finv\Gamma_d \\ {\Gamma_d}^T\mathcal{Y} & {\Gamma_d}^T\Finv & -I \end{bmatrix} < 0 \qquad (32)$$

The inequality (32) cannot be solved via an LMI since it includes the term $B_d K$ to overcome this problem both sides of (32) must be multiplied by the matrix $\mathcal{W} = \begin{bmatrix} \mathcal{Y}^{-1} & 0 \\ 0 & \mathcal{T} \end{bmatrix}$ where $\mathcal{T} = \begin{bmatrix} \mathcal{Y}^{-1} & 0 \\ 0 & S \end{bmatrix}$ where $S$ is a design parameter.

Hence $\mathcal{W}\Pi\mathcal{W}^T = \begin{bmatrix} \mathcal{Y}^{-1} & 0 \\ 0 & \mathcal{T} \end{bmatrix}\begin{bmatrix} \Pi_{11} & \Pi_{12} \\ \Pi_{21} & \Pi_{22} \end{bmatrix}\begin{bmatrix} \mathcal{Y}^{-1} & 0 \\ 0 & \mathcal{T} \end{bmatrix} =$

$$\begin{bmatrix} \mathcal{Y}^{-1}\Pi_{11}\,\mathcal{Y}^{-1} & \mathcal{Y}^{-1}\Pi_{12}\mathcal{T} \\ \mathcal{T}\Pi_{21}\mathcal{Y}^{-1} & \mathcal{T}\Pi_{22}\mathcal{T} \end{bmatrix} \qquad (33)$$

Also, by making a partition of $\Pi_i$ into four parts:

$$\Pi_{11} = {A_d}^T\mathcal{Y} + \mathcal{Y}A_d + K^T {B_d}^T\mathcal{Y} + \mathcal{Y}B_d K + \tau\alpha^2 I \qquad (34)$$

$$\Pi_{12} = [-\mathcal{Y}B_d K - \mathcal{Y}M_d \qquad \mathcal{Y}\Gamma_d] \qquad (35)$$

$$\Pi_{21} = \begin{bmatrix} -K^T {B_d}^T\mathcal{Y} - {M_d}^T\mathcal{Y} \\ {\Gamma_d}^T\mathcal{Y} \end{bmatrix} \qquad (36)$$

$$\Pi_{22} = \begin{bmatrix} {A_d}^T\Finv + \Finv A_d + {C_d}^T {L_d}^T\Finv + \Finv L_d C_d - \Finv M_d - {M_d}^T\Finv & \Finv\Gamma_d \\ {\Gamma_d}^T\Finv & -I \end{bmatrix} \qquad (37)$$

The term $\mathcal{T}\Pi_{22}\mathcal{T}$ can then be described using [17] as:

$$\mathcal{T}\Pi_{22}\mathcal{T} \leq -\lambda(\mathcal{T} + \mathcal{T}^T) - \lambda^2\Pi_{22}^{-1} \qquad (38)$$

where $\lambda > 0$ is used for tuning to get an acceptable response.

$$\therefore\ \mathcal{W}\Pi\mathcal{W}^T = \begin{bmatrix} \mathcal{Y}^{-1}\Pi_{11}\,\mathcal{Y}^{-1} & \mathcal{Y}^{-1}\Pi_{12}\mathcal{T} \\ \mathcal{T}\Pi_{21}\mathcal{Y}^{-1} & -\lambda(\mathcal{T} + \mathcal{T}^T) - \lambda^2\Pi_{22}^{-1} \end{bmatrix} < 0 \qquad (39)$$

By using the Schur complement (39) could rewritten as:

$$\begin{bmatrix} \mathcal{Y}^{-1}\Pi_{11}\,\mathcal{Y}^{-1} & \mathcal{Y}^{-1}\Pi_{12}\mathcal{T} & 0 \\ \mathcal{T}\Pi_{21}\mathcal{Y}^{-1} & -2\lambda\mathcal{T} & \lambda I \\ 0 & \lambda I & \Pi_{22} \end{bmatrix} < 0 \qquad (40)$$

Substituting $\mathcal{P} = \mathcal{Y}^{-1}$ in (40) and also substituting (34), (35), (36) and (37) into (40) yields:

$$\begin{bmatrix} \mathbb{W} & -B_d K\mathcal{P} - M_d\mathcal{P} & \Gamma_d S & 0 & 0 \\ -\mathcal{P}K^T {B_d}^T - \mathcal{P}{M_d}^T & -2\lambda\mathcal{P} & 0 & \lambda I & 0 \\ S{\Gamma_d}^T & 0 & -2\lambda S & 0 & \lambda I \\ 0 & \lambda I & 0 & \mathbb{L} & F\Gamma_d \\ 0 & 0 & \lambda I & {\Gamma_d}^T\Finv & -I \end{bmatrix} < 0 \qquad (41)$$

where $\mathbb{W} = \mathcal{P}{A_d}^T + A_d\mathcal{P} + \mathcal{P}K^T {B_d}^T + B_d K\mathcal{P} + \alpha^2\mathcal{P}\mathcal{P}$ and $\mathbb{L} = {A_d}^T\Finv + \Finv A_d + {C_d}^T {L_d}^T\Finv + \Finv L_d C_d - \Finv M_d - {M_d}^T\Finv$

Choose $= I$ , and substitute $N = K\mathcal{P}$, $R = \Finv L_d$ and $\epsilon = \frac{1}{\alpha^2}$ , by using the Schur complement (41) is re-written as:

$$\begin{bmatrix} \overline{\overline{\mathbb{W}}} & -B_d N - M_d\mathcal{P} & \Gamma_d S & 0 & 0 & \mathcal{P} \\ -N^T {B_d}^T - \mathcal{P}{M_d}^T & -2\lambda\mathcal{P} & 0 & \lambda I & 0 & 0 \\ S{\Gamma_d}^T & 0 & -2\lambda S & 0 & \lambda I & 0 \\ 0 & \lambda I & 0 & \overline{\overline{\mathbb{L}}} & F\Gamma_d & 0 \\ 0 & 0 & \lambda I & {\Gamma_d}^T\Finv & -I & 0 \\ \mathcal{P} & 0 & 0 & 0 & 0 & -\epsilon I \end{bmatrix} < 0 \qquad (42)$$

where $\overline{\overline{\mathbb{W}}} = \mathcal{P}{A_d}^T + A_d\mathcal{P} + N^T {B_d}^T + B_d N$ ,
$\overline{\overline{\mathbb{L}}} = {A_d}^T\Finv + \Finv A_d + {C_d}^T R_i^T + RC_d - \Finv M_d - {M_d}^T\Finv$.
There are *two* approaches to solving the LMI (42)

*Algorithm 1:*
Minimize $\epsilon$ subject to $\mathcal{P} > 0$ , $\Finv > 0$ and (42).
To minimize the gain magnitude the conditioning of the matrices $N$ and $R$ in terms of norm bounds $\|N\|_2 < K_N I$ and $\|R\|_2 < K_R I$ are used as further inequality conditions [18]:
where $K_N$ and $K_R$ are scalar variables, and by using the Schur complement inequalities (43) and (44) can be added to (42) as follows:

$$\begin{bmatrix} -K_N I & N^T \\ N & -I \end{bmatrix} < 0 \text{ and } \begin{bmatrix} -K_R I & R^T \\ R & -I \end{bmatrix} < 0 \qquad (43)$$

Additional inequalities can be added to the matrices $\mathcal{P}$ and $\Finv$ [18].

$$\begin{bmatrix} \mathcal{P} & I \\ I & K_P I \end{bmatrix} > 0 \; and \; \begin{bmatrix} \Finv & I \\ I & K_{\Finv} I \end{bmatrix} > 0 \qquad (44)$$

where $K_P$ and $K_{\Finv}$ are scalar variables.

*Algorithm 2:*
Minimize $(\epsilon + K_N + K_P + K_R + K_{\Finv})$ subject to $\mathcal{P} > 0$ ,$\Finv > 0$ , (42) , (43) and (44).

## IV. Numerical Example

Consider a numerical example consisting of three inter-connected nonlinear systems.

*Subsystem 1:*

$$A_1 = \begin{bmatrix} 0 & -6 \\ 6 & 1 \end{bmatrix}, B_1 = \begin{bmatrix} 0 \\ 1 \end{bmatrix}, C_1 = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, E_1 = \begin{bmatrix} 0.1 \\ 0.3 \end{bmatrix},$$

$$z_1 = (\begin{bmatrix} 0 & 0 \\ 1 & 1 \end{bmatrix}\begin{bmatrix} x_{21} \\ x_{22} \end{bmatrix} + \begin{bmatrix} 0 & 0 \\ 1 & 1 \end{bmatrix}\begin{bmatrix} x_{31} \\ x_{32} \end{bmatrix})$$

$W_1(x_1, t) = \begin{bmatrix} 0 \\ 4\,cos(2t)x_{11} - 2\,sin(t)x_{12} \end{bmatrix}$, $x_1(0) = \begin{bmatrix} 0.4 \\ -0.1 \end{bmatrix}$ and $x_1(t) = \begin{bmatrix} x_{11}(t) \\ x_{12}(t) \end{bmatrix}$

*Subsystem 2:*

$$A_2 = \begin{bmatrix} 0 & -1 \\ -2 & -7 \end{bmatrix}, B_2 = \begin{bmatrix} 0 \\ 1 \end{bmatrix}, C_2 = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, E_2 = \begin{bmatrix} 0.1 \\ 0.3 \end{bmatrix},$$

$$z_2 = (\begin{bmatrix} 0 & 0 \\ 1 & 2 \end{bmatrix}\begin{bmatrix} x_{11} \\ x_{12} \end{bmatrix} + \begin{bmatrix} 0 & 0 \\ 1 & 2 \end{bmatrix}\begin{bmatrix} x_{31} \\ x_{32} \end{bmatrix})$$

$W_2(x_2, t) = \begin{bmatrix} 0 \\ 2\,sin(t)x_{21} + 4\,cos(2t)x_{22} \end{bmatrix}$, $x_2(0) = \begin{bmatrix} 0.3 \\ -0.2 \end{bmatrix}$ and $x_2(t) = \begin{bmatrix} x_{21}(t) \\ x_{22}(t) \end{bmatrix}$

*Subsystem 3:*

$$A_3 = \begin{bmatrix} 0 & -1 \\ -4 & -5 \end{bmatrix}, B_3 = \begin{bmatrix} 0 \\ 1 \end{bmatrix}, C_3 = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, E_3 = \begin{bmatrix} 0.1 \\ 0.3 \end{bmatrix},$$

$$z_3 = (\begin{bmatrix} 0 & 0 \\ 2 & 1 \end{bmatrix}\begin{bmatrix} x_{11} \\ x_{12} \end{bmatrix} + \begin{bmatrix} 0 & 0 \\ -2 & -1 \end{bmatrix}\begin{bmatrix} x_{21} \\ x_{22} \end{bmatrix})$$

$W_3(x_3, t) = \begin{bmatrix} 0 \\ 6\,sin(t)x_{31} + 2\,cos(2t)x_{32} \end{bmatrix}$, $x_3(0) = \begin{bmatrix} -0.3 \\ -0.3 \end{bmatrix}$ and $x_3(t) = \begin{bmatrix} x_{31}(t) \\ x_{32}(t) \end{bmatrix}$

The systems without feedback are unstable.

*Simulation Results*

The continuous control $u_i^{OBC}(t)$ designed by LMI where the solution of Algorithm 2 yields the gains:

$K1 = [-4.9522 \quad -4.4306$ , $K2 = [5.6854 \quad 3.6946]$ and $K3 = [7.6854 \quad 1.6946]$

$L1 = \begin{bmatrix} 5.2947 & -0.1504 \\ 0 & 0 \end{bmatrix}$, $L2 = \begin{bmatrix} 7.7790 & 0 \\ 0 & 0 \end{bmatrix}$, $L3 = \begin{bmatrix} 7.7790 & 0 \\ 0 & 0 \end{bmatrix}$

where the value of the aggregate system tuning design parameter is $\lambda = 1.86$ , where $\mu_1 = \mu_2 = \mu_3 = 5$ and $\mathfrak{z}_1 = \mathfrak{z}_2 = \mathfrak{z}_3 = 0.2$

All three subsystems without controls are unstable. Fig.2 shows the response of all three subsystems using the output decentralized system (LMI+ISMC) with no faults. These results illustrate that the controllers give an acceptable response with stable subsystems.

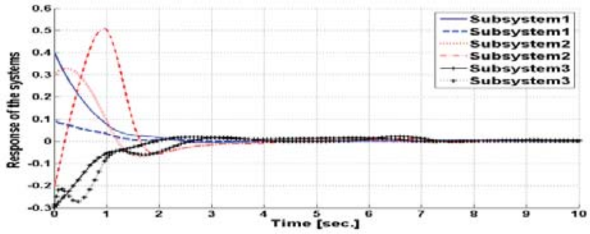

Figure.2 Three subsystems with controls and without faults

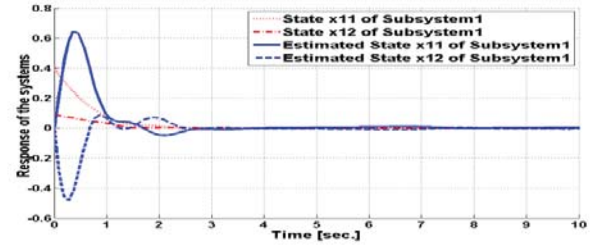

Figure.3 States of 1st subsystem and its estimated

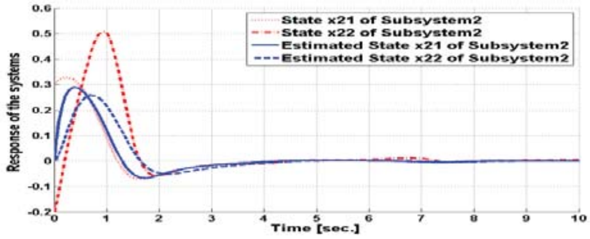

Figure.4 States of 2nd subsystem and it's estimated

Figs. 3, 4 & 5 illustrate the simulation results of the states of every subsystem and their estimates when there are no faults (actuators and sensors). In all subsystems from these results, the estimated and true state values are almost identical, with a little difference at the start of the simulation responses. These estimated states are used as feedback signals to control the subsystems.

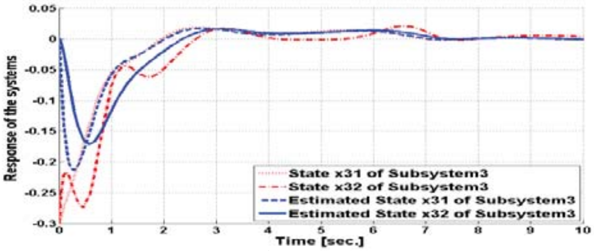

Figure.5 States of 3$^{th}$ subsystem and its estimated

For comparison with the results above, Fig.6 shows the response of all *three* independent linear subsystems using three separate observer-based controls to achieve output decentralized (LMI+ISMC) with no faults, no interconnections and no uncertainties. These results demonstrate very clearly the value of decentralized control approach described in the paper.

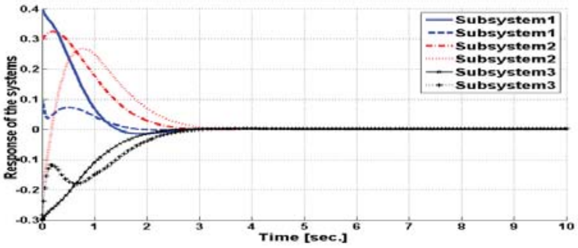

Figure. 6 Three linear subsystems with controls and without ( faults + interconnections + uncertainties)

## V. Conclusion

A major challenge of the control of uncertain inter-connected systems is to remove or compensate for the effects of uncertainly and disturbances acting in the subsystems so that an ideal decentralization can be achieved. In the ideal case, the resulting hitherto inter-connected system now becomes a truly decentralized structure in which the subsystems can be designed independently. This approach to control of complex systems has important consequences for security and fault-tolerance, e.g. if one subsystem fails then this failure does not influence the integrity of the remaining subsystems.

It is assumed in this work that the subsystem states are not available for control and hence the outputs are used together with the classical notion of state estimate feedback to develop a strategy for decentralization. Hence, the output decentralized control is achieved via ISMC together with linear observer design to give robust performance for both matched and unmatched uncertainty and disturbances. The design uses a single LMI to achieve stability of the aggregate system, minimization of matched/unmatched uncertainties and interactions and control performance specification. Whilst the design procedure is considerably complex the system implementation is nothing more than the ISMC and linear observers applied locally to each subsystem.

***Abstract*—This paper proposes a new variable gain controller for a class of uncertain linear systems. The proposed variable gain controller is based on optimal control for the nominal system and consists of the optimal feedback gain and a time-varying adjustable parameter which is designed so as to reduce the effect of uncertainties, i.e. the proposed variable gain controller can achieve good transient performance which is close to LQ optimal control for the nominal system. In this paper, we show sufficient conditions for the existence of the proposed variable gain controller for uncertain linear systems. Finally, numerical examples are presented.**

## I. Introduction

Robustness of control systems to uncertainties has always been the central issue in feedback control and therefore for linear systems with unknown parameters, a large number of design methods of robust controllers have been presented (e.g. [1] and references therein). For a system with structured uncertainties, several quadratic stabilizing control laws have also been suggested and a connection between quadratic stabilization and $\mathcal{H}^{\infty}$ control has been established[2]. It is well known that for robust control for linear dynamical systems with uncertainties, the concept of quadratic stabilization via fixed quadratic Lyapunov functions plays an important role in dealing with the controller design.

By the way in most practical situations, it is desirable to design robust control systems which achieve not only robust stability but also an adequate level of performance. Therefore robust controllers achieving some robust performances such as quadratic cost function, mixed $\mathcal{H}^{\infty}/\mathcal{H}^{2}$ control, robust $\mathcal{H}^{2}$ control and so on have been suggested (e.g.[3], [4], [5]). Additionally, synthesis problems of robust controllers with variable gain have also been tackled (e.g. [6], [7]). Yamamoto and Yamauchi[6] proposed a design method of a robust controller with the ability to adjust control performances adaptively. In [7], an adaptive robust controller with adaptation mechanism has been presented and the adaptive robust controller is tuned on-line based on the information about parameter uncertainties. Besides, we have proposed robust controllers with adaptive compensation inputs[8], [9]. Although the robust controllers in [8] and [9] can achieve not only asymptotical stability but also satisfactory transient behavior, these robust controllers include the additional dynamics of the nominal system. Namely, these robust controllers are dynamic one and their structure is more complex.

From these viewpoints, we propose a variable gain robust controller based on optimal control for a class of uncertain linear systems. The proposed variable gain controller consists of optimal feedback gain designed by using the nominal system and an adjustable time-varying parameter. The adjustable parameter is designed so as to reduce the effect of uncertainties. The proposed variable gain controller can achieve good transient performance which is close to the desirable trajectory generated by the nominal closed-loop system. This paper is organized as follows. In Sec. II, notation and useful lemmas which are used in this paper are shown, and in Sec. III, we introduce the class of uncertain linear systems under consideration. Sec. IV contains the main results. Finally, numerical examples are included to illustrate the results developed in this paper.

## II. Preliminaries

In this section, we show notations and useful and well-known lemmas which are used in this paper.

In the sequel, we use the following notation. For a matrix $\mathcal{A}$, The transpose of matrix $\mathcal{A}$ and the inverse of one are denoted by $\mathcal{A}^T$ and $\mathcal{A}^{-1}$ respectively and $\mathrm{rank}\left\{\mathcal{A}\right\}$ represents the rank of the matrix $\mathcal{A}$. Also, $H_e\{\mathcal{A}\}$ means $\mathcal{A}+\mathcal{A}^T$ and $I_n$ represents $n$-dimensional identity matrix and the notation $\mathrm{diag}\left(\mathcal{A}_1, \cdots, \mathcal{A}_N\right)$ denotes a block diagonal matrix composed of matrices $\mathcal{A}_i$ for $i = 1, \cdots, N$. For real symmetric matrices $\mathcal{A}$ and $\mathcal{B}$, $\mathcal{A} > \mathcal{B}$ (resp. $\mathcal{A} \geq \mathcal{B}$) means that $\mathcal{A} - \mathcal{B}$ is positive (resp. nonnegative) definite matrix. For a vector $\alpha \in \Re^n$, $||\alpha||$ denotes standard Euclidian norm and for a matrix $\mathcal{A}$, $||\mathcal{A}||$ represents a its induced norm. The symbols "$\stackrel{\triangle}{=}$" and "$\star$" means equality by definition and symmetric blocks in matrix inequalities, respectively.

Furthermore, the following well-known lemmas are used in this paper.

**Lemma 1:** For arbitrary vectors $\lambda$ and $\xi$ and the matrices $\mathcal{G}$ and $\mathcal{H}$ which have appropriate dimensions, the following relation holds.

$$H_e\left\{\lambda^T\mathcal{G}\Delta(t)\mathcal{H}\xi\right\} \leq 2\left\|\mathcal{G}^T\lambda\right\|\left\|\mathcal{H}\xi\right\|$$

where $\Delta(t) \in \mathbb{R}^{p\times q}$ is a time-varying unknown matrix satisfying $\left\|\Delta(t)\right\| \leq 1$.

*Proof:* The above relation is easily obtained by Schwartz's inequality[10]. ■

$$\begin{pmatrix} -\mathcal{Q}-(1+\tau_1)\mathcal{P}B\mathcal{R}^{-1}B^T\mathcal{P}+(\delta\tau_1+\tau_2)I_n & \Xi(\mathcal{P}) \\ \star & -\tau_2\Sigma_\sigma^{-1} \end{pmatrix} < 0 \tag{9}$$

**Lemma 2:** ($\mathcal{S}$-procedure) Let $\mathcal{F}(x)$ and $\mathcal{G}(x)$ be two arbitrary quadratic forms over $\mathbb{R}^n$. Then $\mathcal{F}(x) < 0$ for $\forall x \in \mathbb{R}^n$ satisfying $\mathcal{G}(x) \le 0$ if and only if there exist a nonnegative scalar $\tau$ such that

$$\mathcal{F}(x) - \tau\mathcal{G}(x) \le 0 \quad \text{for} \quad \forall x \in \mathbb{R}^n$$

*Proof:* See Boyd et al.[11] ■

**Lemma 3:** (Schur complement) For a given constant real symmetric matrix $\Xi$, the following arguments are equivalent.

(i) $\Xi = \begin{pmatrix} \Xi_{11} & \Xi_{12} \\ \Xi_{12}^T & \Xi_{22} \end{pmatrix} > 0$

(ii) $\Xi_{11} > 0$ and $\Xi_{22} - \Xi_{12}^T\Xi_{11}^{-1}\Xi_{12} > 0$

(iii) $\Xi_{22} > 0$ and $\Xi_{11} - \Xi_{12}\Xi_{22}^{-1}\Xi_{12}^T > 0$

*Proof:* See Boyd et al.[11] ■

## III. Problem Formulation

Consider the uncertain linear system described by the following state equation (see **Remark 1**).

$$\frac{d}{dt}x(t) = \left(A + \sum_{k=1}^{\mathcal{N}} \theta_k(t)\mathcal{D}_k\right)x(t) + Bu(t) \tag{1}$$

where $x(t) \in \Re^n$ and $u(t) \in \Re^m$ are the vectors of the state (assumed to be available for feedback) and the control input, respectively. In (1), the matrices $A$ and $B$ denote the nominal values of the uncertain system of (1). The matrices $\mathcal{D}_k$ $(k = 1, \cdots, N)$ which have appropriate dimensions represent the structure of uncertainties and the time-varying parameter vector $\theta(t) \in \Re^N(\theta(t) = (\theta_1(t), \cdots, \theta_{\mathcal{N}}(t))^T)$ shows unknown parameters which belong to the $\mathcal{N}$-dimensional ellipsoidal set expressed as

$$\begin{aligned} &\Delta \overset{\triangle}{=} \left\{\theta \in \Re^{\mathcal{N}} \mid \theta^T(t)\Sigma^{-1}\theta(t) \le 1\right\} \\ &\Sigma = diag\left(\sigma_1^2, \cdots, \sigma_{\mathcal{N}}^2\right) \end{aligned} \tag{2}$$

where $\Sigma \in \Re^{\mathcal{N}\times\mathcal{N}}$ represents the size of the ellipsoid. Beside the nominal system, ignoring the unknown parameters in (1), is given by

$$\frac{d}{dt}\overline{x}(t) = A\overline{x}(t) + B\overline{u}(t). \tag{3}$$

In this paper first of all, we consider the standard linear quadratic control problem for the nominal system of (3) in order to generate the desired response for the uncertain system of (1) systematically. Namely we define the following quadratic cost function for the nominal system of (3).

$$\mathcal{J} = \int_0^\infty \left(\overline{x}^T(t)\mathcal{Q}\overline{x}(t) + \overline{u}^T\mathcal{R}\overline{u}(t)\right)dt \tag{4}$$

where the matrices $\mathcal{Q} \in \Re^{n\times n}$ and $\mathcal{R} \in \Re^{m\times m}$ are positive definite. It is well-known that the optimal control input minimizing the quadratic cost function of (4) is given by $\overline{u}(t) = -K\overline{x}(t)$, where $K \in \Re^{m\times n}$ represent the optimal control gain matrix. Note that the closed-loop system matrix $A_K \overset{\triangle}{=} A - BK$ is stable and the optimal feedback gain matrix $K \in \Re^{m\times n}$ is derived as $K = \mathcal{R}^{-1}B^T\mathcal{P}$ where $\mathcal{P} \in \Re^{n\times n}$ is unique solution of the algebraic Riccati equation

$$H_e\left\{A^T\mathcal{P}\right\} - \mathcal{P}B\mathcal{R}^{-1}B^T\mathcal{P} + \mathcal{Q} = 0. \tag{5}$$

Now by using the optimal feedback gain matrix $K \in \Re^{m\times n}$ for the nominal system of (3), we consider the following control input.

$$u(t) \overset{\triangle}{=} \gamma(x,t)Kx(t) \tag{6}$$

where $\gamma(x,t) \in \Re^1$ is a time-varying adjustable parameter so as to compensate the effect of unknown parameters.

From eqs.(1) and (6), we have the closed-loop system

$$\frac{d}{dt}x(t) = Ax(t) + \Gamma(x,t)\theta(t) + \gamma(x,t)Kx(t). \tag{7}$$

In (7), $\Gamma(x,t)$ is a matrix expressed as

$$\Gamma(x,t) = \left(\ \mathcal{D}_1x(t), \mathcal{D}_2x(t), \cdots, \mathcal{D}_{\mathcal{N}}x(t)\ \right). \tag{8}$$

From the above discussion, our control objective in this paper is to design the robust stabilizing controller which achieves good transient performance for the uncertain closed-loop system of (7). That is to design the time-varying adjustable parameter $\gamma(x,t) \in \Re^1$ such that the closed-loop system of (7) is robustly stable and achieves satisfactory transient performance close to LQ optimal control for the nominal system of (3).

**Remark 1:** In this paper, we consider the uncertain dynamical system of (1) which has uncertainties in the state matrix only. The proposed design scheme of the variable controller derived in next section can also be applied to the case that the uncertainties are included in both the system matrix and the input matrix. By introducing additional actuator dynamics and constituting an augmented system, uncertainties in the input matrix are embedded in the system matrix of the augmented system[12]. Therefore the same design procedure can be applied.

## IV. Main Results

In this section, we show a design method of the proposed variable gain controller such that the uncertain system of (1) is asymptotically stable.

The following theorem gives sufficient conditions for the existence of the proposed controller.

**Theorem 1:** Consider the uncertain linear system of (1) and the control input of (6).

If there exist the positive scalars $\tau_1$ and $\tau_2$ satisfying the LMI of (9) then the adjustable time-varying parameter

$$\gamma(t) = \begin{cases} -\left(1 + \dfrac{\left\| \Sigma^{1/2} \Gamma^T(x,t) \mathcal{P} x(t) \right\|}{\left\| \mathcal{R}^{-1/2} B^T \mathcal{P} x(t) \right\|^2}\right) & \text{if} \quad x^T(t)\mathcal{P}B\mathcal{R}^{-1}B^T\mathcal{P}x(t) \geq \delta x^T(t)x(t) \\ -\left(1 + \dfrac{\left\| \Sigma^{1/2} \Gamma^T(x,t) \mathcal{P} x(t) \right\|}{\delta x^T(t)x(t)}\right) & \text{if} \quad x^T(t)\mathcal{P}B\mathcal{R}^{-1}B^T\mathcal{P}x(t) < \delta x^T(t)x(t) \end{cases} \tag{10}$$

$$\frac{d}{dt}\mathcal{V}(x,t) = x^T(t)\left[H_e\left\{A^T\mathcal{P}\right\}\right]x(t) + 2x^T(t)\Gamma(x,t)\theta(t) + 2\gamma(t)x^T(t)\mathcal{P}BKx(t) \tag{13}$$

$$\frac{d}{dt}\mathcal{V}(x,t) = -x^T(t)\left(\mathcal{Q} - \mathcal{P}B\mathcal{R}^{-1}B^T\mathcal{P}\right)x(t) + 2x^T(t)\Gamma(x,t)\theta(t) + 2\gamma(t)x^T(t)\mathcal{P}BKx(t) \tag{14}$$

$$\begin{aligned} \frac{d}{dt}\mathcal{V}(x,t) &= -x^T(t)\left(\mathcal{Q} - \mathcal{P}B\mathcal{R}^{-1}B^T\mathcal{P}\right)x(t) + 2x^T(t)\Gamma(x,t)\Sigma^{1/2}\Sigma^{-1/2}\theta(t) + 2\gamma(t)x^T(t)\mathcal{P}BKx(t) \\ &= -x^T(t)\left(\mathcal{Q} - \mathcal{P}B\mathcal{R}^{-1}B^T\mathcal{P}\right)x(t) + 2\left\|\Sigma^{1/2}\Gamma^T(x,t)x(t)\right\| + 2\gamma(t)x^T(t)\mathcal{P}B\mathcal{R}^{-1}B^T\mathcal{P}x(t) \end{aligned} \tag{15}$$

$$\frac{d}{dt}\mathcal{V}(x,t) = \begin{pmatrix} x(t) \\ \xi(t) \end{pmatrix}^T \begin{pmatrix} -\mathcal{Q} + \mathcal{P}B\mathcal{R}^{-1}B^T\mathcal{P} & \Xi(\mathcal{P}) \\ \star & 0 \end{pmatrix} \begin{pmatrix} x(t) \\ \xi(t) \end{pmatrix} + 2\gamma(t)x^T(t)\mathcal{P}B\mathcal{R}^{-1}B^T\mathcal{P}x(t) \tag{17}$$

$$\begin{aligned} &\begin{pmatrix} x(t) \\ \xi(t) \end{pmatrix}^T \begin{pmatrix} -\mathcal{Q} + \mathcal{P}B\mathcal{R}^{-1}B^T\mathcal{P} & \Xi(\mathcal{P}) \\ \star & 0 \end{pmatrix} \begin{pmatrix} x(t) \\ \xi(t) \end{pmatrix} + 2\gamma(t)x^T(t)\mathcal{P}B\mathcal{R}^{-1}B^T\mathcal{P}x(t) < 0 \\ &\text{s.t.} \quad x^T(t)\mathcal{P}B\mathcal{R}^{-1}B^T\mathcal{P}x(t) < \delta x^T(t)x(t) \text{ and } \xi^T(t)\Sigma_\sigma^{-1}\xi(t) \leq x^T(t)x(t) \end{aligned} \tag{20}$$

$$\begin{pmatrix} -\mathcal{Q} - \mathcal{P}B\mathcal{R}^{-1}B^T\mathcal{P} & \Xi(\mathcal{P}) \\ \star & 0 \end{pmatrix} < 0 \quad \text{s.t.} \quad x^T(t)\mathcal{P}B\mathcal{R}^{-1}B^T\mathcal{P}x(t) < \delta x^T(t)x(t) \text{ and } \xi^T(t)\Sigma_\sigma^{-1}\xi(t) \leq x^T(t)x(t) \tag{22}$$

$\gamma(t) \in \mathbb{R}^1$ is determined as (10). In (9), $\delta$ is a positive constant selected by designers and $\Xi(\mathcal{P})$ is a matrix given by

$$\Xi(\mathcal{P}) \overset{\triangle}{=} \begin{pmatrix} \mathcal{P}\mathcal{D}_1 & \mathcal{P}\mathcal{D}_2 & \cdots & \mathcal{P}\mathcal{D}_{\mathcal{N}} \end{pmatrix}. \tag{11}$$

Then the uncertain closed-loop system of (7) is robustly stable.

*Proof:* By using the unique solution $\mathcal{P} \in \mathbb{R}^{n \times n}$ of the algebraic Riccati equation of (5), we consider the following quadratic function.

$$\mathcal{V}(x,t) \overset{\triangle}{=} x^T(t)\mathcal{P}x(t) \tag{12}$$

The time derivative of the quadratic function $\mathcal{V}(x,t)$ can be written as (13). Additionally since the matrix $\mathcal{P}$ is the unique solution of the algebraic Riccati equation of (5), The time derivative of the quadratic function $\mathcal{V}(x,t)$ can be rewritten as (14).

Now, we consider the case of $x^T(t)\mathcal{P}B\mathcal{R}^{-1}B^T\mathcal{P}x(t) \geq \delta x^T(t)x(t)$. In this case using **Lemma 1**, we obtain (15). Here we have used the relation of (2) and $K = \mathcal{R}^{-1}B^T\mathcal{P}$. Besides, by using the adjustable time-varying parameter $\gamma(t)$ of (10), we find that the following relation holds.

$$\begin{aligned} \frac{d}{dt}\mathcal{V}(x,t) &= -x^T(t)\left(\mathcal{Q} + \mathcal{P}B\mathcal{R}^{-1}B^T\mathcal{P}\right)x(t) \\ &< 0 \quad \text{for} \quad \forall x(t) \neq 0 \end{aligned} \tag{16}$$

Next, we consider the case of $x^T(t)\mathcal{P}B\mathcal{R}^{-1}B^T\mathcal{P}x(t) < \delta x^T(t)x(t)$ and then the time derivative of the quadratic function $\mathcal{V}(x,t)$ of (14) can be described as (17). In (17), $\xi(t)$ is a $n \times \mathcal{N}$-dimensional vector given by

$$\xi^T(t) = \begin{pmatrix} \theta_1(t)x^T(t) & \theta_2(t)x^T(t) & \cdots & \theta_{\mathcal{N}}(t)x^T(t) \end{pmatrix}. \tag{18}$$

Note that from the relation of (2) the following inequality for the vector $\xi(t) \in \mathbb{R}^{n \times \mathcal{N}}$ is satisfied.

$$\xi^T(t)\Sigma_\sigma^{-1}\xi(t) \leq x^T(t)x(t) \tag{19}$$

In (19), $\Sigma_\sigma = \mathrm{diag}\left(\sigma_1^2 I_n, \sigma_2^2 I_n, \cdots, \sigma_{\mathcal{N}}^2 I_n\right)$. One can see that if the condition of (20) holds, then the following inequality is also satisfied.

$$\frac{d}{dt}\mathcal{V}(x,t) < 0 \quad \text{for} \quad \forall x(t) \neq 0 \tag{21}$$

Thus we consider the condition of (20). By using the adjustable time-varying parameter $\gamma(t)$ of (10), we have (22) which is a sufficient condition for the inequality of (20). Namely, if the condition of (22) holds, then the inequality of (20) is also satisfied. Applying **Lemma 2** ($\mathcal{S}$-procedure) to the condition of (22) and some trivial manipulations give the LMI of (9). Therefore for the case of $x^T(t)\mathcal{P}B\mathcal{R}^{-1}B^T\mathcal{P}x(t) < \delta x^T(t)x(t)$, if the LMI of (9) is feasible then the relation of (21) is satisfied.

From the above discussion, the quadratic function $\mathcal{V}(x,t)$ becomes a Lyapunov function and the uncertain linear system of (1) is ensured to be stable. It follows that the result of the theorem is true. The proof of **Theorem 1** is completed. ■

**Remark 2:** In this paper, the quadratic function $\mathcal{V}(x,t)$ of (12) is introduced and it becomes a Lyapunov function for the uncertain system of (1). On the other hand, the quadratic function $\mathcal{V}(x,t)$ of (12) is also a Lyapnov function for the nominal closed-loop system, i.e. the standard LQ regulator. Therefore, by selecting the design parameter $\delta \in \mathbb{R}^1$ the proposed controller can achieve the good transient performance and adjust the magnitude of the control input, because the Lyapunov function for the uncertain system of (1) and one of the nominal system of (3) have same level set.

$$\frac{d}{dt}x(t) = \begin{pmatrix} -3.0 & 1.0 \\ 0.0 & 1.0 \end{pmatrix} x(t) + \delta_1(t) \begin{pmatrix} 1.0 & 1.0 \\ 0.0 & 0.0 \end{pmatrix} x(t) + \delta_2(t) \begin{pmatrix} 0.0 & 0.0 \\ 0.0 & 1.0 \end{pmatrix} x(t) + \begin{pmatrix} 0.0 \\ 1.0 \end{pmatrix} u(t) \tag{23}$$

$$\begin{aligned} &\bullet \text{ Case 1)} \ : \ \delta_1(t) = \sqrt{3.0} &&, \ \delta_2(t) = -\sqrt{2.0} \\ &\bullet \text{ Case 2)} \ : \ \delta_1(t) = \sqrt{3.0} \times \sin(5\pi t) &&, \ \delta_2(t) = -\sqrt{2.0} \times \cos(5\pi t) \end{aligned} \tag{27}$$

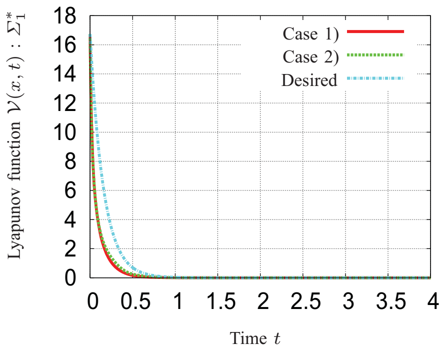

Fig. 4. Time histories of the Lyapunov function $\mathcal{V}(x,t)$ : $\Sigma_1^*$

## V. Illustrative Examples

In order to demonstrate the efficiency of the proposed control scheme, we have run a simple example. Consider the linear system with unknown parameters of (23) and we assume that the parameters $\sigma_1$ and $\sigma_2$ in the matrix $\Sigma \in \mathbb{R}^{2\times 2}$ in (2) are given by $\sigma_1 = 2.0$ and $\sigma_2 = 5.0 \times 10^{-1}$, respectively.

Firstly we select the weighting matrices $\mathcal{Q}$ and $\mathcal{R}$ such as $\mathcal{Q} = 1.0 \times I_2$ and $\mathcal{R} = 9.0$ for the quadratic cost function for the standard linear quadratic control problem, respectively. Then solving the algebraic Riccati equation of (5), we obtain

$$\begin{aligned} K &= \begin{pmatrix} 2.69892 \times 10^{-2} & -4.17080 \end{pmatrix} \\ \mathcal{P} &= \begin{pmatrix} 1.66545 \times 10^{-1} & 2.69892 \times 10^{-2} \\ \star & 4.17080 \end{pmatrix} \end{aligned} \tag{24}$$

In this example, we consider the following two kinds of the design parameters $\delta \in \mathbb{R}^1$ in (9) .

$$\bullet \ \Sigma_1^* \ : \ \delta = 1.0 \times 10^2, \quad \bullet \ \Sigma_2^* \ : \ \delta = 4.0 \times 10^5 \tag{25}$$

For these design parameters, solving the LMI condition of (9), we have

$$\begin{aligned} &\bullet \ \Sigma_1^* \ : \tau_1 = 1.00121 \times 10^{-7} &&, \tau_2 = 3.32679 \times 10^1 \\ &\bullet \ \Sigma_2^* \ : \tau_1 = 1.0 \times 10^{-7} &&, \tau_2 = 4.13381 \times 10^1 \end{aligned} \tag{26}$$

Now in this example, we consider the two cases for the unknown parameters in (27). Furthermore, the initial value for the uncertain system of (23) and its nominal system are selected as $x(0) = \overline{x}(0) = \begin{pmatrix} 1.0 & -2.0 \end{pmatrix}^T$.

The results of the simulation of this example are depicted in Figures 1 – 8. In these figures, "Case 1)" and "Case 2)" represent the time-histories of the state variables $x_1(t)$ and $x_2(t)$, the control input $u(t)$ and the Lyapunov function $\mathcal{V}(x,t)$. Besides, "Desired" represents the desirable transient behavior, the control input and the time-histories of the Lyapunov function $\mathcal{V}(x,t)$ generated by the nominal system.

From Figures 1 – 4, we find that the proposed variable gain controller ($\Sigma_1^*$) achieves good transient performance. However, the proposed control input is excessive comparing with the

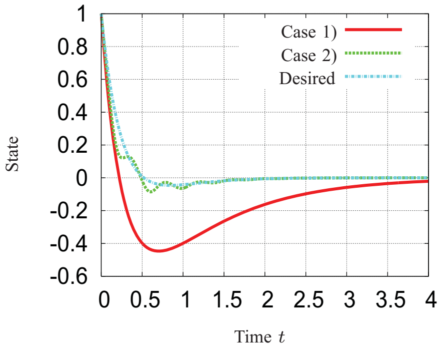

Fig. 5. Time histories of the state $x_1(t)$ : $\Sigma_2^*$

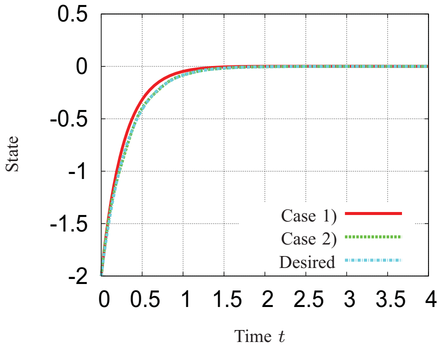

Fig. 6. Time histories of the state $x_2(t)$ : $\Sigma_2^*$

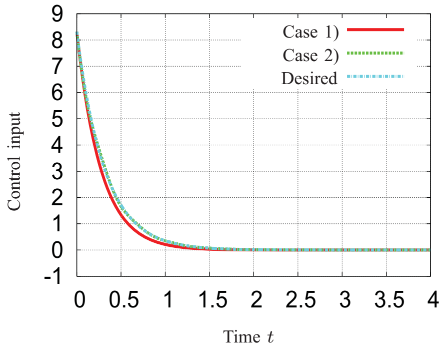

Fig. 7. Time histories of the control input $u(t)$ : $\Sigma_2^*$

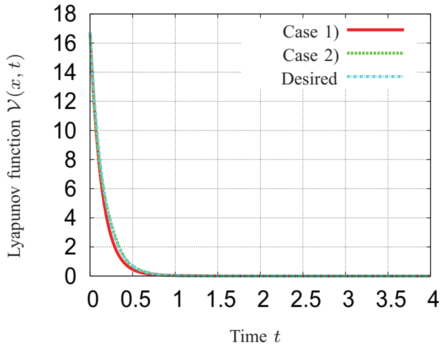

Fig. 8. Time histories of the Lyapunov function $\mathcal{V}(x,t)$ : $\Sigma_2^*$

nominal system. On the other hand, one can see from Figures 5 – 8 that although the error between the transient response for the proposed controller ($\Sigma_2^*$) and the one of the nominal system is large, the control input in $\Sigma_2^*$ is close to the desired one. Namely, the proposed controller can adjust the transient performance and the control input by means of selecting the design parameter $\delta \in \mathbb{R}^1$ in (10). Therefore the effectiveness of the proposed variable gain controller is shown.

## VI. Conclusions

In this paper we have proposed a new variable gain controller for a class of uncertain linear systems. Besides, by numerical simulations, the effectiveness of the proposed controller has been presented. One can see that the crucial difference between the existing results[8], [9] and our new one is that the structure of proposed controller is simple and the proposed variable gain controller can adjust the transient performance and the control input by means of selecting the design parameter.

The future research subjects are an extension of the proposed controller to such a broad class of systems as uncertain large-scale systems, uncertain discrete-time systems, uncertain time-delay systems and so on.

***Abstract*—This paper addresses the output regulation problem for switched linear systems. When each regulation equation has their own solution, we give a sufficient condition for the output regulation problem to be solvable. Firstly, we give the regulation equations of switched linear systems and the relation of the transformed states between two consecutive switching times. Secondly, the existence of a minimal average dwell-time for every switching sequence is assumed, and by virtue of an appropriate Lyapunov analysis, the output regulation is achieved. Our result is of much less conservativeness.**

## I. INTRODUCTION

A switched system is a special kind of hybrid system that consists of a family of continuous time or discrete-time subsystems and a rule orchestrating the switching among the subsystems [1]. This type of systems has wide applications in many fields, for instance, stochastic control [2], fault tolerant cooperative control [3], power systems [4], autonomous aircraft control [5]. A lot of methods have been presented to study stability and stabilization problems for switched systems, such as the convex combination technique, the common Lyapunov function technique, the multiple Lyapunov function method, the switched Lyapunov function method and the average dwell-time approach [6]-[9].

Output regulation is an important and interesting problem in control theory. This problem aims to achieve asymptotic tracking and disturbance rejection for a class of reference inputs and disturbances, which generated by an exosystem, besides closed-loop stability. Thus, the problem of output regulation is more challenging than stabilization and has attracted much attention. The problem for non-switched linear systems was widely studied in [10]-[12]. For non-switched nonlinear systems, there are also many results for the problem [13]-[15].

It is well known that for a non-switched linear system, in order to obtain the solvability condition for the output regulation problem, we need to solve a group of regulator equations. However, for a switched linear system, the solvability of the output regulation problem is more difficult and complicated. In order to get sufficient conditions for the problem, we need to solve a family of groups of regulator equations. If this family of systems has a common solution, then one can give the solvability conditions for the problem of switched linear systems. For instance, the problem for a class of switched systems with disturbances is solved under the assumption that the output regulation problem of a convex combination system is solvable [16]. A necessary and sufficient condition for the output regulation problem of switched systems under an arbitrary switching signal to be solvable is obtained in [17]. In addition, the multiple Lyapunov function method is used to solve the problem of output regulation for a class of discrete-time switched systems in [18]. The optimal output regulation is also guaranteed for the discrete switched linear system in [19]-[20]. However, to the authors' best knowledge, the output regulation problem has not been investigated for different coordinate transformations, which motivates the present study.

In this paper, for reducing the conservativeness, we consider the regulation equations of each subsystem has its own solution. This means that each subsystem of the switched linear system has the different transformation and complicates the solvability of the problem. Based on this case, we fist give the relation of the transformed states between two consecutive switching times. Then, the existence of a minimal average dwell-time for every switching sequence is assumed, and by virtue of an appropriate Lyapunov analysis, the output regulation is achieved.

This paper is organized as follows. Section 2 presents the problem statement and preliminaries. In section 3, the sufficient conditions for the output regulation problem to be solvable are given based on full information feedback controllers and error feedback controllers. Conclusion is stated in Section 4.

## Problem statements and preliminaries

Consider a switched linear system modelled by equations of the form

$$\begin{aligned} \dot{x} &= A_{\sigma(t)}x + B_{\sigma(t)}u + P_{\sigma(t)}\omega, \\ e &= C_{\sigma(t)}x + Q_{\sigma(t)}\omega, \end{aligned} \tag{1}$$

with the state $x \in R^n$, the control input $u \in R^m$, the switching signal $\sigma : [0, \infty) \to I_N = \{1, \cdots, N\}$ is a piecewise constant function of time, the error variable $e \in R^p$, the exogenous input variable $\omega \in R^r$ satisfying the following exosystem

$$\dot{\omega} = S\omega. \tag{2}$$

We are in a position to state the output regulation problem of the switched system (1).

**Output regulation via full information**. Given $\{A_i, B_i, P_i, C_i, Q_i, S\}$ , $i \in I_N$, find full information controllers

$$u = K_i x + L_i\omega \tag{3}$$

and switching law $\sigma(t)$ such that:

1. the system (1) with the controllers (3) is asymptotically stable under the designed switching law $\sigma(t)$ without disturbance input.

2. for each $(x^0, \omega^0)$, the solution $(x(t), \omega(t))$ of

$$\begin{aligned} \dot{x} &= (A_{\sigma(t)} + B_{\sigma(t)}K_{\sigma(t)})x + (P_{\sigma(t)} + B_{\sigma(t)}L_{\sigma(t)})\omega, \\ \dot{\omega} &= S\omega \end{aligned} \tag{4}$$

satisfying $(x(0), \omega(0)) = (x^0, \omega^0)$ is such that

$$\lim_{t\to\infty}(C_{\sigma(t)}x + Q_{\sigma(t)}\omega) = 0.$$

**Output regulation via error feedback.** Given $\{A_i, B_i, P_i, C_i, Q_i, S\}$, $i \in I_N$, find error feedback controllers

$$\begin{aligned} \dot{\xi} &= F_i\xi + G_i e, \\ u &= H_i\xi \end{aligned} \tag{5}$$

and switching law $\sigma(t)$ such that:

1. the system (1) with the controllers (5) is asymptotically stable under the designed switching law $\sigma(t)$ without disturbance input.

2. for each $(x^0, \xi^0, \omega^0)$, the solution $(x(t), \xi(t), \omega(t))$ of

$$\begin{aligned} \dot{x} &= A_{\sigma(t)}x + B_{\sigma(t)}H_{\sigma(t)}\xi + P_{\sigma(t)}\omega, \\ \dot{\xi} &= G_{\sigma(t)}C_{\sigma(t)}x + F_{\sigma(t)}\xi + G_{\sigma(t)}Q_{\sigma(t)}\omega, \\ \dot{\omega} &= S\omega \end{aligned} \tag{6}$$

satisfying $(x(0), \xi(0), \omega(0)) = (x^0, \xi^0, \omega^0)$ is such that

$$\lim_{t\to\infty}(C_{\sigma(t)}x + Q_{\sigma(t)}\omega) = 0.$$

**Remark 1**. The system and the output regulation problem for non-switched system are given in [21]. In [16], the system model (1) and the description of output regulation problem are presented for switched linear systems.

In what follows, we assume the exosystem (2) satisfies the following assumption.

**Assumption 1(A1)** [22]. The system (2) is antistable, i.e. all the eigenvalues of $S$ have nonnegative real part.

Before obtaining the main results, we give a definition of the average dwell time.

**Definition 1** [23] [24]. For switching signal $\sigma(t)$ and any $T \geq t \geq 0$, let $N_\sigma(T, t)$ be the switching numbers of $\sigma(t)$ over the interval $(t, T)$. If for any given $N_0 \geq 0$ and $\tau_a > 0$, we have $N_\sigma(t, T) \leq N_0 + (T - t)/\tau_a$, then $\tau_a$ and $N_0$ are called average dwell time and the chatter bound, respectively.

## Main results

In this section, we will give the solvability conditions for the output regulation problem for the switched linear system (1) with the full information controllers and the error feedback controllers, where the regulation equations for the switched linear system (1) are given.

Now, we give a sufficient condition for the output regulation problem to be solvable based on the full information feedback.

**Theorem 1.** If there exist $\Pi_i$ , $\Gamma_i$ for $\forall i \in I_N$, satisfying the following equations

$$\begin{aligned} \Pi_i S &= A_i\Pi_i + B_i\Gamma_i + P_i, \\ 0 &= C_i\Pi_i + Q_i, \end{aligned} \tag{7}$$

and the system (1) with different coordinate transformation

$$\begin{aligned} \tilde{x}(t_k^-) &= x(t_k^-) - \Pi_{i_k}\omega(t_k^-), \\ \tilde{x}(t_k^+) &= x(t_k^-) - \Pi_{i_{k+1}}\omega(t_k^-), \end{aligned} \tag{8}$$

and

$$x(t_k^-) - \Pi_{i_{k+1}}\omega(t_k^-) = T_{i_k,i_{k+1}}(x(t_k^-) - \Pi_{i_k}\omega(t_k^-)), \tag{9}$$

where $T_{i_k,i_{k+1}}$, $k \in N$, are given matrices, then under the average dwell time

$$\tau_a > \tfrac{ln\mu}{\lambda_0}, \tag{10}$$

where

$$\mu = \sup_{1\leq i,j\leq N} \parallel P^{1/2}T_{i,j}P^{1/2} \parallel, \lambda_0 = \inf_{1\leq i\leq N} \tfrac{\lambda_{\min}(Q_i\prime)}{\lambda_{\max}(P)}, \tag{11}$$

and

$$(A_i + B_iK_i)^TP + P(A_i + B_iK_i) = -Q_i\prime, \tag{12}$$

the full information feedback controllers (3) solve the problem of output regulation for the switched system (1).

*Proof.* Set $L_i = \Gamma_i - K_i\Pi_i$ , and consider the coordinate transformation $\tilde{x} = x - \Pi_i\omega$. According to (7), the system (4) is rewritten as

$$\begin{aligned} \dot{\tilde{x}} &= (A_{\sigma(t)} + B_{\sigma(t)}K_{\sigma(t)})\tilde{x} = \tilde{A}_{\sigma(t)}\,\tilde{x}, \\ \dot{\omega} &= S\omega, \\ e &= C_{\sigma(t)}\tilde{x}. \end{aligned} \tag{13}$$

Therefore, the output regulation problem for the switched system (1) is equivalently converted to the stabilization problem of the system (13). According to (9), we have the relation of the transformed states between the two consecutive switching times $t_k^+$ and $t_k^-$ as follows

$$x(t_k^-) - \Pi_{i_{k+1}}\omega(t_k^-) = T_{i_k,i_{k+1}}(x(t_k^-) - \Pi_{i_k}\omega(t_k^-)).$$

We define the following Lyapunov function candidate

$$V(\tilde{x}) = \tilde{x}^T P \tilde{x}, \tag{14}$$

where $P$ is a positive definite matrix satisfying (12). When $t \in [t_k, t_{k+1})$, we have

$$\begin{aligned} V(t) &\leq \exp\left(-\tfrac{\lambda_{\min}(Q_{i_{k+1}})'}{\lambda_{\max}(P)}(t_{k+1}-t_k)\right)V(t_k^+) \\ &\leq \exp(-\lambda_0(t_{k+1}-t_k))V(t_k^+). \end{aligned}$$

Because the coordinate transformations are different, $V(t_k^+) \neq V(t_k^-)$. By virtue of the properties of the positive definite matrices, there exist $P^{\frac{1}{2}} > 0$ such that $P = P^{\frac{1}{2}}P^{\frac{1}{2}}$, applying (9), we obtain

$$\begin{aligned} V(t_k^+) &= \parallel P^{1/2}\tilde{x}(t_k^+) \parallel^2 = \parallel P^{1/2}T_{i_k,i_{k+1}}\tilde{x}(t_k^-) \parallel^2 \\ &\leq \parallel P^{1/2}T_{i_k,i_{k+1}}P^{-1/2} \parallel^2 \parallel P^{1/2}\tilde{x}(t_k^-) \parallel^2 \\ &\leq \parallel P^{1/2}T_{i_k,i_{k+1}}P^{-1/2} \parallel^2 V(t_k^-) \\ &\leq \mu V(t_k^-). \end{aligned}$$

Based on the above inequalities, we have

$$V(t_{k+1}^+) \leq \mu \exp(-\lambda_0(t_{k+1}-t_k))V(t_k^+). \tag{15}$$

Repeating the inequality (15) from $k=0$ to $k=N_\sigma - 1$ yields

$$V(t^-) \leq V(t_{N_\sigma}) \leq \mu^{N_{\sigma(t)}} \exp(-\lambda_0 t)V(0).$$

According to $N_\sigma(T,t) \leq N_0 + \frac{T-t}{\tau_a}$, we get $V(t^-) \leq \mu^{N_0} \exp\left(t\left(\frac{\ln\mu}{\tau_a} - \lambda_0 t\right)\right)V(0)$. Then, the system (4) without the disturbance input is asymptotically stable under the average dwell time (10). Meanwhile, we get

$$\lim_{t\to\infty}(C_{\sigma(t)}x + Q_{\sigma(t)}w) = \lim_{t\to\infty} C_{\sigma(t)}\tilde{x} = 0.$$

Therefore, we can conclude that the output regulation problem is solved.

**Remark 2.** Note that, each group of regulation equations (7) has their own solution for each subsystem, which leads to the switched system has different coordinate transformations. The above Theorem solves the problem of different transformations for the switched linear systems.

Next, we give another sufficient condition for the problem to be solvable via error feedback.

**Theorem 2.** If there exist $\Pi_i, \Sigma_i, H_i,\ F_i\ \bar{T}_{i,j}$ for $\forall i, j \in I_N$, satisfying the following equations

$$\begin{aligned} &\Pi_i S = A_i\Pi_i + B_iH_i\Sigma_i + P_i, \\ &\Sigma_i S = F_i\Sigma_i, \\ &0 = C_i\Pi_i + Q_i, \end{aligned} \tag{16}$$

and the system (1) with different coordinate transformations

$$\begin{aligned} &\tilde{\chi}(t_k^-) = \chi(t_k^-) - \bar{\Pi}_{i_k}\omega(t_k^-), \\ &\tilde{\chi}(t_k^+) = \chi(t_k^-) - \bar{\Pi}_{i_{k+1}}\omega(t_k^-), \end{aligned} \tag{17}$$

and

$$\chi(t_k^-) - \bar{\Pi}_{i_k}\omega(t_k^-) = \bar{T}_{i,j}(\chi(t_k^-) - \bar{\Pi}_{i_{k+1}}\omega(t_k^-)), \tag{18}$$

where

$$\tilde{\chi} = \left(\begin{array}{c} x - \Pi_i\omega \\ \xi - \Sigma_i\omega \end{array}\right), \chi = \left(\begin{array}{c} x \\ \xi \end{array}\right), \bar{\Pi}_i = \left(\begin{array}{c} \Pi_i \\ \Sigma_i \end{array}\right),$$

then under the average dwell time

$$\tau_a > \tfrac{ln\mu}{\lambda_0}, \tag{19}$$

where

$$\mu = \sup_{1\leq i,j\leq N} \parallel P^{1/2}\bar{T}_{i,j}P^{1/2} \parallel, \lambda_0 = \inf_{1\leq i\leq N} \tfrac{\lambda_{\min}(Q_i\prime)}{\lambda_{\max}(P)}, \tag{20}$$

and

$$\bar{A}_i^T P + P\bar{A}_i = -Q_i\prime, \tag{21}$$

the error feedback controllers (5) solve the problem of output regulation for the switched system (6), where $\bar{A}_i = \left(\begin{array}{cc} A_i & B_iH_i \\ G_iC_i & F_i \end{array}\right)$.

*Proof.* Based on (16), we can rewrite the regulation equations as follows

$$\begin{aligned} &\bar{\Pi}_i S = \bar{A}_i\bar{\Pi}_i + \bar{P}_i, \\ &0 = \bar{C}_i\bar{\Pi}_i + Q_i, \end{aligned} \tag{22}$$

where

$$\bar{P}_i = \left(\begin{array}{c} P_i \\ G_iQ_i \end{array}\right), \bar{C}_i = \left[\begin{array}{cc} C_i & 0 \end{array}\right].$$

Consider the transformations

$$\tilde{\chi} = \chi - \bar{\Pi}_i\omega.$$

According to (22), the system (6) is rewritten as

$$\begin{aligned} &\dot{\tilde{\chi}} = \bar{A}_{\sigma(t)}\tilde{\chi}, \\ &\dot{w} = Sw, \\ &e = \bar{C}_{\sigma(t)}\tilde{\chi}. \end{aligned} \tag{23}$$

For the switched linear system (23), we choose the Lyapunov function as follows

$$V(t) = \tilde{\chi}^T(t)P\tilde{\chi}(t).$$

Similar to the proof of Theorem 1, we can show that the problem of output regulation for the switched linear (6) is solved under the switching law (20).

## II. Conclusion

In this paper, the output regulation problem for switched linear systems is investigated. The problem is difficult for switched systems, therefore, the results are few. The different coordinate transformations for switched systems is always a complicated issue. Because once the coordinate transformation is different, the Lyapunov function is discontinuous, and the decreasing of the Lyapunov function is difficult to verify. For switched linear systems, the problem can be solved by common coordinate transformation, but the conservativeness is always relatively large.

In this work, we address the output regulation problem with the transformations of switching instant between the consecutive time satisfying a relational expressions, based on this relation, we solve the output regulation problem. We easily know that when the disturbance and the state of the switched systems are linearly dependent, the relational expressions given in this paper is automatically satisfied. By virtue of this, we can get that the conditions are easy to implement.

The main contribution in this paper is that the output regulation problem for the switched linear systems with different coordinate transformations is considered. Sufficient conditions for the problem to be solvable are given based on the average dwell time method. For the regulation equations of the switched linear system, we suppose that each subsystem has its own solution, which reduce the conservativeness.

Output regulation for switched systems is a complicated and important problem. Further, studying a robust output regulation problem for switched linear systems and switched nonlinear systems is another task for future work.

*Abstract*— **In this paper, we address the issue of the state tracking control for model reference adaptive control systems. For a given plant with a known structure and unknown parameters, this problem can be solved by designing an adaptive law for traditional model reference adaptive control designs. In this paper, for a plant with finite fixed adaptive laws where none of them guarantees the states of plant track those of the reference model, there are not allowed to design other adaptive law. In this case, we formulate a switching mechanism between these adaptive laws to track the reference model. A sufficient condition is given for the problem to be solvable via the convex combination technique, and a switching law is designed. The theoretical derivations are illustrated by means of an example.**

***Keywords- MRAC; adaptive control; switching law; state tracking; convex combination***

## I. INTRODUCTION

Model reference adaptive control (MRAC) is one of the main approaches in adaptive control. For MRAC, an adaptive controller, which has adjustable parameters and the same structure as the ideal controller, is usually given first. Then, an adaptive law is designed to adjust the parameters of the controller such that it can approach the ideal one to realize the state tracking. Differing from conventional non-adaptive controllers, the adaptive mechanism can improve steady accuracy and transient performance when the parameters of the system are unknown[1]. Several adaptive law design methods, including Lyapunov theory[2, 3], hyperstability theory[4, 5] and dissipative theory[6, 7], ensure that the boundedness of all the signals and state error asymptotically approaching zero

In general, the adaptive law need to be redesigned once the system changes. However, in practice, owing to the restrictions of hardwires and environment, it is difficult to redesign or modify the adaptive law when it is in use in the system. On the other hand, a single adaptive law, though works theoretically, is sometimes too complicated to implement in reality. In both cases, it is necessary to use multiple pre-given fixed adaptive laws to achieve state tracking.

The switched control strategy is very important. This is mainly due to the following reasons. Firstly, in some cases, a single controller (continuous or discrete) in a conventional control system is usually too complicated for sensors and actuators to realize. Secondly, a switched controller may stabilize the system when none of the controllers can stabilize the system alone [8-10]. At present, as a kind of hybrid control, the switched control strategy has been applied to automatic vehicles [11, 12], robot manipulators [13] and traffic system[14, 15], etc.

For adaptive control systems, the problem of stability with rapid variation of parameters can be solved by a switching strategy. At present, switched adaptive control is mainly focused on the multiple models adaptive control in which the transient performance is enhanced by a switching strategy of multiple adaptive controllers with different initial values. Though the system is non-switched, the closed-loop system of multiple model adaptive control is a switched system[16-19] . Another newly-arisen issue in switching adaptive control is the adaptive control problem of a switched system in which individual adaptive controllers are designed for the subsystems[20-23]. In these issues, a single adaptive controller is effective if the switching signal is fixed. How to design a switching law for given ineffective adaptive controllers to stabilize the error system, to the best of the authors' knowledge, has not been addressed in the existing literatures, which partly motivates our present work.

This paper studies the state asymptotically tracking problem of MRAC. For a system with finite fixed adaptive laws, none of which can guarantee state tracking, a sufficient condition is given to design a switching law between these adaptive laws via the convex combination

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

technique. State tracking is achieved for the closed-loop system.

The result of this paper has two features. First, unlike conventional MRAC adaptive law design, we design a switching law that orchestrates finite fixed adaptive laws to solve the state tracking problem. Additionally, the proposed method can deal with the case where the adaptive law must be designed with new system, which enlarges the applicability of adaptive control theory.

The rest of this paper is organized as follows. The state tracking MRAC problem is formulated in section II. In Section III, a switching strategy is proposed for the adaptive laws to solve the state tracking problem. Section IV gives a simulation to show the effectiveness of the proposed approach and Section V concludes the paper.

## II. Problem Statement

Consider a system

$$\dot{x}(t) = A(t)x(t) + B(t)u(t), \tag{1}$$

where $A(t) \in R^{n\times n}$ and $B(t) \in R^{n\times m}$ are the system matrix and input matrix, respectively, both of which have known structure and unknown parameters; $x(t) \in R^{n}$ is the system state; and $u(t) \in R^{m}$ is the control input.

The control objective is that the state $x(t)$ of the system (1) tracks the state $x_m(t) \in R^n$ of a reference model specified by the LTI system

$$\dot{x}_m(t) = A_m x_m(t) + B_m r(t), \tag{2}$$

where $A_m \in R^{n\times n}$ is a constant Hurwitz matrix, $B_m(t) \in R^{n\times m}$ is a constant input matrix, $x_m(t)$ is the system state of the reference model, and $r(t) \in R^m$ is the bounded reference input. The reference model and the input $r$ are chosen so that $x_m(t)$ represents a desired trajectory that $x(t)$ has to follow.

In order to achieve state tracking, we introduce a state error vector

$$e = x_m - x. \tag{3}$$

However, as well-understood, the parameters of the system (1) are difficult to be adjusted directly. In order to solve the state tracking problem, we introduce an adjustable feedback compensation matrix $F(t) \in R^{m\times n}$ and an adjustable feedforward gain matrix $K(t) \in R^{m\times m}$. Thus we apply a control law as follows

$$u = K(t)r + F(t)x. \tag{4}$$

Combining (4) with (1), we get the closed-loop system

$$\dot{x} = [A(t) + B(t)F(t)]x + B(t)K(t)r. \tag{5}$$

Furthermore, from (3) and (5), we can get the dynamical equation of the state error for the closed-loop system

$$\dot{e} = A_m e + [A_m - A(t) - B(t)F(t)]x + [B_m - B(t)K(t)]r. \tag{6}$$

When the dynamic response of system (6) is identical to that of the reference model (2) under the input $r(t)$, the system (1) is matched with reference model (2), that is,

$$\begin{aligned} A_m &= A(t) + B(t)F^*, \\ B_m &= B(t)K^*, \end{aligned} \tag{7}$$

where $F^*, K^*$ denote the ideal values of $F(t), K(t)$ when the system matches with the reference model, and $F(t)$, $K(t)$ are the estimate of $F^*(t)$, $K^*(t)$, respectively.

In conventional MRAC system, the adaptive law is expressed as [24]

$$\begin{aligned} \dot{F} &= R_F^{-1}(B_m K^{*-1})^T Pex^T, \\ \dot{K} &= R_K^{-1}(B_m K^{*-1})^T Per^T, \end{aligned} \tag{8}$$

where $R_F, R_K$ and $P$ are the positive definite symmetric matrices.

Then, for the closed-loop system, the dynamical equation of the state error is given by

$$\dot{e} = A_m e + B_m K^{*-1}\tilde{F}x + B_m K^{*-1}\tilde{K}r, \tag{9}$$

where $\tilde{F} = F^* - F$ and $\tilde{K} = K^* - K$ are the parameter errors.

The following problem is considered in this paper. Several fixed adaptive laws are offered and none of them satisfies the matching condition (7), meanwhile, it is not allowed to design any other adaptive law. How to design a switching law between these adaptive laws to achieve state tracking, that is, the adaptive laws are given by

$$\begin{aligned} \dot{F}(t) &= \Gamma_i ex^T, \\ \dot{K}(t) &= \Phi_i er^T, \end{aligned} \quad i = 1, 2, ..., N, \tag{10}$$

where $\Gamma_i \in R^{m\times n}$ and $\Phi_i \in R^{m\times n}$ are the adaptive adjustable matrices, but none of them satisfies the matching condition (7). Again, the parameter error are $\tilde{F} = F^* - F$ and $\tilde{K} = K^* - K$ with $F$ and $K$ given by the $i$-th adaptive (10). In order to make the state of the closed-loop system (5) track the state of the reference model (2), that is $e \to 0$, $t \to \infty$, we design the switching law for the error system (9) and (10).

## III. Main Result

In this section, we will design a switching law for the adaptive laws by means of the convex combination technology.

*Theorem 1.* If there exist scalars $\alpha_i \in (0,1), (i = 1, \cdots N)$ satisfying $\sum_{i=1}^{N} \alpha_i = 1$ and some positive definite symmetric matrices $R_F, R_K$ and $P$ satisfying

$$\begin{aligned} &\sum_{i=1}^{N} \alpha_i \Gamma_i = -R_F^{-1}(B_m K^{*-1})^T P, \\ &\sum_{i=1}^{N} \alpha_i \Phi_i = -R_K^{-1}(B_m K^{*-1})^T P. \end{aligned} \tag{11}$$

Then, there exists a switching law such that the adaptive controllers (4) and (10) make the state $x(t)$ of the closed-loop system (1) asymptotically track the state $x_m(t)$ of a reference model (2).

*Proof.* Based on the error system (9) and (10), we construct the combined error system

$$\begin{aligned} &\dot{e} = A_m e + B_m K^{*-1} \tilde{F} x + B_m K^{*-1} \tilde{K} r, \\ &\dot{F} = \sum_{i=1}^{N} (\alpha_i \Gamma_i e x^T), \\ &\dot{K} = \sum_{i=1}^{N} (\alpha_i \Phi_i e r^T), \end{aligned} \tag{12}$$

where (12) is the convex combination of the adaptive control law (10).

Consider the following Lyapunov function candidate

$$V = \frac{1}{2}[e^T P e + tr(\tilde{F}^T R_F \tilde{F} + \tilde{K}^T R_K \tilde{K})]. \tag{13}$$

The time derivative of the Lyapunov function (13) along the trajectory of the combined error system (12) is

$$\begin{aligned} \dot{V} &= \frac{1}{2}\Big\{\dot{e}^T P e + e^T P \dot{e} \\ &+ tr[\sum_{i=1}^{N} (\alpha_i \Gamma_i e x^T)^T R_F \tilde{F} + \tilde{F}^T R_F \sum_{i=1}^{N} (\alpha_i \Gamma_i e x^T) \\ &+ \sum_{i=1}^{N} (\alpha_i \Phi_i e r^T)^T R_K \tilde{K} + \tilde{K}^T R_K \sum_{i=1}^{N} (\alpha_i \Phi_i e r^T)]\Big\} \\ &= \frac{1}{2}[e^T (P A_m + A_m^T P) e] + e^T P B_m K^{*-1} \tilde{F} x + e^T P B_m K^{*-1} \tilde{K} r \\ &+ \frac{1}{2} tr[\sum_{i=1}^{N} (\alpha_i \Gamma_i e x^T)^T R_F \tilde{F} + \tilde{F}^T R_F \sum_{i=1}^{N} (\alpha_i \Gamma_i e x^T) \\ &+ \sum_{i=1}^{N} (\alpha_i \Phi_i e r^T)^T R_K \tilde{K} + \tilde{K}^T R_K \sum_{i=1}^{N} (\alpha_i \Phi_i e r^T)]. \end{aligned} \tag{14}$$

With the help of

$$\begin{aligned} &e^T P B_m K^{*-1} \tilde{F} x = tr(x e^T P B_m K^{*-1} \tilde{F}), \\ &e^T P B_m K^{*-1} \tilde{K} r = tr(r e^T P B_m K^{*-1} \tilde{K}), \end{aligned} \tag{15}$$

(14) can be rewritten as

$$\begin{aligned} \dot{V} &= \frac{1}{2}[e^T (P A_m + A_m^T P) e] \\ &+ tr[\sum_{i=1}^{N} (\alpha_i \Gamma_i e x^T)^T R_F \tilde{F} + x e^T P B_m K^{*-1} \tilde{F}] \\ &+ tr[\sum_{i=1}^{N} (\alpha_i \Phi_i e r^T)^T R_K \tilde{K} + r e^T P B_m K^{*-1} \tilde{K}] \\ &= \frac{1}{2}[\sum_{i=1}^{N} \alpha_i e^T (P A_m + A_m^T P) e] \\ &+ tr[\sum_{i=1}^{N} (\alpha_i \Gamma_i e x^T)^T R_F \tilde{F} + x e^T P B_m K^{*-1} \tilde{F}] \\ &+ tr[\sum_{i=1}^{N} (\alpha_i \Phi_i e r^T)^T R_K \tilde{K} + r e^T P B_m K^{*-1} \tilde{K}]. \end{aligned} \tag{16}$$

According to (11), for the combined error system (12), we get $\dot{V} < 0$ ,that is,

$$\begin{aligned} \dot{V} &= \sum_{i=1}^{N} \alpha_i \{\frac{1}{2}[e^T (P A_m + A_m^T P) e] \\ &+ tr\left[(\Gamma_i e x^T)^T R_F \tilde{F} + x e^T P B_m K^{*-1} \tilde{F}\right] \\ &+ tr[(\Phi_i e r^T)^T R_K \tilde{K} + r e^T P B_m K^{*-1} \tilde{K}]\} \\ &< 0. \end{aligned} \tag{17}$$

Because $\alpha_i > 0$ and $\sum_{i=1}^{N} \alpha_i = 1$, there exists $l \in N$ at least for (17) such that

$$\begin{aligned} &\frac{1}{2}[e^T (P A_m + A_m^T P) e] \\ &+ tr\left[(\Gamma_l e x^T)^T R_F \tilde{F} + x e^T P B_m K^{*-1} \tilde{F}\right] \\ &+ tr[(\Phi_l e r^T)^T R_K \tilde{K} + r e^T P B_m K^{*-1} \tilde{K}] \\ &< 0. \end{aligned} \tag{18}$$

Now, we turn to the error system (9) and (10).

Consider the following Lyapunov function candidate

$$V = \frac{1}{2}[e^T P e + tr(\tilde{F}^T R_F \tilde{F} + \tilde{K}^T R_K \tilde{K})]. \tag{19}$$

When the $j$ -th adaptive control law is active, the time derivative of the Lyapunov function (19) along the trajectory of the error system (9) and (10) is

$$\begin{aligned} \dot{V} &= \frac{1}{2}[e^T (P A_m + A_m^T P) e] \\ &+ tr\left[(\Gamma_j e x^T)^T R_F \tilde{F} + x e^T P B_m K^{*-1} \tilde{F}\right] \\ &+ tr[(\Phi_j e r^T)^T R_K \tilde{K} + r e^T P B_m K^{*-1} \tilde{K}]. \end{aligned} \tag{20}$$

Therefore, for the error system (9) and (10), the switching law can be designed as

$$\begin{aligned}\sigma(e,t) = \arg\min_i\{&\frac{1}{2}[e^T(PA_m + A_m^T P)e]\\ &+tr[(\Gamma_i ex^T)^T R_F \tilde{F} + xe^T PB_m K^{*-1}\tilde{F}] \\ &+tr[(\Phi_i er^T)^T R_K \tilde{K} + re^T PB_m K^{*-1}\tilde{K}]\}.\end{aligned} \qquad (21)$$

Owing to (18) and (21), adaptive laws (10) is orchestrated so that $V$ decreases along the solutions of the error system (9) and (10). Then, the state $x(t)$ of the system (1) asymptotically track the state $x_m(t)$ of the reference model (2) with the given controller (4) and (10).

*Remark 1.* For the given adaptive law (10), if there exists $h \in N$, such that the $h$-th adaptive control law satisfying (8), the state tracking problem can be solved by the $h$-th adaptive control law. In this case, we choose $\alpha_h = 1$, $\alpha_i = 0,\ i \neq h,$ therefore, Theorem 1 contains the result of [24] as a special case.

*Remark 2.* In the case of $N = 1$, the issue is degenerated into the design of a single controller.

*Remark 3.* The switching law is designed when $\tilde{F}$ and $\tilde{K}$ are available. If $\tilde{F}$ and $\tilde{K}$ they are unavailable, an estimator can be used instead[25] .

## IV. EXAMPLE

In order to show the effectiveness of the proposed switching adaptive controllers, we consider an example.

Consider the following system

$$\dot{x} = \begin{pmatrix} 0 & 1 \\ -6 & -7 \end{pmatrix} x + \begin{pmatrix} 0 \\ 8 \end{pmatrix} u.$$

The reference model is given by

$$\dot{x}_m = \begin{pmatrix} 0 & 1 \\ -10 & -5 \end{pmatrix} x_m + \begin{pmatrix} 0 \\ 2 \end{pmatrix} r.$$

We compare the simulation results of the system under two given adaptive laws none of which satisfies the state tracking respectively to those under the designed switching law.

For controller (4), there are two adaptive laws as follows

$$\left.\begin{aligned}\dot{F}(t) &= \Gamma_i ex^T, \\ \dot{K}(t) &= \Phi_i er^T,\end{aligned}\right. \quad i = 1,2, \qquad (22)$$

where

$$\Gamma_1 = [49.4 \quad 49.4], \Phi_1 = [4 \quad 4],$$

$$\Gamma_2 = [0.15 \quad 0.15], \Phi_2 = [1.5 \quad 1.5].$$

Simulations are performed for these adaptive laws, respectively.

For $B_m = B(t)K^*$, we have

$$B(t) = B_m K^{*-1} = \begin{pmatrix} 0 \\ 8 \end{pmatrix}.$$

Choose $N = 2, P = \begin{pmatrix} 3 & 1 \\ 1 & 1 \end{pmatrix}.$

The parameter errors and the state error are shown in Figure 1 and Figure 2.

Obviously, Figure 1 and Figure 2 show that none of these adaptive laws makes the parameter errors and the state error convergent.

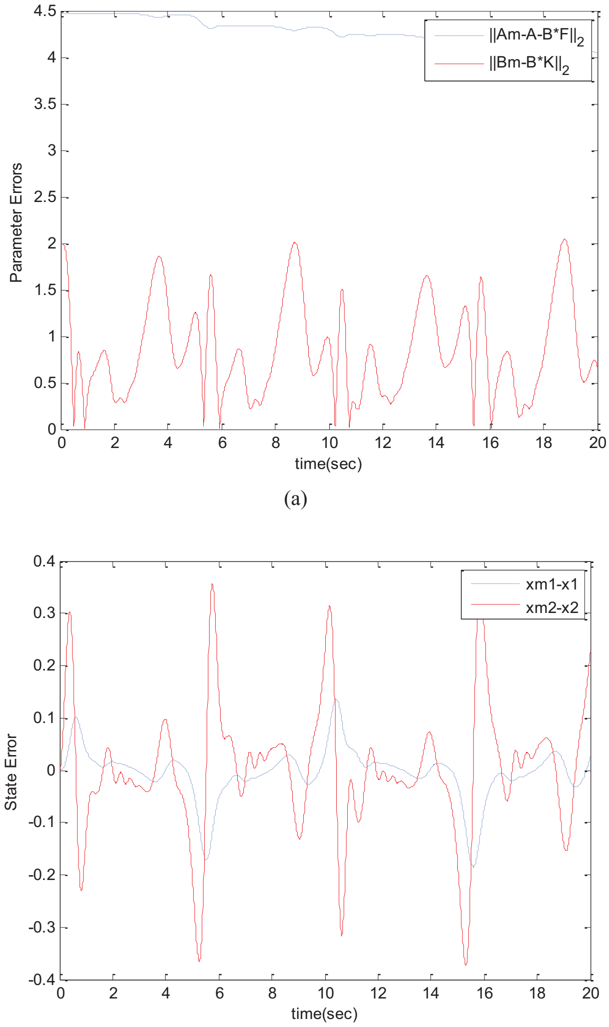
(a): The parameter errors. (b): The state error



(a)

(b)

Figure 2. The simulation result ( $i = 2$ ).

(a): The parameter errors. (b): The state error

In order to achieve the objective, we will design a switching law by Theorem 1

With the help of (4) and (22), we obtain switching adaptive laws

$$\begin{aligned}\dot{F}(t) &= \Gamma_\sigma e x^T, \\ \dot{K}(t) &= \Phi_\sigma e r^T,\end{aligned} \quad \sigma = 1, 2,$$

where the switching law $\sigma$ is chosen by (21) as Figure 3.

Here, we choose $\alpha_1 = 0.2$, $\alpha_2 = 0.8$, $R_F = 1.25$, $R_K = 0.25$, such that (11) hold. From Figure 4, it is easy to see that the parameter errors and the state error are convergent under the switching law. Then, state tracking is achieved.

## V. Conclusions

We have studied the state asymptotically tracking control problem for model reference adaptive control systems. For a system with several fixed adaptive laws, a sufficient condition has been developed to solve the state tracking problem via the convex combination technique by designing the controller switching strategy. A simulation example has been given to show the effectiveness of the proposed method.

# An Adaptive Observer-based parameter estimation algorithm with application to Road Gradient and Vehicle's Mass Estimation

Muhammad Nasiruddin Mahyuddin*, Jing Na**, Guido Herrmann***, Xuemei Ren**** and Phil Barber*****

***Abstract*—A novel observer-based parameter estimation algorithm with sliding mode term has been developed to estimate the road gradient and vehicle weight using only the vehicle's velocity and the driving torque from the engine. The estimation algorithm exploits all known terms in the system dynamics and a low pass filtered representation to derive an explicit expression of the parameter estimation error without measuring the acceleration. The proposed algorithm which features a sliding-mode term to ensure the fast and robust convergence of the estimation in the presence of persistent excitation is augmented to an adaptive observer and analyzed using Lyapunov Theory. The analytical results show that the algorithm is stable and ensures finite-time error convergence to a bounded error even in the presence of disturbances. A simple practical method for validating persistent excitation is provided using the new theoretical approach to estimation. This is validated by the practical implementation of the algorithm on a small-scaled vehicle, emulating a car system. The slope gradient as well as the vehicle's mass/weight are estimated online. The algorithm shows a significant improvement over a previous result.**

## I. INTRODUCTION

In the automotive industry, reliable online vehicle parameter estimation is important to reduce emissions, improve fuel efficiency and enhance the safety of the vehicle. The vehicle's mass and the road grade are two parameters that largely influence a vehicles performance. This is particularly true for heavy duty vehicles where the loadings due to the mass and the grade can be significant [1]. The road gradient and mass estimation provides useful information to a vehicle in improving the transmission shift scheduling and vehicle longitudinal control, including cruise control, hill holding and traction control [2].

Having road inclination measured by a dedicated sensor such as an inclinometer may be inaccurate. Inclinometers are in fact accelerometers which can distort road gradient measurement due to its susceptibility to noise in dynamic conditions of a vehicle [3]. Therefore, the road grade should be accurately estimated [4-7]. It is evident that the transmission control unit and the anti-lock brake system can benefit from mass and road gradient estimates [7]. To address this issue, there has been significant interest in the estimation of the road gradient and vehicle mass [2-9]. Some of these results were developed based on on-board sensors and the use of sensor/data fusion methods. For instance, in [1], a GPS or barometer sensor is utilized in addition to torque and velocity sensors to obtain absolute road height information, while Barrho, et al. in [9] require accurate information of the vehicle mass which is not always possible. In recent work by [10], [11] and [12], low-cost sensors were placed in the vehicle to estimate the road grade ahead. In [13], the vehicle's mass in addition to vehicle speed and torque information is required. Bae et al. [4] suggest a recursive least squares approach which essentially requires acceleration information and then assumes the existence of sufficient data points to solve for the missing parameters, i.e. vehicle mass and gradient, by inverting a regressor matrix in a batch process. Similarly, the work in [7] and [2] estimate the road grade using the position, velocity and driving torque or force signal. In [8], a combination of an observer is suggested which provides for known mass the exact estimation of the road gradient. In all of the aforementioned approaches, however, some of the required information, e.g. acceleration, mass and vehicle's current location through GPS, may not be readily available. Although most of the approaches show good results, the convergence speed and complexity may cast some problems.

In this paper, we revisit the online road gradient and mass estimation of vehicular systems using only the vehicle's velocity and the driving torque. This is achieved based on a novel adaptive nonlinear observer design. Compared to previous results (e.g. [14]) concerning the parameter estimation, some appropriate information of the parameter error is derived, and then incorporated into the parameter adaptation for the observer design. In our work, the parameter estimation scheme uses a filtered regressor matrix. Measurable system states, a regressor vector and the known dynamics are collected and filtered to form auxiliary variables. Moreover, vehicle acceleration is not required in our estimation algorithm. Owed to the special feature of a sliding mode term, the adaptation algorithm guarantees robust finite-time convergence to a compact set, provided that there is a Persistent Excitation (PE) condition fulfilled so that the regressor matrix remains positive definite. In contrast to [15], our scheme calculates the inverse of the filtered and integrated regressor matrix without prior invertibility checking of the matrix and direct matrix inverse computation. The parameter error information can be explicitly formulated by virtue of the filtered auxiliary variables. The possible instability and infinite growth found in [15] due to the existence of an unstable integrator (as a result of auxiliary matrix and vector) are prevented in this paper. We also show robustness of our adaptive scheme and *we can verify* the PE condition in a straightforward and practical manner. The proposed method is verified experimentally in a reduced-scale vehicular system, which provide a significant improvement over a previous algorithm.

## II. SYSTEM FORMULATIONS

Consider a nonlinear system of the following structure:

$$\dot{x} = Ax + B_1 u_1 + B_2 f(x, u_2) + \zeta, \quad y = Cx \tag{1}$$

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

where $A \in \mathbb{R}^{n\times n}$ is the known system matrix, $B_1 \in \mathbb{R}^{n\times m_1}$ and $B_2 \in \mathbb{R}^{n\times m_2}$ are known input matrices, $u_1 \in \mathbb{R}^{m_1}$ and $u_2 \in \mathbb{R}^{\bar{m}_2}$ are known inputs, whilst $C \in \mathbb{R}^{p\times n}$ is the corresponding output matrix and $\zeta \in L_\infty$ is bounded disturbance. The function $f(x, u_2) : \mathbb{R}^n \times \mathbb{R}^{\bar{m}_2} \to \mathbb{R}^{m_2}$ is partially unknown for which the detail will be outlined below and the pair $(A, B_1)$ is controllable. It is assumed that $p \geq m_2$. The following assumptions are made:

**Assumption 1** $(C, A, B_2)$ is minimum phase and $(CB_2)$ is full rank.

**Assumption 2** The function $f(x, u_2)$ can be represented in a linear parameterized form: $f(x, u_2) = \varphi(x, u_2)\Theta$, where $\varphi : \mathbb{R}^n \times \mathbb{R}^{m_2} \to \mathbb{R}^{m_2\times l}$ is a known Lipschitz continuous function, while $\Theta = const., \Theta \in \mathbb{R}^l$ is an unknown parameter vector which is to be estimated.

**Assumption 3** The signals $x$, $u_1$ and $u_2$ are measurable and bounded.

Assumption 3 is a common assumption for observer design and can be easily achieved by suitable choice of the control signal $u_1$ (e.g. [15] [17]).

Under these conditions, the system is assumed to take the following structure

$$\begin{aligned} \begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{bmatrix} &= \begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + \\ & \begin{bmatrix} B_{11} \\ B_{12} \end{bmatrix} u_1 + \begin{bmatrix} 0 \\ \bar{B}_2 \end{bmatrix} \varphi\Theta + \begin{bmatrix} \zeta_1 \\ \zeta_2 \end{bmatrix} \\ y &= [0 \quad I] \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} \end{aligned} \tag{2}$$

where $\bar{B}_2 \in \mathbb{R}^{p\times m_2}$, $I \in \mathbb{R}^{p\times p}$ and $x_2 = Cx$. Note that this reformulation is always possible from Assumptions 1 and 3 using Proposition 6.3 in [17]. Moreover, we make the following assumption.

**Assumption 4** $A_{21} = 0$, the second state equation in 2 is decoupled.

Assumption 4 is possibly a strong assumption but it will fit the generic practical system structures (e.g. vehicular) investigated in this paper.

## III. Adaptive Observer Design

We will design an adaptive observer to estimate the state vectors which will be suitably combined with a novel parameter estimation algorithm. The adaptive observer takes the following form:

$$\dot{\hat{x}} = A\hat{x} + B_1u_1 + B_2\varphi\hat{\Theta} + L(y - C\hat{x}) \tag{3}$$

where $\hat{x}$ is the estimated state vector, $\hat{\Theta}$ is the estimated parameter vector. $L$ is the observer gain matrix such that $A_c = A - LC$ is a stable matrix and there exist, according to Proposition 6.3 in [17], positive definite matrices, $P$ and $Q$ so that,

$$A_c^T P + PA_c = -Q, \quad P = \begin{bmatrix} P_1 & 0 \\ 0 & P_2 \end{bmatrix} > 0 \tag{4}$$

$$Q = \begin{bmatrix} Q_1 & Q_{12} \\ Q_{12}^T & Q_2 \end{bmatrix} > 0, \quad PB_2 = C^T F^T \tag{5}$$

and $F \in \mathbb{R}^{m_2\times p}$ is a positive definite matrix. From (4), it follows,

$$\begin{bmatrix} A_{c11}^T P_1 + P_1A_{c11} & P_1A_{c12} \\ A_{c12}^T P_1 & P_2A_{c22} + A_{c22}^T P_2 \end{bmatrix} = -Q \tag{6}$$

Let $\tilde{x} = x - \hat{x}$ and $\tilde{\Theta} = \Theta - \hat{\Theta}$. We can then use (1) and (3) to define the error dynamics $\tilde{x} = x - \hat{x}$ as

$$\begin{aligned} \dot{\tilde{x}} &= (A - LC)\tilde{x} + B_2\varphi\tilde{\Theta} + \zeta \\ &= A_c\tilde{x} + B_2\varphi\tilde{\Theta} + \zeta \end{aligned} \tag{7}$$

where $\tilde{\Theta} = \Theta - \hat{\Theta}$ is the estimated parameter error vector.

In the next section, the adaptive laws that will update the estimated parameter vector, $\hat{\Theta}$ will be developed.

## IV. Adaptive Law Formulation

In this section, we shall define the adaptive law for our parameter estimator.

### A. Filter design

From (2), the second state equation can be expressed as,

$$\dot{x}_2 = (A_{22}x_2 + B_{12}u_1) + \bar{B}_2\varphi\Theta + \zeta_2 \tag{8}$$

Let,

$$\psi = A_{22}x_2 + B_{12}u_1, \quad \phi = \bar{B}_2\varphi \tag{9}$$

then, the following filtered variables can be defined as,

$$\begin{aligned} k\dot{x}_{2f} + x_{2f} &= x_2, \quad x_{2f}(0) = 0 \\ k\dot{\psi}_f + \psi_f &= \psi, \quad \psi_f(0) = 0 \\ k\dot{\phi}_f + \phi_f &= \phi, \quad \phi_f(0) = 0 \end{aligned} \tag{10}$$

In addition, we may introduce an auxiliary filter for the bounded disturbance (which is only used for analysis),

$$k\dot{\zeta}_{2f} + \zeta_{2f} = \zeta_2, \quad \zeta_{2f}(0) = 0 \tag{11}$$

i.e. $\zeta_{2f} \in L_\infty$. Consequently, we can obtain from (8) and (10) that,

$$\dot{x}_{2f} = \frac{x_2 - x_{2f}}{k}, \qquad \frac{x_2 - x_{2f}}{k} - \psi_f = \phi_f\Theta + \zeta_{2f} \tag{12}$$

### B. Auxillary integrated regressor matrix and vector

The filtered variables introduced above will be used in the definition of a filtered regressor matrix, $M(t)$, and a vector, $N(t)$ as,

$$\dot{M}(t) = -k_{FF}M(t) + k_{FF}\phi_f^T(t)\phi_f(t), M(0) = 0 \tag{13}$$

$$\dot{N}(t) = -k_{FF}N(t) + k_{FF}\phi_f^T(t)\left(\tfrac{x_2 - x_{2f}}{k} - \psi_f\right), \tag{14}$$

where, $k_{FF} \in \mathbb{R}^+$, can be implemented as a forgetting factor and the initial condition of $N(t)$ is $N(0) = 0$. Note that (14) is equivalent to:

$$\dot{N}(t) = -k_{FF}N(t) + k_{FF}\phi_f^T(t)(\phi_f(t)\Theta + \zeta_{2f}) \tag{15}$$

Consequently, we can find the solution to (13), (14) and (19),

$$\begin{aligned} M(t) &= \textstyle\int_0^t e^{-k_{FF}(t-r)} k_{FF}\phi_f^T(r)\phi_f(r)dr \\ N(t) &= \textstyle\int_0^t e^{-k_{FF}(t-r)} k_{FF}\phi_f^T(r)\left(\tfrac{x_2 - x_{2f}}{k} - \psi_f\right)dr \end{aligned} \tag{16}$$

and

$$N(t) = M(t)\Theta + \zeta_{2N} \tag{17}$$

where $\zeta_{2N} = \int_0^t e^{-k_{FF}(t-r)} k_{FF}\phi_f^T(r)\zeta_{2f}dr$. Note that $\phi$ is bounded since it is Lipschitz continuous and $x, u_2$ are bounded (Assumption 1). Thus, $\phi_f$ is bounded. Since $\zeta_{2f} \in L_\infty$, it follows that $N(t), M(t)$ and $\zeta_{2N}$ are bounded.

*Lemma 1: The auxiliary regressor matrix $M(t) \in \mathbb{R}^{l\times l}$ is positive definite, $M(t) > 0$, if and only if $\int_0^t \phi_f^T \phi_f > 0$.* •

*Proof :* It can be easily shown that

$$\int_T^t \phi_f^T(r)\phi_f(r)dr \geq \int_T^t e^{-k_{FF}(t-r)}\phi_f^T(r)\phi_f(r)dr \tag{18}$$
$$\geq e^{-k_{FF}t}\int_T^t \phi_f^T(r)\phi_f(r)dr$$

when $T < t$. For $T = 0$, the claim follows. ■

Thus, if $\phi_f$ is persistently excited, $M(t) > 0$ is positive definite. Clearly, if $\phi$ is persistently excited, then $\phi_f$ is also persistently excited and $M(t) > 0$ [22], [20] (as derived from the linear system (10) and definition (9)). Thus, if $\phi$ is persistently excited then $M(t) > 0$ and $\int_T^t \phi_f^T\phi_f > 0$. In this paper, it is important to achieve $M(t) > 0$ for our adaptation algorithm to work. This can be achieved through persistent excitation of $\phi$:

*Remark 1: The Persistent Excitation (PE) condition for the regressor $\phi$ can be achieved in the experiment through an appropriate control signal, $u$. For instance, the control signal can be augmented by a noise signal or the controller can introduce for the system states, $x$, a tracking demand which achieves 'sufficient richness' (SR) of $x$ and guarantees $M(t) > \lambda_m I, \lambda_m > 0$ as in [19]. Suitable analytical detail is avoided here due to space reasons.* ○

Another auxillary matrix $K(t)$ may be defined as,

$$\dot{K}(t) = k_{FF}K(t) - k_{FF}K(t)\phi_f^T(t)\phi_f(t)K(t), \tag{19}$$

where the initial condition $K(0) > 0$ is specified as a diagonal matrix, $K(0) = \frac{1}{\lambda}I$ with $\lambda > 0$ being constant. It will be seen that $K(t)$ is an approximation of the inverse of $M(t)$ where $\lim\limits_{t\to\infty} K(t)M(t) = I$. With the help of the following derivative matrix identity,

$$\frac{d}{dt}KK^{-1} = K\tfrac{d}{dt}K^{-1} + K^{-1}\tfrac{d}{dt}K = 0 \tag{20}$$

we can obtain,

$$K(t) = [e^{-k_{FF}t}K^{-1}(0) + M(t)]^{-1} \tag{21}$$

This also implies boundedness of $K(t)$, if $M(t) > 0$. To show the invertibility of $K(t)$ as well as $K(t)M(t)$ approaches unity, we are to employ the singular value decomposition for the matrix, $M(t)$,

$$M(t) = U(t)S(t)V^T(t) \tag{22}$$

where $S(t) = diag(s_1, \dots, s_n)$ is the matrix with $s_i$ being the singular values of matrix, $M(t)$ whilst, $U(t)$ and $V(t)$ are unitary matrices.

We know that $K(0) = \frac{1}{\lambda}I$ is a diagonal matrix, thereby,

$$K(t) = V(t)(S(t) + e^{-k_{FF}t}\lambda I)^{-1}U^T(t) \tag{23}$$

Then,

$$K(t)M(t) = V(t)diag(\tfrac{s_1}{s_1+e^{-k_{FF}t}\lambda}, \dots, \tfrac{s_n}{s_n+e^{-k_{FF}t}\lambda})V^T(t) \tag{24}$$

and $\lim\limits_{t\to\infty} \dfrac{s_i}{s_i + e^{-k_{FF}t}\lambda} = 1, \quad if \quad M(t) \geq \lambda_m I > 0,$ for $\lambda > 0$, adhering to the Persistent Excitation (PE) condition [14]. Since $V(t)$ is unitary, the matrix $K(t)M(t)$ can be represented as,

$$K(t)M(t) = I - \Delta(t) \tag{25}$$

where $\Delta$ converges to zero in infinite time. This shows that $K(t)$ is indeed a representation of the inverse of $M(t)$ where $\Delta(t)$ denotes the effects of the initial condition $K(0)$. Hence, the parameter estimation error vector can be written as,

$$\tilde{\Theta} = \Theta - \hat{\Theta} = [K(t)M(t) + \Delta(t)]\Theta - \hat{\Theta} \tag{26}$$

where $\lim\limits_{t\to\infty} \Delta(t) \to 0$

*Remark 2: Note that a practical test for $M(t) > 0$ is to verify in an experiment if $K(t)M(t) \approx I$ holds. This implies non-singularity of $K(t)$ and $M(t)$. Again, this condition can be achieved through PE of $\phi$ (see Remark 1) which can be verified experimentally as will be seen in Section VII on Practical Application Results.* ○

### C. Parameter Estimation

We shall write our adaptive law as,

$$\dot{\hat{\Theta}} = \Gamma[\varphi^T F(y - C\hat{x}) - \Omega R(t)] \tag{27}$$

In (27), $\Gamma$ and $\Omega$ are positive definite and diagonal design matrices, i.e. $\Gamma = diag(\gamma_1, \dots, \gamma_l)$ and $\Omega = diag(\omega_1, \dots, \omega_l)$ respectively. The term $R(t)$ contains a sliding mode type term to ensure fast parameter convergence,

$$R(t) = \Omega_1 \frac{\hat{\Theta} - K(t)N(t)}{\delta + \left\|\hat{\Theta} - K(t)N(t)\right\|} + \Omega_2(\hat{\Theta} - K(t)N(t)) \tag{28}$$

where $\Omega_1$ and $\Omega_2$ are diagonal positive definite matrices, whilst $\delta$ is a positive constant. It will be proven that the parameter error matrix, $\tilde{\Theta}$, converges to a small residual set around zero, $\left\|\tilde{\Theta}\right\| \leq c$, in finite time, where $c > 0$ is a positive constant.

*Remark 3: Compared to previous results (i.e. the parameter adaptation is only driven by the observer error in (27)), the extra term $R(t)$ taking parameter error information, $\hat{\Theta} - K(t)N(t)$ is employed, which could enhance the parameter convergence performance [21]. In particular, we incorporate the sliding mode technique in (28) such that the finite-time convergence to a set of ultimate boundedness is guaranteed as stated in the next section.* ○

## V. Stability and Performance

*Theorem 1: Given a system (1), which satisfies Assumption 1-4, an adaptive observer (3) with adaptation law (27) using (13) - (19), (28) can be designed for persistently excited $\phi$ (9) so that the unknown parameter vector $\Theta$ can be estimated via $\hat{\Theta}$ within finite time satisfying an ultimate bounded stability characteristic for $\tilde{\Theta}$ and the estimated state $\tilde{x}$. The set of ultimate boundedness can be arbitrarily small for $\zeta = 0$.* ◇

*Proof :* The following Lyapunov candidate shall be employed,

$$V(t) = \frac{1}{2}\tilde{x}^T P\tilde{x} + \frac{1}{2}\tilde{\Theta}^T\Gamma^{-1}\tilde{\Theta} \tag{29}$$

For ease of analysis, we shall decompose (29) as,

$$V(t) = \tfrac{1}{2}\tilde{x}_1^T P_1\tilde{x}_1 + \tfrac{1}{2}\tilde{x}_2^T P_2\tilde{x}_2 + \tfrac{1}{2}\tilde{\Theta}^T\Gamma^{-1}\tilde{\Theta} = V_1 + V_2 + V_3 \tag{30}$$

We now analyse the functions of $V_1 = \frac{1}{2}\tilde{x}_1^T P_1\tilde{x}_1$ and $\tilde{V} = V_2 + V_3 = \frac{1}{2}\tilde{x}_2^T P_2\tilde{x}_2 + \frac{1}{2}\tilde{\Theta}^T\Gamma^{-1}\tilde{\Theta}$ separately for convenience. The derivative of $\tilde{V} = \frac{1}{2}\tilde{x}_2^T P_2\tilde{x}_2 + \frac{1}{2}\tilde{\Theta}^T\Gamma^{-1}\tilde{\Theta}$ can be verified as,

$$\begin{aligned}\dot{\tilde{V}} &= \tfrac{1}{2}[\tilde{x}_2^T P_2(A_{c22}\tilde{x}_2 + \bar{B}_2\varphi\tilde{\Theta}) + (A_{c22}\tilde{x}_2 \\ &\quad +\bar{B}_2\varphi\tilde{\Theta})^T P_2\tilde{x}_2] + \tilde{\Theta}^T\Gamma^{-1}\dot{\tilde{\Theta}} + 2\tilde{x}_2^T P_2\zeta_2\end{aligned}$$

Using (27), it follows:

$$\begin{aligned}\dot{\tilde{V}} &= -\tfrac{1}{2}\tilde{x}_2^T Q_2\tilde{x}_2^T + \tilde{x}_2^T P_2\bar{B}_2\varphi\tilde{\Theta} \\ &\quad -\tilde{\Theta}^T\Gamma^{-1}[\Gamma(\varphi^T FC\tilde{x} - \Omega R(t))] + 2\tilde{x}_2^T P_2\zeta_2\end{aligned} \tag{31}$$

The observer error, $C\tilde{x}$ can be written as $\tilde{x}_2$ from (2), $Cx = x_2$. From (5), knowing that $P_2B_2 = (FC)^T$, equation (31) can be further simplified as,

$$\dot{\tilde{V}} = -\tfrac{1}{2}\tilde{x}_2^T Q_2\tilde{x}_2^T + \tilde{\Theta}^T\Omega R(t) + 2\tilde{x}_2 P_2\zeta_2 \tag{32}$$

Taking care of the diagonal positive definite matrices, i.e. $\tilde{\Omega}_1 = \Omega\Omega_1$ and $\tilde{\Omega}_2 = \Omega\Omega_2$ with $\zeta_{2KN} = K(t)\zeta_{2N}$ for ease of analysis, equation (32) can be written with the sliding-mode term, $R(t)$ using (26),

$$\begin{aligned}\dot{\tilde{V}} &= -\tfrac{1}{2}\tilde{x}_2^T Q_2\tilde{x}_2 + (\Theta - \hat{\Theta})^T\tilde{\Omega}_1\tfrac{\hat{\Theta}-K(t)N(t)}{\delta+\|\hat{\Theta}-K(t)N(t)\|} \\ &\quad +(\Theta - \hat{\Theta})^T\tilde{\Omega}_2[\hat{\Theta} - K(t)N(t)] + 2\tilde{x}_2P_2\zeta_2 \\ &\leq -\tfrac{1}{2}\tilde{x}_2^T Q_2\tilde{x}_2 - \lambda_{min}(\tilde{\Omega}_1)\tfrac{\|\hat{\Theta}-K(t)N(t)\|^2+\delta\|\hat{\Theta}-K(t)N(t)\|}{\delta+\|\hat{\Theta}-K(t)N(t)\|} \\ &\quad +\lambda_{min}(\tilde{\Omega}_1)\tfrac{\delta\|\hat{\Theta}-K(t)N(t)\|}{\delta+\|\hat{\Theta}-K(t)N(t)\|} + 2\tilde{x}_2P_2\zeta_2 \\ &\quad +(K(t)N(t) - \hat{\Theta})^T\tilde{\Omega}_2[\hat{\Theta} - K(t)N(t)] \\ &\quad +(\Delta(t)\Theta - \zeta_{2KN})^T[\tilde{\Omega}_2\left(\hat{\Theta} - K(t)N(t)\right) \\ &\quad +\tilde{\Omega}_1\left(\tfrac{\hat{\Theta}-K(t)N(t)}{\delta+\|\hat{\Theta}-K(t)N(t)\|}\right)] \\ &\leq -\tfrac{1}{2}\lambda_{min}(Q_2)\lambda_{min}(P_2^{-1})V_2 - \lambda_{min}(\tilde{\Omega}_2)\tfrac{\lambda_{min}(\Gamma)}{2}V_3 \\ &\quad -(\lambda_{min}(\tilde{\Omega}_1)\lambda_{min}(\Gamma^{1/2}) \\ &\quad -\lambda_{max}(\tilde{\Omega}_2)\|\Delta(t)\Theta\|\lambda_{max}(\Gamma^{1/2}))\sqrt{V}_3 \\ &\quad +2\lambda_{max}(\tilde{\Omega}_2)\|\Delta(t)\Theta - \zeta_{2KN}\|^2 + \lambda_{min}(\tilde{\Omega}_1)\delta \\ &\quad +2\lambda_{max}(\tilde{\Omega}_1)\|\Delta(t)\Theta - \zeta_{2KN}\| + 2\|\tilde{x}_2\|\|P_2\|\|\zeta_2\|\end{aligned} \tag{33}$$

There are suitable positive scalars $c_1, c_2, c_3$ for large enough time, $t > 0$ such that:

$$\tilde{V} \leq -c_1\tilde{V} - c_2\sqrt{V}_3 + c_4 \tag{34}$$

Therefore, $\tilde{x}_2$ and $\tilde{\Theta}$ converge to a compact set bounded by parameter $\delta$, $\|\Delta(t)\|(\lim_{t\to\infty}\Delta(t) \to 0)$ and $\|\zeta_{2KN}\|$. The term $\Delta(t)$ denotes the effect of the initial conditions of $K^{-1}(0)$. For $\zeta_{2KN} = 0$, the size of the compact set can be adjusted to be smaller by reducing $\delta$ and the elements $\lambda_i$ in matrix $K^{-1}(0)$. Note that ultimate bounded stability for $\tilde{x}_1$ and subsequently for $\tilde{x}$, now trivially follow. Again, for $\zeta = 0$, the set of ultimate boundedness can be arbitrarily small for suitable choice of $\delta$. ■

*Remark 4: The result in Theorem 5.1 in fact is quite generic. It also allows for analysis of measurement errors of $x_2$ and $\phi$. For this reason, we may have in the observer some measurement errors affecting both $x_2$ and also $\phi(x, u_2)$ measurement and in reality $\check{x}_2$ and $\check{\phi}(x, u_2)$ are provided in the practical system. Thus, the observer equation is*

$$\dot{\hat{x}} = A\hat{x} + B_1u_1 + B\check{\phi}\hat{\Theta} + L(\check{x}_2 - C\hat{x}) \tag{35}$$

*The plant dynamics in (8) can be rewritten as,*

$$\begin{aligned}\dot{\check{x}} &= (A\check{x} + B_1u_1) + B_2\check{\phi}\Theta + \zeta + (\dot{\check{x}} - \dot{x}) \\ &\quad +A(x - \check{x}) + B_2(\phi - \check{\phi})\Theta\end{aligned} \tag{36}$$

*where $\check{x} = [x_1^T \quad \check{x}_2^T]^T$. Assuming the measurement errors and its derivative are bounded, (i.e. $(x-\check{x}), (\dot{x}-\dot{\check{x}}), (\phi-\check{\phi}) \in L_\infty$), so that $\check{x}_2, \dot{\check{x}}_2 \in L_\infty$, then the plant dynamics (8) are,*

$$\dot{\check{x}} = (A\check{x} + B_2u_1) + B_2\check{\phi}\Theta + \check{\zeta}, \tag{37}$$

*where $\check{\zeta} = \zeta+(\dot{\check{x}}-\dot{x})+A(x-\check{x})+B_1(\phi-\check{\phi})\Theta$ can be regarded as a bounded disturbance. Defining the error dynamics as $\tilde{\check{x}} = (\check{x} - \hat{x})$ it follows that,*

$$\dot{\tilde{\check{x}}} = A_c\tilde{\check{x}} + B_2\check{\phi}\Theta + \check{\zeta} \tag{38}$$

*Under the assumption that $\check{\zeta}$ is bounded, we can continue the analysis as for Theorem 5.1. Boundedness of $\check{\zeta}$ might be achieved under suitable assumptions on the measurement errors affecting $x_2$ and an additional assumption on the nonlinear functions $\phi$.* ○

## VI. Parameter Estimation in the Vehicle Dynamics

In this section, we will discuss the previously formulated parameter estimation algorithm in the context of its application to road gradient and vehicle's weight estimation. Figure 1 shows the simplified model of the small-scaled model car used in the experiment to validate the parameter estimation algorithm.

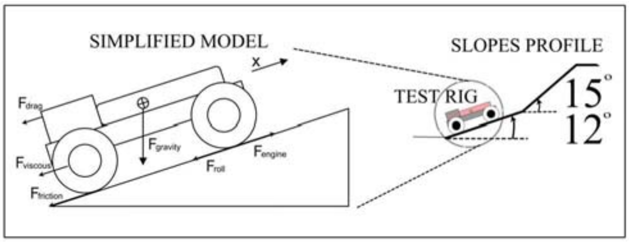

Fig. 1. Simplified model of the small-scaled model car and the slope profile

### A. Vehicle model

The parameters to be estimated are the road inclination, $\theta$, on which the vehicle traverses, the mass of the vehicle, $m$ and the viscous friction coefficient, $C_{vf}$. Referring to Figure 1, assuming the air drag, $F_{drag}$ and the rolling friction, $F_{roll}$ are negligible, and the braking force, $F_{brake}$ is subsumed in the driving force, $F_{engine}$, we may model the small-scaled model car using Newton's Second Law in the longitudinal direction to yield,

$$m\ddot{x} = F_{engine} - mgsin(\theta) - C_{VF}\dot{x} \tag{39}$$

where $m$ is the mass of the vehicle, $\theta$ is the road gradient on which the vehicle traverses, $\dot{x}$ is the vehicle's velocity and $C_{VF}$ is the viscous damping coefficient.

### B. Observer Design

Following the general structure presented in (3), the adaptive observer with finite-time parameter estimation can be written as,

$$\dot{\hat{\mathbf{x}}} = A\hat{\mathbf{x}} + \begin{bmatrix} 0 \\ 1 \end{bmatrix}[g \quad F_{engine} \quad \dot{x}]\begin{bmatrix} \hat{s} \\ \hat{b} \\ \hat{f} \end{bmatrix} + L(y - \hat{y}) \tag{40}$$

where $A$ is the system matrix (adheres to the Assumption 4), $\hat{s}$, $\hat{b}$, $\hat{f}$ are the estimated parameters of $-sin\theta$, $\frac{1}{m}$ and $-\frac{C_{VF}}{m}$ respectively whereas $L$ is the observer gain chosen to deliver the positive definite Lyapunov matrix, $P$, such that it satisfies (4). The engine driving force, $F_{engine}$ is assumed to be bounded to ensure that the system states, $x$ remains bounded. The vector $\hat{y} = C\hat{\mathbf{x}}$ will be the corresponding observer output and $\hat{\mathbf{x}} = [\hat{x} \quad \dot{\hat{x}}]$ is the observed state vector. Thus, using this structure it follows,

$$B_2 = \begin{bmatrix} 0 \\ 1 \end{bmatrix}, \quad \hat{\Theta} = \begin{bmatrix} \hat{s} \\ \hat{b} \\ \hat{f} \end{bmatrix}, \quad \varphi = \begin{bmatrix} g \\ F_{engine} \\ \dot{x} \end{bmatrix}^T \tag{41}$$

The observer adaptive weights are lumped such that,

$$\Gamma = diag(\gamma_1, \gamma_2, \gamma_3), \quad \Omega = \Gamma^{-1} diag(r_s, r_b, r_f) \tag{42}$$

## VII. Practical Application Results

The small-scale model car, previously built by Foreman *et al.* [18],was used in the experiment to evaluate the estimation algorithm. The vehicle's mass (nominally weighs 10kg) and the road gradients on which it traverses were the two parameters to be estimated. Figure 2 shows the implemented controller system network and architecture which emulates the system network of a road vehicle. Together with Matlab$^{TM}$, dSPACE MicroAutoBox, used in the experiment, is a dedicated Rapid Prototyping embedded system suited to test the proposed estimation algorithm. The drive train comprises of an EPOS 24/5 motor driver and the brushless DC motor (EC-i 40 Maxon) representing the vehicle's engine. The motor is current-controlled via the MicroAutoBox which subsequently provides the driving force, $F_{engine}$, proportional to the current signal being controlled. Gradient measurements provided by the installed SCA61T inclinometer is entirely for reference purpose and not to be used in the algorithm. In our experiment, we would avoid the occurrence of significant slippage as this would invalidate our estimation effort. The test slope was constructed using three stiff wooden planks of 2 m in length each. They are tilted and bolted together to give a slope profile with tilting angle of 12° for the first slope, 15° for the second slope and the last slope is horizontal i.e. parallel to the ground. The small-scaled model car was required to traverse up the designated slope at a constant speed of 0.2 m/s (Figure 1).

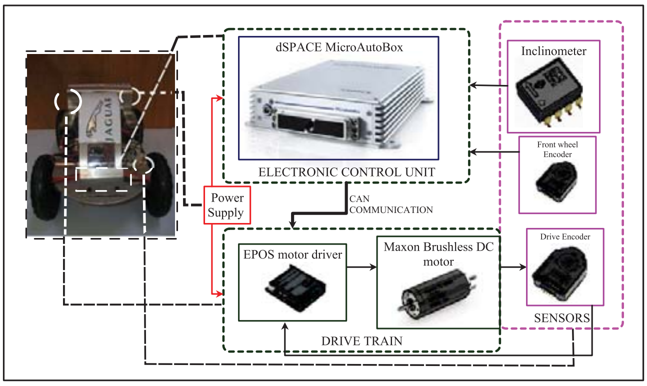

Fig. 2. Functional Structure of the System Onboard

### A. Parameters tuning

In our experiment, there were important parameters (see Table I) of the adaptive observer algorithm needed to be tuned to achieve satisfactory results. Realistic and acceptable physical bounds/limits were considered and shown in Table II. The corresponding values of the parameters displayed in the table are used in the experiment. Noise injected to the velocity and the control signal was kept constant in terms of power so that the actuating signal applied to the motor exerts sufficient and persistent excitation.

TABLE I
Parameters to be tuned

| Parameter Description | Symbols | Values |
|---|---|---|
| Observer Adaptive weights, $\Gamma$ | $\gamma_1$ | 0.01 |
| | $\gamma_2$ | 0.001 |
| | $\gamma_3$ | 0.001 |
| Sliding-Mode Adaptive weights, $\Omega$ | $r_s$ | 0.01 |
| | $r_b$ | 1 |
| | $r_f$ | 0.00001 |
| Forgetting Factor | $k_{FF}$ | 0.6 |
| Filter Poles | $k$ | 0.005 |
| Regressor Matrix, K initial condition | $K(0)$ | diag(0.4,0.4,1) |

TABLE II
Saturation Limits

| Plant Parameters | Estimation | Lower Limit | Upper Limit |
|---|---|---|---|
| Mass(m,kg) | $\hat{m}$ | 0.1 | 20 |
| | $\hat{b} = 1/\hat{m}$ | 0.05 | 10 |
| Gradient($\theta$,°) | $\hat{\theta}$ | -20 | 20 |
| | $\hat{s} = sin(\hat{\theta})$ | -0.4 | 0.4 |
| Friction Coefficient | $-C_{VF}$ | 240 | 0.1 |
| ($C_{VF}$,$kg/s$) | $\hat{f} = C_{VF}/\hat{m}$ | -12 | -1 |

### B. Results

The proposed adaptive observer algorithm with sliding-mode term performance is compared with that of the recent adaptive observer (without the term in (28)) previously carried out by [18]. Referring to Table III, the Integral Absolute Error (IAE), $\int_0^\infty |e(t)|dt$, is used as the performance index measuring the difference between the actual and the estimated road gradient. The low value of IAE translates to good parameter estimation as the estimated value converges to the true value. Figure 3(a) versus Figure 5(a) shows an excellent estimation performance of the new algorithm, having the estimated gradient converging close to the actual gradient during the climbing of the slope although there is a slight offset during the vehicle traversing the flat ground. A very consistent mass estimation of the new estimator is evident in Figure 3(b) as compared to the previous algorithm as shown in Figure 5(b). The estimated mass value settles at approximately 14 kg throughout the test slope profile and slightly descends to 12 kg towards reaching the flat ground at the end. The recorded IAE for the road gradient estimation for the proposed algorithm is 178.2402. In contrast, the previous algorithm lacks in performance when it exhibits a large increase in IAE of 229.9736. The estimated parameters, $\hat{s}, \hat{b}, \hat{f}$ in Figure

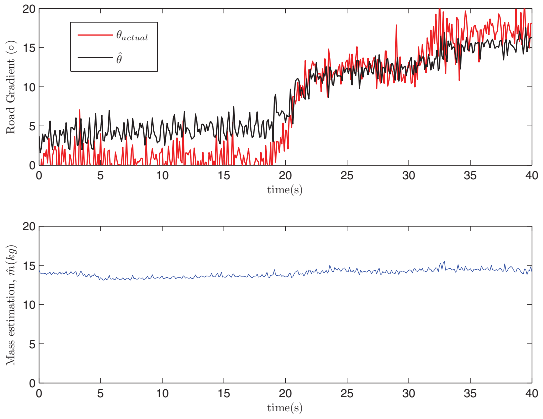

Fig. 3. (a) Gradient comparison(in Degree) between the actual, $\theta$ and estimated, $\hat{\theta}$ (b) Mass Estimation (kg) of the proposed novel algorithm

TABLE III
SUMMARY OF THE PERFORMANCE IN IAE

| Algorithm | IAE |
|---|---|
| Previous algorithm | 229.9736 |
| Proposed Finite-Time Estimation algorithm | 178.2402 |

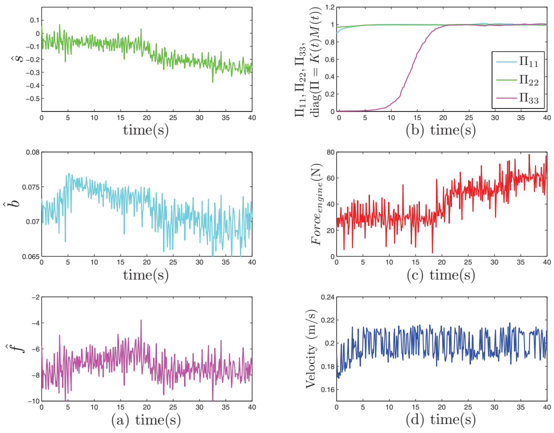

Fig. 4. (a) Estimated parameters($\hat{\Theta}$) consisting of $\hat{s}, \hat{b}, \hat{f}$, (b) proof of PE by which $K(t)M(t) \approx I$ holds experimentally, (c) Driving force,$F_{engine}$ and (d) vehicle's velocity, $V$

4(a) also show excellent behaviour as they remain within the bound of the given physical limit without saturation whereas in Figure 5(b), the estimated parameters saturate at the given bounds. Interestingly, the engine driving force, $F_{engine}$ signal in Figure 4(c) exhibits persistent excitation (PE) throughout the test slope profile which assures the finite-time convergence to the true value. Note that persistent excitation has been also verified via the approach of Remark 3. The product $K(t)M(t)$ has converged to unity as evident in the experimental data shown in Figure 4(b). Table III sums up the performance of the proposed algorithm compared with the previous one in terms of IAE.

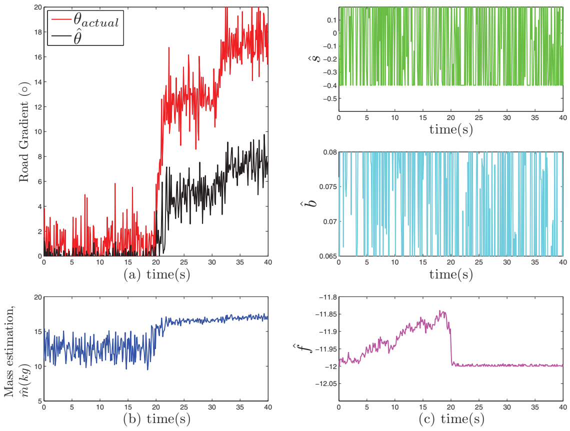

Fig. 5. (a) Gradient comparison between the actual, $\theta$ and the estimated, $\hat{\theta}$, (b) Mass Estimation (kg) and (c) Estimated parameters($\Theta$) consisting $\hat{s}, \hat{b}, \hat{f}$ of algorithm from [18]

## VIII. CONCLUSION

An adaptive observer with novel sliding-mode based parameter estimation algorithm to estimate the vehicle's mass and the road gradient is presented. The proposed parameter estimator with the sliding-mode term has been proven analytically to be finite time convergent to an error of well defined bound. The algorithm shows significant levels of robustness to disturbances and a particular class of measurement errors. The analytical results are further supported and validated by the practical implementation in a form of experiments conducted on a small-scale vehicle traversing a designated test slope profile with certain parameters tuned. The practical results show a significant improvement over the previous algorithm in terms of persistent excitation (PE), realistic values within the physical bound, estimation accuracy and convergence.

# Experimental Study of a Capsubot for Two Dimensional Movements

M. Nazmul Huda, Hongnian Yu and Michael J. Goodwin

*Abstract*— **A capsubot (capsule robot) which works on the principle of internal reaction force has no external moving parts whereas a conventional robot has legs and/or wheels. It is an underactuated mechanical system and has a lot of potential applications such as medical diagnosis, underground pipe leakage detection, rescue work in the hazardous environment etc. However, most capsule robots studied/developed can only move in one dimension (1D). This paper presents the implementation of the recently proposed double parallel mass capsubot which uses two parallel inner masses (IMs) to move the capsubot in two dimensions (2D). A three stage control strategy is proposed to resolve the control issue of underactuated mechanical system. A closed-loop control approach is applied to the IMs of the capsubot. The comparison with the simulation studies are also obtained and analyzed.**

## I. INTRODUCTION

Minimally invasive diagnosis and interventions feature safe and reliable techniques and result in shorter hospital stays, less pain, more rapid return to daily work, and improved immunological response compare to the conventional ways. Thus relevant researches have gotten extensive interest to develop minimally invasive devices for surgical and diagnostic applications [1], [2], [3], [4]. Robot-assisted laparoscopic and thoracoscopic surgeries are becoming popular because of its less invasiveness and reliability [5]. Researchers are designing mobile robots to perform abdominal surgery which will further decrease the invasiveness [6], [7], [8].

Passive capsule endoscopy has been used to diagnose GI (gastro-intestinal) tract diseases which is safer for the patient and easier to perform compare to the conventional probe endoscopy. Research is ongoing in order to add mobility to capsule endoscope to increase the reliability, performance and add functionalities such as biopsy, drug delivery, surgery etc. Mobile robots designed for abdominal cavity as well as GI tract can be divided based on the propulsion mechanism used as 1) external propulsion robot (i. magnetic propulsion [9]) 2) internal propulsion robot (i. wheeled [10] ii. legged [11] iii. internal reaction force propulsion robot [12]) and 3) hybrid propulsion robot (combination of external and internal) [13].

The sharp edges of legs or wheels of the internal propulsion robots create the risk to injure the tender GI track and internal organs. Also to perform magnetic propulsion it requires large external magnet [9] which makes the system expensive.

On the contrary the capsubots based on internal reaction force are simple in construction and have no external legs or wheels [14], [15]. The structure of the principle is derived from [16] where impact force and dry friction is utilised to create motion. A mass attached to the main object through a piezoelectric element, is made to move away from the main object rapidly and then to return to the initial position slowly with a sudden stop. The main object moves during the rapid motion and at the stopping moment and remains stationary for the rest of the time. The object can move along a straight line by repeating the above process. In [17] the propulsion principle was analyzed from the viewpoint of physics and a control law and optimum parameters of the system were proposed. In [18], [19], the motion generation of a single mass capsubot was explained on the basis of a four step velocity profile which is, fast motion for first two steps and slow motion in the last two steps. In [15], the motion generation of the capsubot was explained on the basis of a seven step velocity profile which is, fast motion in the first three steps and slow motion in the rest of the steps. A pendulum-driven cart was analysed in [14] with a six step velocity profile. In [12], motion of a single mass capsubot was explained on the basis of a novel four step acceleration profile and a stand-alone prototype was developed based on the profile.

However, except [20] all the capsubots researched so far can only move in one dimension (1D) with their present designs. In practical applications, high dimensional movements of a capsubot is required. In [21] a double-pendulum driven cart was proposed for 2D movements and simulation results was presented. But this cart has wheels and thus lacks the advantages of a capsubot which is legless and wheelless. In [20] a capsubot with 2D movements was proposed and theoretical analysis was performed. In this paper practical implementation of the capsubot proposed in [20] is presented. The experimental results are analyzed and compared with the theoretical results.

The paper is structured as below. Section II presents the modelling and motion generation of the capsubot. Prototyping and programming of the capsubot prototype is explained in section III. Section IV proposes a control strategy for the underactuated mechanical system and explains the control of the 2D capsubot. Section V presents experimental results, compares them with simulation results and analyses them. Finally in section VI the paper is concluded and future direction of the research is presented.

This work has been supported by the European Erasmus-Mundus Sustainable eTourism project 2010-2359, the EPSRC UK-Japan Network on Human Adaptive Mechatronics Project (EP/E025250/1) and EU Erasmus Mundus Project-ELINK (EM ECW-ref.149674-EM-1- 2008-1-UK-ERAMUNDUS). The authors thank Mr. Sam Wane and Dr Ian Moorcroft for their comments and assistances while performing this research.

## II. Modelling and Motion Generation

### A. Dynamic Modelling

The capsubot proposed in [20] is shown in Fig. 1. Two IMs are placed in the hollow spaces within the capsubot. IMs can move along the hollow spaces. By controlling the movements of IMs the capsubot can be moved in a 2D plane. It can perform linear, rotational, and 2D motions.

The capsubot dynamic models are as follows [20]:

$$F_i = m_i \ddot{x}_i + sgn(\dot{x}_i - \dot{r})\mu_i m_i g \quad \forall \;\; i = 1, 2 \qquad (1)$$

$$\sum F = -m_1 \ddot{x}_1 - m_2 \ddot{x}_2 = M\ddot{r} + sgn(\dot{r})\mu M g \qquad (2)$$

$$\sum M_G = m_2 \ddot{x}_2 l_2 - m_1 \ddot{x}_1 l_1 = I\ddot{\theta} + M_f \qquad (3)$$

where $sgn(\dot{x}_i - \dot{r})\mu_i m_i g$ is the friction force between the $IM_i$ and the capsubot; $sgn(\dot{r})\mu M g$ is the friction force between the capsubot with the environment; $M_f = sgn(\dot{\theta})\frac{2}{3}\mu_r P(r_2 + \frac{wl - \pi r_2^2}{\pi r_1})$ [20] is the frictional moment of the capsubot with surface of movement and $I = \frac{1}{12}M(l^2 + w^2)$ is the moment of inertia of the capsubot about z-axis through the mass centre of the capsubot. Rest of the parameters are explained in Table I.

### B. Motion Generation

In motion generation, we consider the following 3 cases: 1) Linear motion; 2) Rotational motion and 3) 2D motion. Here we design that $m_1 = m_2$ and $l_1 = l_2$.

*1) Linear Motion:* If both the IMs move with same acceleration i.e $\ddot{x}_1 = \ddot{x}_2$ then $\sum M_G = 0$, and $\sum F \neq 0$. Thus for linear motion both IMs follow the acceleration profile proposed in [12]. As $\sum M_G = 0$, so $\theta = 0$. Thus, $x = r \;\; and \;\; y = 0$ ( using $x = r\cos\theta \;\; and \;\; y = r\sin\theta$).

*2) Rotational Motion:* If both the IMs move with same acceleration in opposite direction i.e. $\ddot{x}_1 = -\ddot{x}_2$ then $\sum M_G \neq 0$, and $\sum F = 0$. Here one of the IMs follows the acceleration profile same as linear motion. The remaining IM follows an acceleration profile that is same in magnitude but opposite in direction. As $\sum F = 0$, so $r = 0$. Thus, $x = y = 0$. As $\sum M_G \neq 0$, so $\theta \neq 0$.

TABLE I

Parameters of the Capsubot

| | |
|---|---|
| $F_i$ | Force applied on $IM_i$ |
| $\sum F$ | Resultant reaction force acting on the mass centre of capsubot |
| $\sum M_G$ | Resultant moment on the capsubot about z-axis through the mass centre of the capsubot |
| $m_i$ | Mass of $IM_i$ (cylindrical rod with extra mass) |
| $x_i$ | Position of $IM_i$ with respect to an external fixed frame |
| $r$ | Position of the mass centre of the casubot with respect to an external fixed frame |
| $\theta$ | Angular position of the casubot with respect to an external fixed frame |
| $x$ | $r\cos\theta$ |
| $y$ | $r\sin\theta$ |
| $M$ | Total mass of the capsubot |
| $w$ | Width of the capsubot |
| $l$ | Length of the capsubot |
| $h$ | Height of the capsubot |
| $\mu$ | Dynamic friction coefficient between capsubot and environment (plywood table) |
| $\mu_r$ | Rotational friction coefficient between capsubot and environment (plywood table) |
| $\mu_i$ | Dynamic friction coefficient between $IM_i$ and linear DC motor ($LM_i$) |
| $g$ | Acceleration of gravity |
| k | Total stroke length in one direction |
| $F_{ipmax}$ | Maximum peak force on $IM_i$ |
| $F_{icmax}$ | Maximum continuous force on $IM_i$ |
| $\ddot{x}_{imax}$ | Maximum achievable acceleration of $IM_i$ |
| $l_i$ | Perpendicular distance of the mass centre of the capsubot from the direction of forces $F_i$ |
| $r_1$ | $\frac{1}{2}\sqrt{l^2 + w^2}$ |
| $r_2$ | $w/2$ |
| $P$ | $Mg$ |

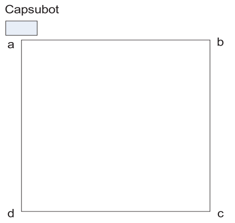

Fig. 2. Squared motion path

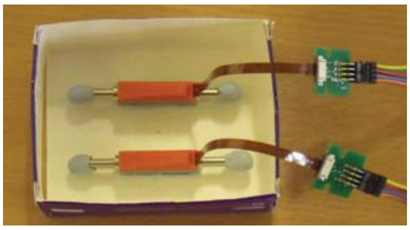
*3) 2D Motion:* By combining the linear and rotational motion, the capsubot can perform a 2D motion. Squared motion, rectangular motion, circular motion etc. are examples of this type of motion.

To travel a-b-c-d-a squared path of Fig. 2 the capsubot would move 'a' to 'b' using linear motion mode and then it would rotate 90 degree using rotational motion mode and then again would use linear motion. By using linear motion and rotational motion alternately the capsubot completes its travel path a-b-c-d-a.

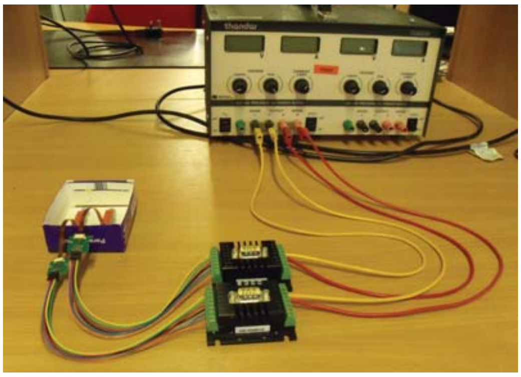
## III. Experimental Setup

A prototype shown in Fig. 3(a) has been developed to validate the theoretical analysis performed in [20]. Here the cylindrical rods of two linear DC motors (LM0830-015-01) [22] (see Fig. 4(A)) are used as two IMs. The linear

DC motors (LMs) are placed and attached using adhesive on a housing made of thin paperboard and thus forms the prototype. It is connected to a motion controller through wires. The parameters of the capsubot are listed in Tables I and II.



(a) Capsubot prototype



(b) Capsubot prototype with controllers and power supply

Fig. 3. Implemented Capsubot

The main components of the linear DC motor (LM) are a housing or motor shell which houses the coil, Hall sensors, a PCB (printed circuit board) etc. and a cylindrical rod which is a permanent magnet. The cylindrical rod can move back and forth through the housing. The cylindrical rod can move 7.5mm in each direction from its middle position. Here we used 6 mm and left the rest as a clearance. We added extra mass to the both ends of the cylindrical rod to increase the IM mass to capsubot mass ratio. We shall use the term IM (inner mass) for the cylindrical rod with extra mass in the rest of the paper.

The motion of the IM is controlled by the motion controller shown in Fig. 4(B). A linear force is applied to the IM when the coil in the motor shell is energised by the motion controller. The linear DC motor (LM) can be connected to the motion controller through wires and a connector. It takes power from the motion controller. The Hall sensors sense the position of the IM and feed the data to the motion controller to form a closed loop system.

The controller is programmed to move the IM from one location to another location by using a given acceleration and deceleration. The controller by itself calculates the time it has to use for acceleration and then deceleration to reach the desired location. The controller uses three Hall sensors on each linear DC motor (LM) to take feedback about the position of the IM and corrects the input to the IM accordingly to maintain the desired acceleration or deceleration and velocity.

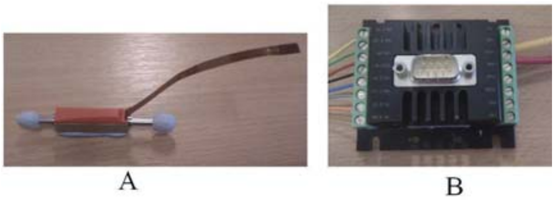


Fig. 4. A) Modified linear DC motor (LM) B) Motion controller

The motion controller is driven by $12V - 30V$ DC which is taken from a DC power supply. The motion controller of the capsubot system is programmed using the Motion Manager software [22] and the program is transferred from PC to the motion controller by a RS-232 cable and stored in the EEPROM of the motion controller. Then the motion controller can be disconnected from the PC. When the motion controller is powered the stored program is executed and the IM moves accordingly. If the motion controller is connected to the PC the Motion Manager software logs the data of the linear DC motor (LM).

## IV. CONTROL APPROACH

To use the capsubot in various applications the movement of the capsubot needs to be controlled precisely. The capsubot should be able to change its velocity while moving according to the requirement of the application. Thus we can state the problem as a position or velocity trajectory tracking problem. The capsubot is a underactuated system i.e degrees of freedom to be controlled are greater than number of control inputs. For underactuated systems trajectory tracking is still an open issue to be solved. To solve this problem we divide the problem into three stages which are described below. The schematic diagram of the complete control system is shown in Fig. 5.

- *Stage 1:* For a given trajectory of the capsubot, desired trajectories of IMs are calculated.
- *Stage 2:* For the desired trajectories of the IMs, control inputs i.e forces are calculated (open-loop). The closed-loop control is achieved by correcting the control inputs using the error which is the difference between the measured and the desired trajectories of the IMs.
- *Stage 3:* Feedback should also be taken from the capsubot position and the control input should be corrected according to the error value for tracking the position of the capsubot properly.

In this paper stage 2 of the control system is performed i.e. simulation analysis and experimentation of closed loop control of IMs are performed for the capsubot. Stages 1 and 3 shall be completed in our future research. The schematic diagram of the control system for stage 2 is shown in Fig. 6. By implementing this stage the capsubot can perform linear and rotational motion and by combining these two can perform 2D motion. If the IMs follow a fixed set of accelerations the capsubot would have a constant average linear or rotational velocity in every cycle. To change the velocity a different set of acceleration has to be chosen.

Stage 1
Stage 2

Fig. 5. Schematic diagram of 3-stage control system for capsubot

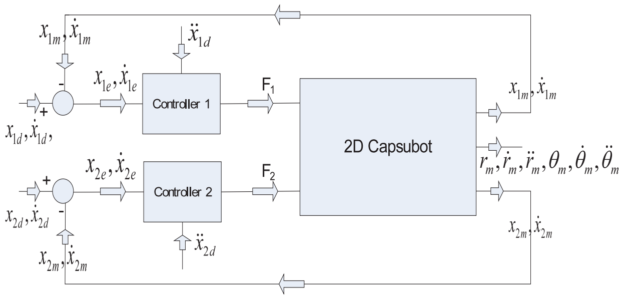

Fig. 6. Schematic diagram of Stage 2 of the control system

Two open loop control laws for the IMs for all the motion cases are:

$$F_{id} = m_i\ddot{x}_{id} + sgn(\dot{x}_{id} - \dot{r}_d)\mu_i m_i g \quad (4)$$

The closed loop control laws for the IMs can be selected, using partial feedback linearization, as [14]:

$$F_{id} = \alpha\tau_{id} + \beta \quad (5)$$

where $\alpha = m_i$ and $\beta = sgn(\dot{x}_{id} - \dot{r}_d)\mu_i mg$

Let $\tilde{x}_i = x_i - x_{id}$ be the tracking error; choosing the linear control law $\tau_{id} = \ddot{x}_i - k_1\dot{\tilde{x}}_i - k_2\tilde{x}_i$ and applying the control laws of (5) to (1) we get,

$$\ddot{\tilde{x}}_i + k_1\dot{\tilde{x}}_i + k_2\tilde{x}_i = 0 \quad (6)$$

The values of $k_1$ and $k_2$ can properly be selected using (6). Then by using the control laws of (5) the IMs can be made to follow the desired accelerations, velocities and positions which are given below. The impact of $\dot{r}_d$ on $\beta$ is neglected in simulation.

From the acceleration profiles in [12] and [20] desired IMs accelerations for linear and rotational motions are given below:

$$\ddot{x}_{id} = \begin{cases} b_{1\_i} & t \in [0, t_1) \\ b_{2\_i} & t \in [t_1, t_3) \\ b_{1\_i} & t \in [t_3, t_4] \end{cases}$$

where $b_{1\_i}$ is the acceleration of $IM_i$ in steps 1 and 4; $b_{2\_i}$ is the acceleration of $IM_i$ in steps 2 and 3; $t_1$, $t_2$, $t_3$ and $t_4$ are the time after steps 1, 2, 3 and 4 respectively.

Desired IMs velocities and positions can be calculated from the desired accelerations. All the simulations in this paper are performed using Matlab and Simulink with the help of the control law of (5) and motion equations (1), (2) and (3).

## V. EXPERIMENTAL RESULTS AND ANALYSIS

The acceleration of $IM_i$ is constrained by $\ddot{x}_i \leq min(\ddot{x}_{imax}, \frac{F_{icmax}}{m_i})$. Here $\ddot{x}_{imax}$ is $30ms^{-2}$ which is a physical constraint of $IM_i$. $F_{icmax}$ is the maximum force that can be achieved on the $IM_i$ continuously. On the other hand $F_{ipmax}$ is the maximum force that the $IM_i$ can sustain for a short time. In this experiment maximum acceleration used is $20ms^{-2}$.

The data of $IM_s$ are obtained from the Motion Manager software and then the curves are plotted using Matlab. To obtain the data for capsubot movements we recorded the motion of the capsubot using a video camera and then a video analysis software Quintic Biomechanics [23] was used to calculate the position, velocity and acceleration.

### A. Experimental Results

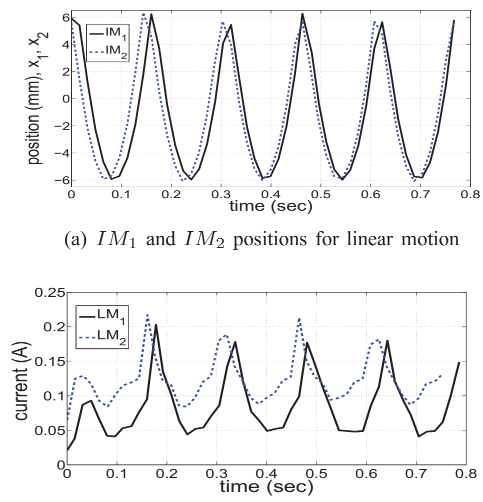
- Linear Motion: Fig. 7(a) shows the positions of $IM_1$ and $IM_2$, and Fig. 7(b) shows the currents of $LM_1$ and $LM_2$ for linear motion. We can see that the IMs move in the range of -6 mm to 6 mm with a cycle period of 0.15s. The shape of the curves of positions are similar with a very small difference. Motor currents are also similar in patterns though there is a small difference between them.
- Rotational motion: Fig. 8(a) shows the positions of $IM_1$ and $IM_2$, and Fig. 8(b) shows the currents of $LM_1$ and $LM_2$ for rotational motion. We can see that the two IMs move in the range of -6 mm to 6 mm in the opposite direction with a cycle period of 0.15s. Though the IMs are moving in the opposite direction the motor currents are similar in patterns as the magnitude of the accelerations are same.

### B. Comparison with Simulation

The parameters for the simulation of the capsubot is taken from the developed prototype and are listed in Table II.

Figs. 9(a)-9(d) and 10(a)-10(d) show the comparison between experimental and simulation results for the linear motion and rotational motion. For the linear motion both $IMs$ has the same acceleration profile. Thus comparison for $IM_1$ is shown only in Figs. 9(a)-9(d). For the rotational motion one of the $IMs$ follows the same acceleration profile as the linear motion and the other $IM$ follows an acceleration profile that is opposite to the previous one. Thus for the rotational motion comparison for $IM$ that has the opposite acceleration profile i.e. $IM_2$ is shown in Figs. 10(a)-10(d).

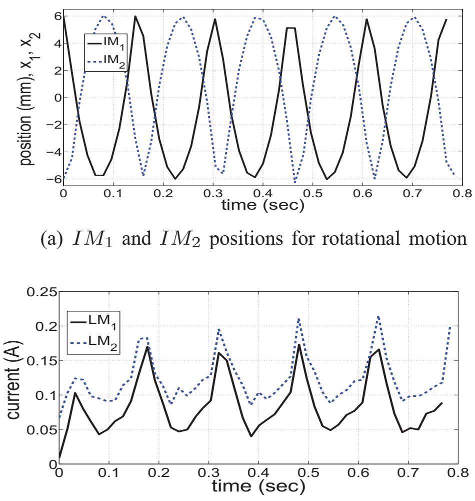
Although there are some differences between the experimental and simulation results, their trends are similar.



(a) $IM_1$ and $IM_2$ positions for linear motion

(b) Currents of $LM_1$ and $LM_2$ for linear motion

Fig. 7. Experimental results for linear motion



(a) $IM_1$ and $IM_2$ positions for rotational motion

(b) Currents of $LM_1$ and $LM_2$ for rotational motion

Fig. 8. Experimental results for rotational motion

The differences may be due to several reasons, such as motor dynamics, sensor dynamics, the other disturbances etc. which are not considered in the simulation model. We will investigate these issues further in future experiments.

From Figs. 9(d) and 10(d) we see that in the linear motion mode the capsubot moves with 8.4 mm/s average velocity. To move the capsubot in the opposite direction we just need to change the acceleration of the $IMs$ to the opposite direction. In the rotational motion the capsubot moves with 13 degrees/s average angular velocity. To rotate the capsubot in the opposite direction we need to swap the acceleration profiles between the IMs.

By using the linear motion and rotational motion alternately the capsubot can move in a 2D plane.

TABLE II

Parameter values of the Capsubot

| $m_1$, $m_2$ | $\mu_1$, $\mu_2$ | k | $w$ | $l$ | $h$ |
|---|---|---|---|---|---|
| $6.4gm$ | 0.2 | $6mm$ | $7cm$ | $8.7cm$ | $3.2cm$ |
| $g$ | $M$ | $F_{max}$ | $l_1$,$l_2$ | $\mu_r$ | $\mu$ |
| $9.8ms^{-2}$ | $42.9gm$ | $1.03N$ | $11.5mm$ | 0.08 | 0.28 |

| $2.74N$ | $1.03N$ | | Motion | $-20m/s^2$ | $5m/s^2$ |
| Rotational | $b_{1\_1}$ | $b_{1\_2}$ | $b_{2\_1}$ | $b_{2\_2}$ | |
| Motion | $-20m/s^2$ | $20m/s^2$ | $5m/s^2$ | $-5m/s^2$ | |

[]

## VI. Conclusions and Future Works

This paper has investigated the 2D capsubot from both simulation and experimentation. The paper has the following contributions: 1) proposed a control strategy for the motion control of underactuated mechanical systems which is an open problem till date; 2) validated the early proposed 2D capsubot design [20] through an initial experimentation; 3) implemented the closed-loop control strategy for the IMs of the 2D capsubot; 4) conducted both simulation and experimentation; 5) compared the experimental and simulation results for demonstrating the proposed capsule robot movability; 6) proposed measuring the position/velocity of a capsubot using video analysis software.

This has built our confidence to conduct further research along this line. We will conduct further experimental test using different control approaches. Also we will select/propose more realistic friction model and validate its performance in different environments.

# *Wind Turbine Sensor Fault Tolerant Control via a Multiple-Model Approach*

Montadher Sami and Ron J Patton

Department of Engineering, University of Hull, Hull HU6 7RX, UK

(e-mail: r.j.patton@hull.ac.uk; M.s.Shaker@2008.hull.ac.uk)

*Abstract*— **This paper presents a new strategy for wind turbine fault tolerant control (FTC) to optimise the wind energy captured by a wind turbine operating at low wind speeds. The FTC strategy uses Takagi-Sugeno (T-S) fuzzy observers with state feedback control to maintain nominal wind turbine control without changes in both the fault and fault-free cases. The proposed strategy obviates the need for sensor fault residual evaluation and observer switching by using a fuzzy proportional multiple integral observer (PMIO) to mask i.e. *'implicitly compensate'* the sensor fault(s) from the controller input and provide good estimation over a wide range of sensor fault scenarios. The proposed FTC method is applied to a 5 MW offshore wind turbine (OWT) benchmark model.**

## I. INTRODUCTION

Recently, FTC methods have stimulated research in a wide range of industrial control communities and academia, particularly for the systems that demand a high degree of reliability and availability (sustainability) and at the same time are characterised by expensive and/or safety critical maintenance work. The recently developed OWTs are foremost example for these systems having highly non-linear aerodynamics and with a stochastic and uncontrollable driving force as input in the form of wind speed. Moreover, the OWT site accessibility and system availability is not always ensured during or soon after malfunctions, primarily due to changing weather conditions. Indeed, maintenance work for OWTs is more expensive than the maintenance of onshore wind turbines by a factor of 5-10 times [1]. Hence, to be competitive with other energy sources, the main challenges for the deployment of wind turbine systems are to maximise the amount of good quality electrical power extracted from wind energy over a significantly wide range of weather conditions and minimise both manufacturing and maintenance costs.

In the literature, FTC and fault detection and diagnosis (FDD) systems have been recognised as the proper solution of ensuring the above mentioned requirements [2-6].

Specifically, in [5] the authors proposed linear parameter-varying (LPV) FTC systems for pitch actuator faults occurring in the full load operation with more emphasis on controller design rather than on fault estimation. In [6] fuzzy T-S observer based sensor FTC design is proposed to be capable of achieve maximization of wind power extraction. Their proposed FTC method is based on evaluation of *two* residual signals generated using the *generalised observer* idea of [7] to switch the estimation from faulty to healthy observers with the assumption that no simultaneous sensors faults are occur. It is clear that switching between two different observers produces unavoidable spikes that specifically affect the drive train torsion of low inertia wind turbines. Also the performance of the proposed FTC strategy is highly affected by the robustness and the computation time of the residual evaluation unit. Moreover, there is a significant probability of simultaneous occurrence of generator and rotor speed sensor faults [2].

This paper describes a new T-S fuzzy observer-based sensor FTC scheme designed to optimise the wind energy captured in the low wind speed range of operation. To cover a wider than usual range of sensor fault scenarios, the FTC strategy uses a fuzzy extension to the well-known PMIO [8] to provide simultaneous estimation of states and sensor faults. The nominal fuzzy controller remains unchanged during faulty and fault-free cases.

The main contributions of the paper are: (1) the use of the PMIO to mask or *implicitly compensate* the effect of drive train sensor faults, hence obviating the need for residual evaluation and observer switching. The PMIO simultaneously estimates the states and the sensor fault signals. Moreover, information about the fault severity can also be provided through the fault estimation signals; (2) the new fuzzy PMIO scheme is shown to cover a wide range of sensor fault scenarios [8].

The paper is organised as follows, Section 2 presents the flexible two mass OWT drive train model Section 3 describes the proposed FTC strategy. In Section 4 simulation results are presented showing the application of the FTC scheme to a 5MW wind turbine benchmark model. Section 5 gives a concluding statement.

## II. WIND TURBINE MODELLING

Normally, wind turbine models are obtained by combining the constituent subsystem models that make up the overall wind turbine dynamics. In this section a flexible low speed shaft, two mass wind turbine models are presented. The aerodynamic torque ($T_a$) representing the source of nonlinearity of the wind turbine. $T_a$ , depending on the rotor speed $\omega_r$, the blade pitch angle $\beta$ and the wind speed $v$ *is* given by:

$$T_a = 0.5\rho\pi R^2 C_p(\lambda,\beta)\frac{v^3}{\omega_r} \qquad (1)$$

where $\rho$ is the air density, $R$ is the radius of the rotor, and $C_p$ is the power coefficient that depends on the blade pitch angle ($\beta$) and the tip-speed-ratio ($\lambda$) (TSR) defined as:

$$\lambda = \omega_r R/v \qquad (2)$$

The drive train is responsible for gearing up the rotor speed to a higher generator rotational speed. The drive train model includes low and high speed shafts linked together by a

*Montadher Shaker acknowledges funding support for his PhD scholarship from the ministry of higher education and scientific research of Iraq.*

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

gearbox modelled as a gear ratio. The state space model of the wind turbine drive train has the form:

$$\begin{bmatrix}\dot{\omega}_r\\ \dot{\omega}_g\\ \dot{\theta}_\Delta\end{bmatrix} = \begin{bmatrix}a_{11} & a_{12} & a_{13}\\ a_{21} & a_{22} & a_{23}\\ a_{31} & a_{32} & a_{33}\end{bmatrix}\begin{bmatrix}\omega_r\\ \omega_g\\ \theta_\Delta\end{bmatrix} + \begin{bmatrix}b_{11} & 0\\ 0 & b_{22}\\ 0 & 0\end{bmatrix}\begin{bmatrix}T_a\\ T_g\end{bmatrix} \quad (3)$$

where:

$$a_{11} = -\frac{(B_{dt}+B_r)}{J_r} \qquad a_{12} = \frac{B_{dt}}{n_g J_r} \qquad a_{13} = -\frac{K_{dt}}{J_r}$$

$$a_{21} = \frac{B_{dt}}{n_g J_g} \qquad a_{22} = -\frac{(B_{dt}+n_g B_g)}{n_g^2 J_g} \qquad a_{21} = \frac{K_{dt}}{n_g J_g}$$

$$a_{31} = 1 \qquad a_{32} = -\frac{1}{n_g} \qquad a_{33} = 0$$

$$b_{11} = \frac{1}{J_r} \qquad b_{22} = -\frac{1}{J_g}$$

where $J_r$ is the rotor inertia, $B_r$ is the rotor external damping, $J_g$ is the generator inertia, $\omega_g$ and $T_g$ are the generator speed and torque, $B_g$ is the generator external damping, $n_g$ is the gearbox ratio, $K_{dt}$ is the torsion stiffness, $B_{dt}$ is the torsion damping coefficient, and $\theta_\Delta$ is the torsion angle.

It should be noted that the blade pitch subsystem model is not considered here as the pitch angle is held at the optimal pitch angle $\beta = 0$ value during low wind speed range to achieve maximum power extraction. The converter and generator subsystem is not considered here as the proposed controller presented here is designed as an outer controller to provide the inner generator controller with the required reference torque command. This approach to controller design separation is acceptable since the converter-generator subsystem is faster than the aerodynamic subsystem.

## III. THE PROPOSED STRATEGY

The nonlinear behaviour of the aerodynamic subsystem and its dependence on wind speed, it is decided to use the T-S fuzzy model based control strategy to design active sensor FTC.

This Section focuses on the description of the proposed active sensor FTC strategy for wind turbine power maximisation. Fig.1 schematically illustrates the proposed strategy.

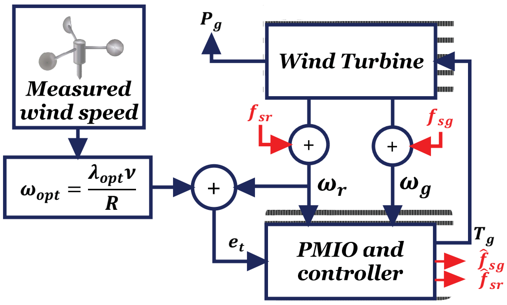

**Figure 1:** wind turbine sensor FTC scheme

The aim is to tolerate the effects of the drive train sensor fault. An estimator is used to estimate the fault signal and implicitly tolerate its effect on the state estimate signals delivered to the controller input. This strategy can be considered as a *fault-hiding* approach to FTC where the main objective of fault hiding is to maintain the same controller in both faulty and fault-free system cases.

The T-S fuzzy extension to the model given in (3) is:

$$\left.\begin{array}{l}\dot{x} = A(p)x(t) + \ Bu + E(p)v\\ y = \ Cx(t) + D_f f_s\end{array}\right\} \quad (4)$$

The system matrices $A(p) \in \mathcal{R}^{n*n}(= \sum_{i=1}^{r} h_i\,(p)A_i)$, $B \in \mathcal{R}^{n*m}$, $E(p) \in \mathcal{R}^{n*m_v}(= \sum_{i=1}^{r} h_i\,(p)E_i)$, $D_f \in \mathcal{R}^{l*g}$and $C \in \mathcal{R}^{l*n}$are known, $r$ is the number of fuzzy rules and the term $h_i\,(p)$ is the weighting function satisfying $\sum_{i=1}^{r} h_i\,(p) = 1$, and $1 \geq h_i\,(p) \geq 0$, for all $i$.

**Remark1:** The system given in Eq.(4) can be obtained from Eq.(3) by linearising the rotor aerodynamic torque equation. The central point to note in the T-S model given in Eq.(4) is that the system has common $B$ and $C$ matrices which will be utilized throughout the derivation of the proposed observer based controller. Details of linearization are given in [6, 9].

An augmented system consisting of the system (4) and the integral of the tracking error $e_t = \int (y_r - Sy)$ is defined as:

$$\left\{\begin{array}{l}\dot{\bar{x}} = \bar{A}(p)\bar{x} + \ \bar{B}u + \bar{E}(p)v + Ry_r\\ \bar{y} = \bar{C}\,\bar{x} + \bar{D}_f f_s\end{array}\right. \quad (5)$$

$$\bar{A}(p) = \begin{bmatrix}0 & -SC\\ 0 & A(p)\end{bmatrix}, \bar{x} = \begin{bmatrix}e_t\\ x\end{bmatrix}, \bar{B} = \begin{bmatrix}0\\ B\end{bmatrix}$$

$$\bar{E}(p) = \begin{bmatrix}0\\ E(p)\end{bmatrix}, R = \begin{bmatrix}I\\ 0\end{bmatrix}$$

$$\bar{C} = \begin{bmatrix}I_q & 0\\ 0 & C\end{bmatrix}, \bar{D}_f = \begin{bmatrix}0\\ D_f\end{bmatrix}$$

where $S \in \mathcal{R}^{w*l}$ is used to define which output variable is considered to track the reference signal.

Hence, the tracking problem is transferred to a fuzzy state feedback control, for which the proposed control signal is as:

$$u = K(p)\hat{\bar{x}} \quad (6)$$

where $K(p) \in \mathcal{R}^{m*(n+w)}(= \sum_{i=1}^{r} h_i\,(p)K_i)$ is the controller gain and $\hat{\bar{x}} \ \in \mathcal{R}^{(n+w)}$is the estimated augmented state vector.

If it is assumed that the $q^{th}$ derivative of the sensor fault signal is bounded, then an augmented state system consisting from the original local linear systems state and the $q^{th}$ derivative of the $f_s$, can be constructed.

Now let:

$$\varphi_i = f_s^{q-i} \qquad (i = 1,2, \dots, q)$$

$$\dot{\varphi}_1 = f_s^q; \dot{\varphi}_2 = \varphi_1;\ \dot{\varphi}_3 = \varphi_2; \dots; \dot{\varphi}_q = \varphi_{q-1}$$

Then the system (2) with augmented fault derivatives will become:

$$\left.\begin{array}{l}\dot{x}_a = A_a(p)x_a + B_a u + E_a(p)v + R_a y_r + Gf_s^q\\ y_a = C_a x_a\end{array}\right\} \quad (7)$$

where

$$x_a = \begin{bmatrix}\bar{x}^T & \varphi_1^T & \varphi_2^T & \varphi_3^T & \dots. & \varphi_q^T\end{bmatrix}^T \in \mathcal{R}^{\bar{n}}$$

$$A_a = \begin{bmatrix}\bar{A} & 0 & \dots & 0 & 0\\ 0 & 0 & \dots & 0 & 0\\ 0 & I & \dots & 0 & 0\\ \vdots & \vdots & \ddots & \vdots & \vdots\\ 0 & 0 & \dots & I & 0\end{bmatrix} \in \mathcal{R}^{\bar{n}\times\bar{n}}$$

$$B_a = [\bar{B}^T 0\ 0\ \dots 0]^T \ \in \mathcal{R}^{\bar{n}\times m}$$

$$G \ = [0\ I_k\ \ 0\ \dots 0]^T \ \in \mathcal{R}^{\bar{n}\times g}$$

$$C_a = \begin{bmatrix}\bar{C}\ 0\ \ 0\ \dots \bar{D}_f\end{bmatrix} \quad \in \mathcal{R}^{l*\bar{n}}$$

$$\bar{n} = (n + w) + gq$$

Hence, the following T-S fuzzy PMI observer is proposed to simultaneously estimate the system states and sensor faults:

$$\left.\begin{aligned}\dot{\hat{x}}_a &= A_a(p)\hat{x}_a + B_a u + E_a(p)v + R_a y_r + L_a(p)(y_a - \hat{y}_a)\\ \hat{y}_a &= C_a x_a\end{aligned}\right\} \qquad (8)$$

The state estimation error dynamics are obtained by subtracting Eq. (8) from Eq. (7) to yield:

$$\dot{e}_x = (A_a(p) - L_a(p)C_a)e_x + Gf_s^q \qquad (9)$$

The augmented system combining the augmented state space system (5), the controller (6), and the state estimation error (9) is given by:

$$\dot{\tilde{x}}_a(t) = \sum_{i=1}^{r} h_i\,(p)\{\tilde{A}_i\tilde{x}_a + \tilde{N}_i\tilde{d}\} \qquad (10)$$

where:

$$\tilde{A}_i = \begin{bmatrix}\bar{A}(p) + \bar{B}K(p) & -\bar{B}[K(p)\ 0_{m\times q}]\\ 0 & A_a(p) - L_a(p)C_a\end{bmatrix}$$

$$\tilde{x}_a = \begin{bmatrix}\bar{x}\\ e_x\end{bmatrix},\quad \tilde{N}_i = \begin{bmatrix}\bar{E}(p) & R & 0\\ 0 & 0 & G\end{bmatrix},\tilde{d} = \begin{bmatrix}d\\ y_r\\ f_s^q\end{bmatrix}$$

The objective here is to compute the gains $L_a(p)$ *and* $K(p)$ such that the effect of the input $\tilde{d}$ in Eq.(10) is attenuated below the desired level $\gamma$, to ensure robust stabilisation performance.

***Theorem1***: *For t>0 and* $h_i\,(p)h_j\,(p) \neq 0$, *The closed-loop fuzzy system in (6) is asymptotically stable and the $H_\infty$ performance is guaranteed with an attenuation level* $\gamma$, *provided that the signal* $(\tilde{d})$ *is bounded, if there exist symmetric positive definite matrices* $P_1, P_2$, *and matrices* $H_i, Y_i$, *and scalar* $\gamma$ *satisfying the following LMI constraints (11&12):*

$Minimise\ \gamma, such\ that$:

$$P_1 > 0, \qquad P_2 > 0 \qquad (11)$$

$$\begin{bmatrix}\Psi_{11} & \Psi_{12} & \bar{E}(p) & R & 0 & 0 & 0 & 0 & 0 & X_1C_p^T\\ * & -2\mu\bar{X}_1 & 0 & 0 & 0 & \mu I & 0 & 0 & 0 & 0\\ * & * & -2\mu I & 0 & 0 & 0 & \mu I & 0 & 0 & 0\\ * & * & * & -2\mu I & 0 & 0 & 0 & \mu I & 0 & 0\\ * & * & * & * & -2\mu I & 0 & 0 & 0 & \mu I & 0\\ * & * & * & * & * & \Psi_{55} & 0 & 0 & P_2G & 0\\ * & * & * & * & * & * & -\gamma I & 0 & 0 & 0\\ * & * & * & * & * & * & * & -\gamma I & 0 & 0\\ * & * & * & * & * & * & * & * & -\gamma I & 0\\ C_pX_1 & * & * & * & * & * & * & * & * & -\gamma I\end{bmatrix} < 0 \qquad (12)$$

where:

$K_i = Y_i X_1^{-1}$, $L_a = P_2^{-1}H_{ai}$ , $X_1 = P_1^{-1}, \bar{X}_1 = \begin{bmatrix}X_1 & 0\\ 0 & I_{q\times q}\end{bmatrix}$

$\Psi_{11} = \bar{A}_iX_1 + (\bar{A}_iX_1)^T + \bar{B}Y_i + (\bar{B}Y_i)^T$; $\Psi_{12} = [-\bar{B}Y_i \quad 0]$;

$\Psi_{55} = P_2A_{ai} + (P_2A_{ai})^T - H_{ai}C_a - (H_{ai}C_a)^T$.

***Proof:*** From Theorem 1, to achieve the performance and required closed-loop stability of (10) the following inequality must hold [10]:

$$\dot{v}(\tilde{x}_a) + \frac{1}{\gamma}\tilde{x}_a^T C_p^T C_p\tilde{x}_a - \gamma\tilde{d}^T\tilde{d} < 0 \qquad (13)$$

where $\dot{v}(\tilde{x}_a)$ is the time derivative of the candidate Lyapunov function $(v(\tilde{x}_a) = \tilde{x}_a^T\,\bar{P}\,\tilde{x}_a\ , where\ \bar{P} > 0)$ for the augmented system (10). Using Eq.(10), inequality (13) becomes:

$$\dot{v}(\tilde{x}_a) = \sum_{i=1}^{r} h_i\,\{\tilde{x}_a^T(\tilde{A}_i^T\bar{P}\ + \bar{P}\tilde{A}_i)\tilde{x}_a +\ \tilde{x}_a^T\bar{P}\tilde{N}_i\tilde{d} + \tilde{d}^T\tilde{N}_i^T\bar{P}\tilde{x}_a\} \qquad (14)$$

After simple manipulation, inequality (13) implies that the inequality (15) must hold:

$$\begin{bmatrix}\tilde{A}_{ij}^T\bar{P}\ + \bar{P}\tilde{A}_{ij} + \frac{1}{\gamma}I & \bar{P}\tilde{N}_{ij}\\ \tilde{N}_{ij}^T\bar{P} & -\gamma I\end{bmatrix} < 0 \qquad (15)$$

To be consistent with (10) $\bar{P}$ is structured as follows:

$$\bar{P} = \begin{bmatrix}P_1 & 0\\ 0 & P_2\end{bmatrix} > 0 \qquad (16)$$

Then after simple manipulation and using the variable change $(H_{ai} = P_2L_a(p))$ the inequality (15) can be reformulated as:

$$\Pi_{ij} = \left[\begin{array}{c:cccc}\Omega_{11} & -P_1[\bar{B}K_j\ 0] & P_1\bar{E}(p) & P_1R & 0\\ \hdashline * & \Omega_{22} & 0 & 0 & P_2G\\ * & * & -\gamma I & 0 & 0\\ * & * & * & -\gamma I & 0\\ 0 & (P_2G)^T & 0 & 0 & -\gamma I\end{array}\right] < 0 \qquad (17)$$

where:

$\Omega_{11} = \bar{A}_iX_1 + (\bar{A}_iX_1)^T + \bar{B}Y_i + (\bar{B}Y_i)^T + \frac{1}{\gamma}C_p^TC_p$

$\Omega_{22} = P_2A_{ai} + (P_2A_{ai})^T - \bar{H}_iC_a - (\bar{H}_iC_a)^T$

A single step design formulation of the matrix inequality in (17) is proposed to avoid the complexity of separate design steps characterised by repeated iteration to determine the gains required. Hence, $\Pi_{ij}$ as shown in (17) becomes:

$$\Pi_{ij} = \begin{bmatrix}\Pi_{11} & \Pi_{12}\\ * & \Pi_{22}\end{bmatrix} \qquad (18)$$

where

$\Pi_{11} = \Omega_{11}$ ; $\Pi_{12} = \begin{bmatrix}-P_1[\bar{B}K_j\ 0] & P_1\bar{E}(p) & P_1R & 0\end{bmatrix}$

$\Pi_{22}$ = lower right block

to do variable change, the following Lemma is required:

***Lemma 1*.** (Congruence) Consider two matrices $P$ and $Q$, if $P$ is positive definite and if $Q$ is a full column rank matrix, then the matrix $Q * P * Q^T$ is positive definite.

Let $Q = \begin{bmatrix} P_1^{-1} & 0 \\ 0 & X \end{bmatrix}$, $and\ X = \begin{bmatrix} \bar{X}_1 & 0 & 0 & 0 \\ 0 & I & 0 & 0 \\ 0 & 0 & I & 0 \\ 0 & 0 & 0 & I \end{bmatrix}$

Then $Q * \Pi_{ij} * Q^T < 0$ is also true and can be written as:

$$\begin{bmatrix} P_1^{-1}\Pi_{11}P_1^{-1} & P_1^{-1}\Pi_{12}X \\ * & X\Pi_{22}X \end{bmatrix} < 0 \tag{19}$$

Inequality (19) implies that $\Pi_{22} < 0$ so that the following inequality holds true [11, 12]:

$$(X + \mu\Pi_{22}^{-1})^T\Pi_{22}(X + \mu\Pi_{22}^{-1}) \leq 0 \Leftrightarrow X\Pi_{22}\mathrm{X} \leq -2\mu X - \mu^2\Pi_{22}^{-1} \tag{20}$$

where $\mu$ is a scalar.

By substituting (20) into (19) and using the Schur complement Theorem, then (19) holds if the following inequality holds:

$$\begin{bmatrix} P_1^{-1}\Pi_{11}P_1^{-1} & P_1^{-1}\Pi_{12}X & 0 \\ X\Pi_{12}P_1^{-1} & -2\mu X & \mu I \\ 0 & \mu I & \Pi_{22} \end{bmatrix} < 0 \tag{21}$$

After substitution for $\Pi_{11}, \Pi_{12}, \Pi_{12}, \Pi_{22}$ from (18) and by simple manipulation, the LMI in (12) is obtained. This completes the proof.

## IV. SIMULATION RESULTS

The simulation of the proposed T-S fuzzy observer based sensor FTC design is based on the wind turbine benchmark system described in [2]. The drive train subsystem is modelled by a two-mass system assuming a flexible low speed shaft. The model is implemented with band-limited measurements noise. The generator sensor faults are represented by two scale factor errors. The scale factors of 1.1 & 0.9 are multiplied by the simulated real generator rotational speeds. The expected fault effects would be a deviation of the wind turbine from the optimal operation.

**Remark2:** Without loss of generality, the output matrix parametric fault presented in wind turbine benchmark model [2] can be represented as an additive fault in which the fault signal depends on the measured state, as illustrated below:

$$y_f = C_f x = \begin{bmatrix} 1 & 0 \\ 0 & 0.9 \end{bmatrix}\begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = Cx + \begin{bmatrix} 0 \\ 1 \end{bmatrix}(-0.1 * x_2) \tag{22}$$

Hence, parameter changes in the output matrix $C$ can be considered as a special case of additive faults in which the fault signal $(f_s)$ is a scaled version of the measured state.

**Remark3:** The sensor fault considered has a direct effect on the wind energy conversion efficiency since the controller starts to drive the wind turbine away from its optimal operation. Noticeably, in spite that this fault involves no damage risk, a study presented in [13] shows that a specific wind turbine operation in a 100 MW rated wind farm and operating with a realistic 35% capacity factor can generate about 307 GWh of energy in a given year. If the cost of the energy is \$0.04 per kWh, each GWh is worth about \$40,000, meaning that a 1% loss of energy on this wind farm corresponds to a loss of \$123,000 per year.

Fig. 2 shows the expected effects of the sensor bias fault on the power conversion efficiency. In fact, this sensor fault scenario simulates the effect of $C_p$ uncertainty encountered in the standard control law since in both cases the control signal drives the turbine away from the optimal trajectory.

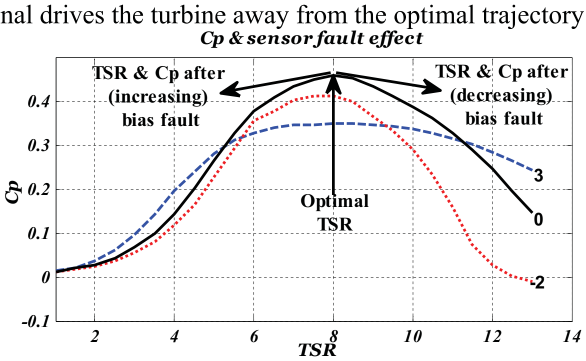

**Figure 2:** Effects of bias sensor fault on $C_p$ [$\boldsymbol{\beta}$=-2, 0, 3]

Fig. 3 shows how the wind turbine operation is affected by the two fault scenarios and helps to illustrate the success of the proposed strategy to tolerate the effects of the sensor faults, maintaining optimal wind turbine operation.

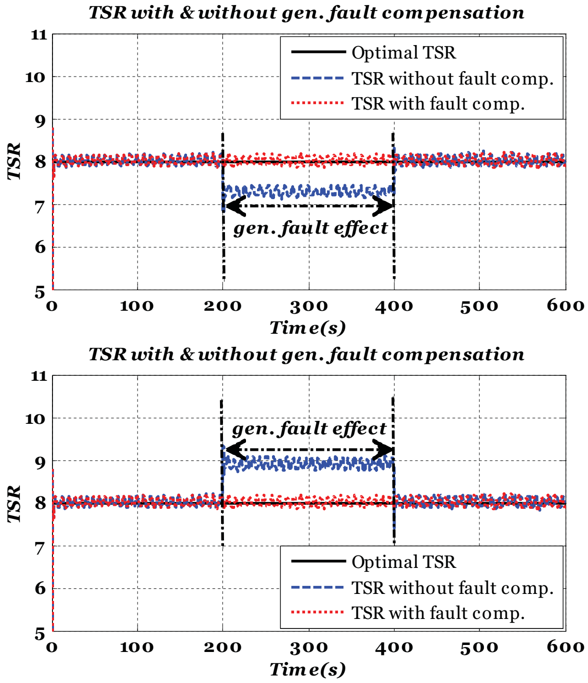

**Figure 3:** Effect of 1.1 (upper) and 0.9 (lower) sensor bias faults with(out) fault compensation

It is clear that the 1.1 bias sensor fault causes a deceleration of $\omega_r$ & $\omega_g$. Based on the faulty measurement the controller forces the turbine to reduce the rotational speed by increasing the reference generator torque which in turn increases the drive train load. This fault scenario is shown in Fig. 5 without sensor fault compensation.

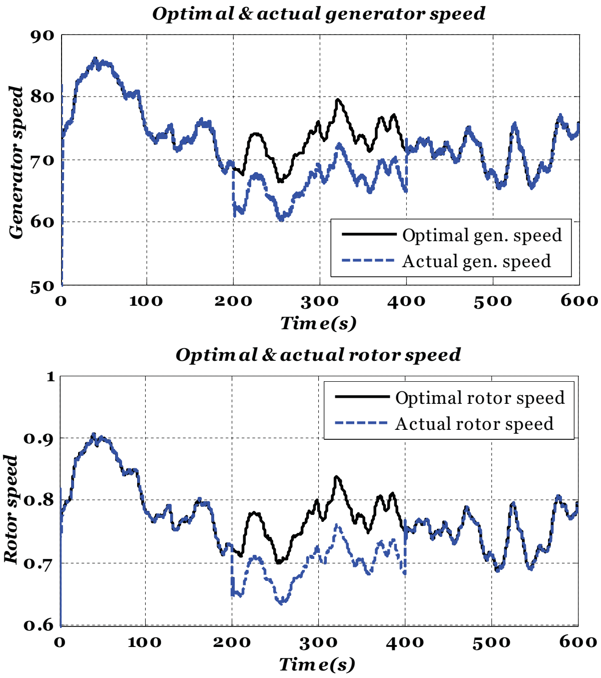

**Figure 4:** 1.1 sensor bias fault decelerate $\boldsymbol{\omega_r}$ & $\boldsymbol{\omega_g}$

On the other hand Fig. 6, shows the time variations of $\omega_r$ & $\omega_g$ in response to the proposed sensor FTC strategy.

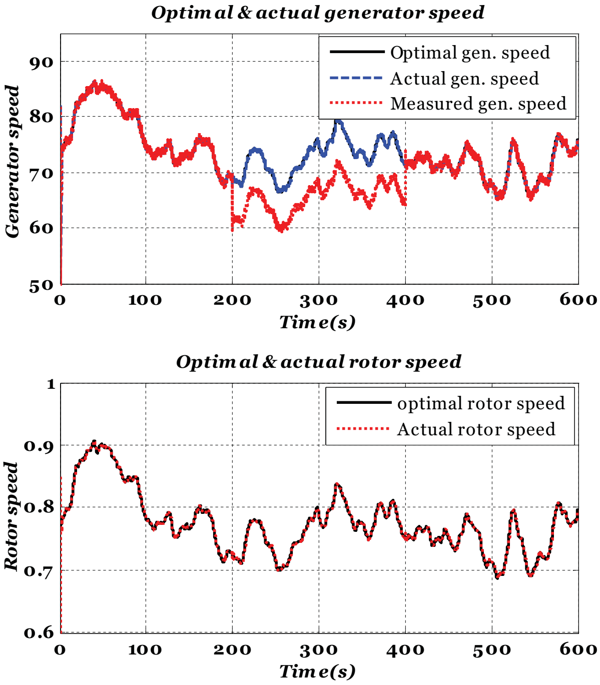

**Figure 5:** Actual and optimal $\boldsymbol{\omega_r}$ & $\boldsymbol{\omega_g}$ using the proposed sensor FTC strategy

Conversely, the 0.9 bias sensor fault causes acceleration of $\omega_r$ & $\omega_g$ since, based on faulty measurement; the controller releases the aerodynamic subsystem to rotate according to the available wind speed. Fig 7 shows the effect of the 0.9 sensor fault without compensation.

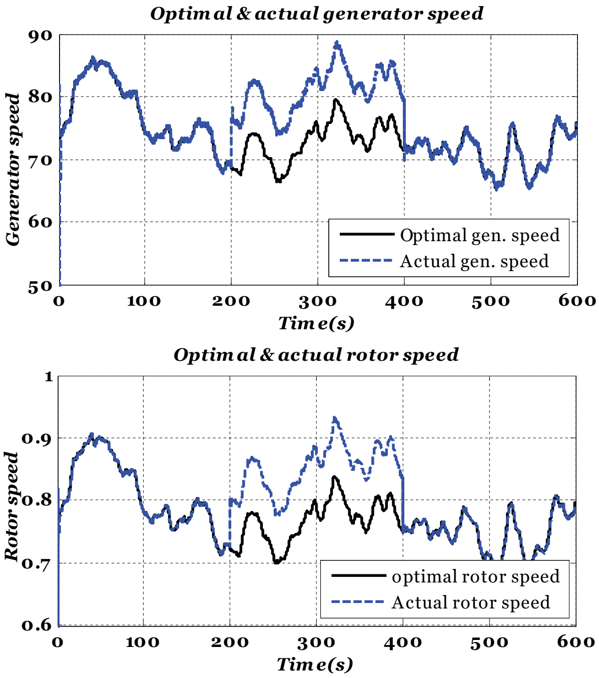

**Figure 6:** 0.9 sensor bias fault accelerate $\boldsymbol{\omega_r}$ & $\boldsymbol{\omega_g}$

The fault estimation signals for both sensor fault scenarios are shown in Fig.7.

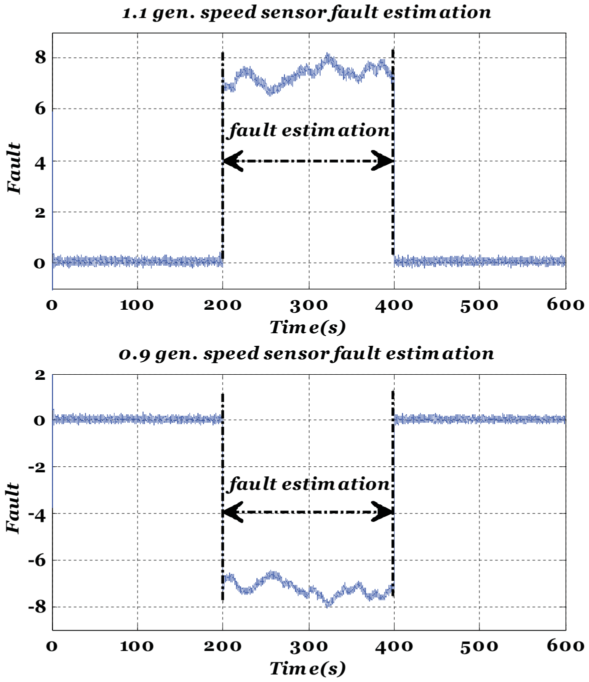

**Figure 7:** Estimation of 1.1 (upper) and 0.9 (lower) sensor bias faults

The use of the PMIO can also help to produce information about the severity of each fault. This is achieved through taking the ratio between the measured generator speed and the estimated signal. Hence, if there are no faults the ratio should be 1 otherwise any deviation from unity indicates the occurence of the fault and the magnitude of the deviation represents the fault severity. Fig. 8 shows the fault evaluation signal for both fault scenarios.

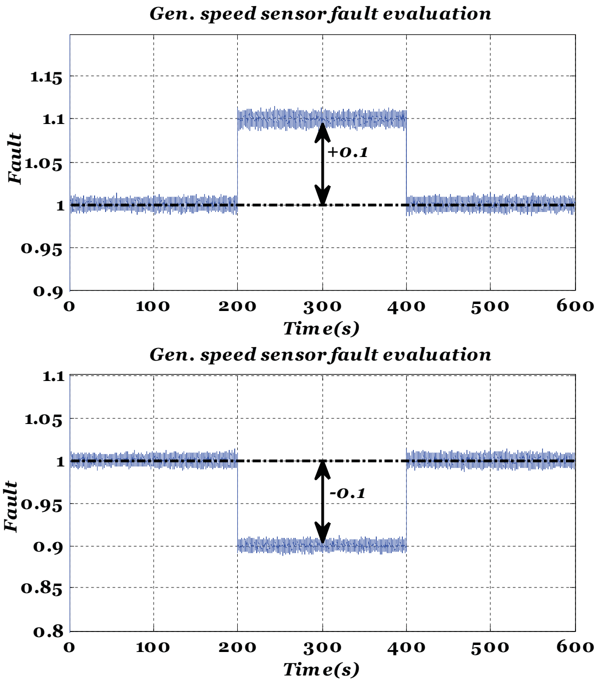

**Figure 8:** Deviation of 1.1 (upper) and 0.9 (lower) sensor measurement from unity

**Remark4:** Note that maintaining state estimation without changes during the whole range of operation is due to the fact that the PMIO perform *implicit fault estimation and compensation* of sensor fault from the input of PMIO. This fact is clearly interpreted from the error signal $(y_a - C_a\hat{x}_a)$ which can be rewritten as $(\bar{C}\bar{x} + \bar{D}f_s - \bar{C}\hat{\bar{x}} - \bar{D}\hat{f}_s)$, then as long as there are no sensor faults, $\hat{f}_s = 0$. However, once a sensor fault occurs the fault estimation $\hat{f}_s$ compensates the effect of the fault signal $f_s$ and hence the observer always receives a fault-free error signal.

## V. CONCLUSION

OWTs are complex and nonlinear systems that are driven by a stochastic and uncontrollable wind force and require a high degree of reliability and availability (sustainability). OWTs are also characterised by expensive and/or safety critical maintenance work. The main challenges for the deployment of wind turbine systems are to maximise the amount of good quality electrical power extracted from wind energy over a significantly wide range of weather conditions and minimise both manufacturing and maintenance costs. This paper has shown that active FTC can be of potential benefit as a very suitable solution for ensuring wind turbine reliability and sustainability requirements, particularly for offshore wind farms. This is illustrated through the use of the T-S extension to the well known PMIO fault estimation method in the observer based control strategy. However, OWTs are derived by uncontrollable signal in the form of effective wind speed which is not precisely measured due to the large vertical profile of blade swept area. Therefore, robustness of the FTC against this uncertain measurement is the direction of future work. Moreover, tolerate the effect of simultaneous actuator and sensor faults is the other direction of research in this field.

***Abstract*—Work presented in this paper studies the potential of employing inerters –a novel mechanical device used successfully in racing cars– in active suspension configurations with the aim to enhance railway vehicle system performance. The particular element of research in this paper concerns railway wheelset lateral stability control. Controlled torques are applied to the wheelsets using the concept of absolute stiffness. The effects of a reduced set of arbitrary passive structures using springs, dampers and inerters integrated to the active solution are discussed. A multi-objective optimisation problem is defined for tuning the parameters of the proposed configurations. Finally, time domain simulations are assessed for the railway vehicle while negotiating a curved track. A simplification of the design problem for stability is attained with the integration of inerters to the active solutions.**

***Index Terms*—Railway vehicles, wheelsets stability control, absolute stiffness, active suspensions, inerter.**

## I. Introduction

A range of challenges is present in the design of modern railway vehicles, which are rather complex mechanical systems. Over the past thirty years, the use of sensors, electronic controllers, and actuators technology has enabled important changes in modern trains to deal with some of those difficulties hence enhancing vehicle system performance capabilities. In this context, the introduction of "active suspension" solutions, either in complementing or replacing conventional passive suspensions, did play a major role [1]. Conventional passive suspensions, via the vehicle geometry, both define important vehicle dynamics characteristics and are subject to operational constraints and limitations mainly due to the mechanical setup (e.g. combinations of springs, dampers, or pneumatic suspensions, and related mechanical linkages).

Admitting the role of passive suspensions as mechanical compensators of the vehicle's bodies dynamic interaction, a dominant factor in the overall performance results is in the type of structures that can be synthesised using simple elements like springs and dampers. Moreover, the nature of passive suspensions constrains the set of variables available for mechanical feedback. This highly determines the kind of resultant forces applied on the bodies and may cause some undesirable coupling between the system modes.

The use of active suspensions, i.e. usually the introduction of a controlled force-element (actuator), does offer enhanced suspension performance and some flexibility in the way the suspension structure evolves (actuator location and characteristics). However, this approach introduces the issue of energy consumption of the controlled element. Dynamic performance encompasses the problems associated to ride quality, dynamic stability and response to track features (e.g. curved sections of the rail track), for which active suspensions have been shown to facilitate higher speed and/or reduced track interaction [2]. Notwithstanding that active technologies cover a wide range of solutions for railway vehicles dynamic, passive compensation possibilities have grown with the introduction of the *inerter* [3]. The inerter is a novel concept and mechanical device with kinetic energy storage capabilities. This concept has been employed in automotive applications (being very successful in Formula 1 $^{\text{TM}}$ cars [4]), in motorcycles [5] and in building suspension control [6]. Also, there have been recent discussions on the use of inerters in pure passive railway suspension performance enhancement (see for example [7]).

This paper studies an approach that is different to the ones arising from current literature on inerters for railway vehicles. In particular, it investigates the performance merits of introducing the inerter together with the concept of active stability control of wheelsets via the absolute stiffness approach [8].

## II. Railway vehicle dynamics

Motions in a railway vehicle normally accept a certain degree of separation for suspension design and performance assessment purposes (for a typical railway vehicle schematic refer to Fig. 1). The study in this paper concerns wheelset stability control, and hence the modelling refers to only the lateral and yaw vehicle dynamic characteristics. Lateral and yaw motions are usually controlled by primary suspensions,

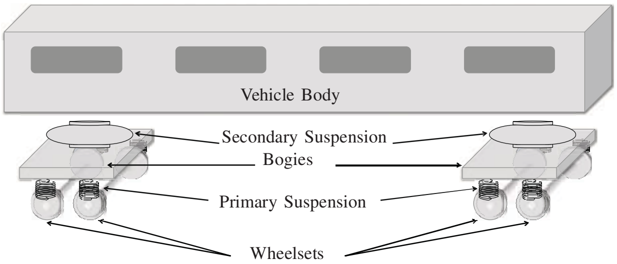

Fig. 1. Bodies and suspension stages of a railway vehicle.

with the main concern being the vehicle running behaviour at the wheel-rail interface, for which a design conflict between the vehicle stability and curving performance exists. Bruni et al. [2] presented a survey on the concepts and trends on active suspensions, where a detailed description of the control strategies for active primary suspensions is provided. They explain the essential kinematic instability of the solid axle wheelsets of the railway vehicle. Active solutions based on either lateral or yaw actuation controlled by feedback of yaw angles or lateral velocities re-locate the unstable poles of the wheelsets to the stable semi-plane. Yaw damping, both relative and absolute yaw stiffness, and lateral damping are some of the previously studied and widely known stabilising solutions in this field. The current study considers the application of relative yaw stiffness with the use of novel mechanical devices, in the search for complementing the active control strategy based on absolute yaw stiffness. The design of both structures is integrated so that they provide a synergetic solution.

Besides stability, the forces emerging from the wheel-rail interface when wheelsets negotiate curved tracks impose additional requirements to the design, albeit the control solutions for this aim are normally separated from the stability solutions. Steering control is dedicated to the ‘perfect curving’ [2], targeting: a) equal lateral creep forces on all the wheelsets to minimise track shifting forces, and b) zero steady-state longitudinal creep forces on all wheelsets. Some lateral creep is required in order to provide the necessary force to counterbalance the centrifugal force on curves [9], while longitudinal creep forces are associated to wear and noise and thus the requirement design is to significantly reduce them. Some steering solutions are also summarised in [2].

This paper assesses the curving behaviour as an outcome of the synergy between novel passive and active solutions designed for stability. Although some conditions in the overall design are established in regard to the steering problem, it is not defined as control objective for the active solution.

## III. Mathematical model of the system

The mathematical model approximating the lateral and inherent dynamics of a railway vehicle can be described by linear differential equations. The modelling is based upon the plan-view schematic representation presented in Fig.1. The use of linearised models is a normal practice in the design of active controllers, justified by the fact that active solutions reasonably overcome the effects of nonlinearities associated with the rail-wheel contact effects and other sources of nonlinear behaviour [10], in particular avoiding significant contact between the wheel flange and the rail. The mathematical description employed here for the assessment of a railway vehicle stability control corresponds to half of the vehicle comprising a two-axle bogie and half vehicle body. Primary and secondary suspensions in the vehicle provide the vertical linkages between the solid-axle wheelsets and the bogie frame, and the bogie frame and the vehicle body, respectively (Fig. 1). In the model, the lateral and longitudinal stiffness of the primary suspension are considered. Although the lateral primary damping is also modelled, the longitudinal is neglected. Likewise, the lateral stiffness and damping of the secondary suspension are included. The wheelsets consist of two wheels with conical profile rigidly joined together through a common axle, for which a nominal —ideally invariable— conicity coefficient, $\lambda$, and radius, $r_0$, are assumed. Rail/wheels interaction is taken into account through the longitudinal and lateral creep forces with ideally constant creep coefficients, $f_{11}$, and $f_{22}$. The creep forces arise at the contact points as consequence of the difference in strain rates of the wheels and the track (Fig. 2) –see Garg and Dukkipati [11] for an extended explanation. For every wheelset, those are given by:

$$F_x = 2 f_{11} l_{wy} \left( \frac{1}{R} - \frac{1}{V} \dot{\theta}_w \right) - \frac{2 f_{11} \lambda}{r_0} \left( y_w + y_t \right) \qquad (1)$$

$$F_y = -2 f_{22} \left( \frac{\dot{y}_w}{V} - \theta_w \right) \qquad (2)$$

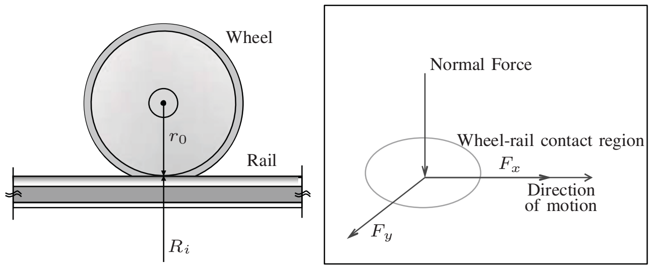

Fig. 2. Left: principal wheel and rail radii of curvatures. Right: Longitudinal and lateral creep forces.

Table I lists the parameters and the corresponding numerical values, while the schematic diagram of a wheelset is shown in Fig. 3. The differential equations (3)-(8) represent the dynamics of the seven degrees-of-freedom of the vehicle, namely: the lateral displacement and yaw angle of the wheelsets, respectively $y_{wi}$ and $\theta_{wi}$ for $i$=1, 2 (1: front, 2: rear), and the bogie, respectively $y_b$ and $\theta_b$, and also the vehicle body lateral motion $y_v$. This model with the default parameters values is equivalent to that used by Jiang et al. [12], except for the disregarded longitudinal primary damping and that the steering

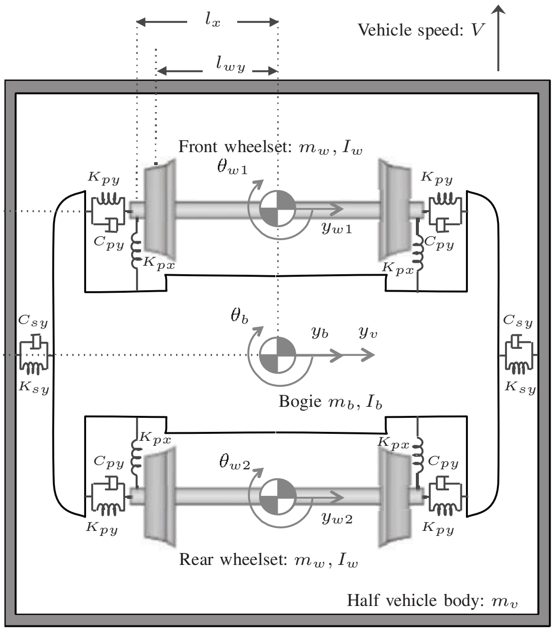

Fig. 3. Plan-view of the railway vehicle.

TABLE I
NOMINAL PARAMETERS VALUES OF THE HALF-VEHICLE MODEL

| Symbol | Description |
|---|---|
| $V$ | Vehicle speed ($55\text{ms}^{-1}$) |
| $m_w$ | Wheelset mass (1376 kg) |
| $I_w$ | Wheelset yaw inertia (766 kgm$^2$) |
| $m_g$ | Bogie frame mass (3477 kg) |
| $I_g$ | Bogie frame yaw inertia (3200 kgm$^2$) |
| $m_v$ | Half vehicle body mass (17230 kg ) |
| $r_0$ | Wheel radius (0.445 m) |
| $\lambda$ | Wheel conicity (0.3) |
| $f_{11}$ | Longitudinal creepage coefficient ($10^7$ N) |
| $f_{22}$ | Lateral creepage coefficient ($10^7$ N) |
| $l_{wx}$ | Semi-longitudinal spacing of wheelsets (1.225 m) |
| $l_{wy}$ | Half gauge of wheelset (0.75 m) |
| $l_x$ | Semi-lateral spacing of steering linkages and primary longitudinal suspension (1.2 m) |
| $K_{px}$ | Primary longitudinal stiffness per axle box ($10^6$ Nm$^{-1}$) |
| $K_{py}$ | Primary lateral stiffness per axle box ($4.71 \times 10^6$ Nm$^{-1}$ ) |
| $C_{py}$ | Primary lateral damping per axle box ($1.2 \times 10^4$ Nsm$^{-1}$ ) |
| $K_{sy}$ | Secondary lateral stiffness per axle box ($2.45 \times 10^5$ Nm$^{-1}$) |
| $C_{sy}$ | Secondary lateral damping per axle box ( $2 \times 10^4$ Nsm$^{-1}$) |
| $R_i$ | Radius of the curved track (1000 m) |
| $\theta_{c,i}$ | Cant angle of the curved track ( $6 \times \pi/180$ rad) |
| $g$ | Gravity (9.81ms$^{-2}$) |

linkage is not included.

$$\begin{aligned}
m_w\ddot{y}_{w,i} =& 2K_{py}\left(y_b + (-1)^{i-1}\, l_{wx}\theta_b - y_{w,i}\right) + \ F_{y,i} \\
& + 2C_{py}\left(\dot{y}_b + (-1)^{i-1}\, l_{wx}\dot{\theta}_b - \dot{y}_{w,i}\right) \qquad (3)\\
I_w\ddot{\theta}_{w,i} =& \ 2K_{px}l_x^2\left(\theta_b - \theta_{w,i}\right) + l_{wy}F_{x,i} \\
& + 2\, l_x^2 F_{pn,i} + \tau_{u,i} \qquad (4)\\
m_b\ddot{y}_b =& \ 2K_{py}\left(y_{w1} + y_{w2} - 2y_b\right) + 2K_{sy}\left(y_v - y_b\right) \\
& + 2C_{py}\left(\dot{y}_{w1} + \dot{y}_{w2} - 2\dot{y}_b\right) + 2C_{sy}\left(\dot{y}_v - \dot{y}_b\right) \\
& + \frac{m_b V^2}{2}\left(\frac{1}{R_1} + \frac{1}{R_2}\right) - m_b g\left(\frac{\theta_{c1} + \theta_{c2}}{2}\right) \qquad (5)\\
I_b\ddot{\theta}_b =& \ 2K_{py}l_{wx}\left(y_{w1} - y_{w2} - 2l_{wx}\theta_b\right) \\
& + 2K_{px}l_x^2\left(\theta_{w1} + \theta_{w2} - 2\theta_b\right) \qquad (6)\\
& + 2C_{py}l_{wx}\left(\dot{y}_{w1} - \dot{y}_{w2} - 2l_{wx}\dot{\theta}_b\right) \\
& - 2\, l_x^2\left(F_{pn1} + F_{pn2}\right) - \tau_{u1} - \tau_{u2} \qquad (7)\\
m_v\ddot{y}_v =& \ 2K_{sy}\left(y_b - y_v\right) + 2C_{sy}\left(\dot{y}_v - \dot{y}_v\right) \\
& + \frac{m_v V^2}{2}\left(\frac{1}{R_1} + \frac{1}{R_2}\right) - \frac{m_v g}{2}\left(\theta_{c1} + \theta_{c2}\right) \qquad (8)
\end{aligned}$$

It is noticeable from the model above that the suspensions in the longitudinal direction affect the wheelsets and bogie yaw mode only. This is explained by the symmetric allocation of those suspensions in the plane with respect to the centre of gravity of the bogie and every wheelset. That partly justifies the structure of the active control configuration exposed later.

For simulations and optimisation purposes, the state-space representation of this open-loop model was derived as

$$\begin{aligned}
\dot{x} =& A\,x + B\,u + B_\eta\,\eta \\
y_o =& C_o x \\
y_m =& C_m x \qquad (9)
\end{aligned}$$

with

$$\begin{aligned}
x =& [\dot{y}_{w1},\, y_{w1},\, \dot{\theta}_{w1},\, \theta_{w1},\, \dot{y}_{w2},\, y_{w2},\, \dot{\theta}_{w2},\, \theta_{w2},\, ... \\
& \dot{y}_b, y_b, \dot{\theta}_b, \theta_b, \dot{y}_v, y_v]^T \\
u =& [\tau_{u1},\, \tau_{u2},\, F_{pn1},\, F_{pn2})^T \\
\eta =& [{}^1\!/R_1,\, \theta_{c1},\, y_{t1},\, {}^1\!/R_2,\, \theta_{c2},\, y_{t2}]^T \\
y_o =& [F_{x1},\, F_{x2},\, F_{y1},\, F_{y2}]^T \\
y_m =& [\theta_{w1},\, \theta_{w2},\, \dot{\theta}_b - \dot{\theta}_{w1},\, \dot{\theta}_b - \dot{\theta}_{w2}]^T,
\end{aligned}$$

where $u$ is the vector of the active and passive control inputs applied to the system, $\eta$ are the exogenous inputs from the railway track, $y_o$ are the outputs related to the performance of the excited system, and $y_m$ are the variables/measurements to be fed back through the passive and active control configurations described in this paper.

## IV. ABSOLUTE STIFFNESS FOR STABILITY CONTROL

Highly stiff passive connections in the longitudinal direction between every axle and the bogie frame of a railway vehicle are known to provide the required levels of wheelset stability at high speeds on straight tracks [1]. However, since the bogie is relatively light, the two wheelsets and bogie become strongly coupled. The consequence is that an even higher longitudinal stiffness is necessary to achieve satisfactory stability levels, but because this stiffness also affects curving performance there is an increase in wheel and rail wear.

Mei and Goodall in [8] presented a more effective implementation for stiffness-based stabilisation in contrast with the conventional passive stiffness, the absolute stiffness *–skyhook stiffness* approach. This is an active configuration in which a longitudinal/yaw force/torque proportional to the high-pass filtered absolute wheelset yaw angle is applied between every wheelset and the bogie frame. The strategy decouples the wheelsets dynamic, preventing their stability being affected by the bogie dynamic and hence overcoming the complexity of the wheelsets stabilisation due to the wheelsets and bogie interaction. As pointed out by Mei and Goodall [8] the use of pure absolute yaw stiffness would cause problems for curving, so the high-pass filtering is necessary. In this manner absolute stiffness is an appealing solution to the stability problem.

The implementation of the strategy in this approach consists of the measurement of the wheelsets' yaw angles, which are filtered using individual second order high-pass filters of the same cut-off frequency, and are fed-back through a proportional controller to the respective actuators mounted between the wheelsets axles and the bogie frame applying the control torques, as represented in Fig. 4 and Eq. (10):

$$\hat{\tau}_{u,i}{=}-K_u \left( \frac{s^2/(2\pi f_c)^2}{s^2/(2\pi f_c)^2 + 1.414\, s/2\pi f_c + 1} \right) \hat{\theta}_{w,i} \qquad (10)$$

The controllable realisation of (10) is obtained in $A_\tau$, $B_\tau$, $C_\tau$, $D_\tau$ for a definition of the individual sub-systems (i.e. front—$i = 1$ and rear—$i = 2$ controllers) in the state-space as

$$\begin{aligned} \dot{x}_{\tau,i} &= A_\tau\, x_{\tau,i} + B_\tau\, \theta_{w,i} \\ \tau_{u,i} &= C_\tau\, x_{\tau,i} + D_\tau\, \theta_{w,i} \end{aligned} \qquad (11)$$

Variants of the implementation would be the estimation of the wheelsets yaw angle if the physical measurements are difficult to obtain, and/or to use linear actuators in the longitudinal direction instead of rotational ones. In this paper, the availability of the measurements and ideal actuators were supposed. Note, however, that Mei and Goodall [8] explain how a robust yaw gyro might effectively be used to derive the high-pass filtered yaw angle. Also in [8] Mei and Goodall point out the analogy between absolute stiffness and a "skyhook spring", i.e. a spring virtually connected between the wheelset and the "sky". As the authors noted in their paper [8], the analogy is not exact since in any practical implementation through a linear or rotational actuator there must be an equal and opposite reaction/force between the wheelset and bogie. The true reaction forces/torques are shown in Fig. 4 and implemented in the dynamic equations (3)-(8).

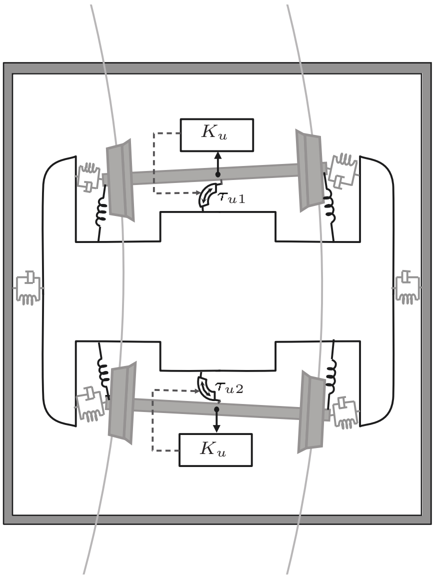

Fig. 4. Absolute stiffness stability control.

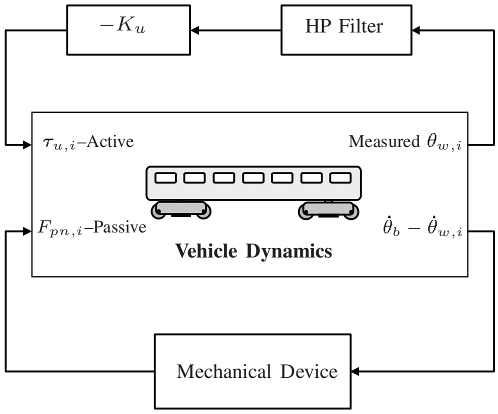

Fig. 5. Block diagram representation of absolute stiffness and novel mechanical devices integration.

## V. Absolute stiffness control and inerters

In this research, there is an interest on studying the potential of creating a synergy between passive and active solutions for railway vehicles dynamics, especially with the use of inerters, a recent concept in mechanical devices. Thereby, in combination with the active stability control strategy exposed above, different passive suspensions allocated in the longitudinal direction are proposed as represented in Fig. 5. The objective is to enhance the active solution through arbitrary passive networks, for which a cooperation between the two schemes is desirable to increase the possibilities of guaranteeing stability using absolute stiffness.

In the previous section, a description of two solutions for the bogie stability problem was provided, based on the use of passive and active stiffness. After having exposed that one of the major difficulties of applying either yaw or longitudinal stiffness alone between the wheelsets and the bogie is the response during curving, a frequency-based focus is provided

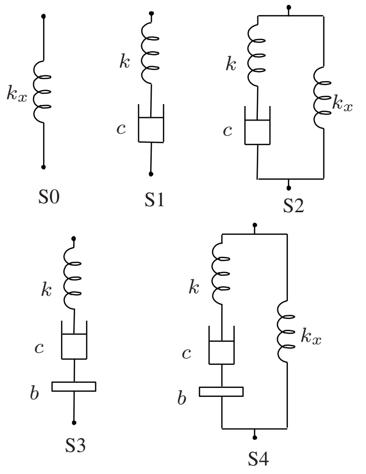

Fig. 6. Candidate suspension layouts.

in this section to introduce the role of more extensive passive suspensions.

In general, rail geometry characteristics in the lateral direction can be separated into high frequency for stochastic irregularities (predominant in straight tracks), and low frequency for curves. In fact, for the application of absolute stiffness it was already mentioned that high-pass filtering would alleviate the issues arising on curving. From the control perspective, the frequency response of mechanical suspensions is clearly a distinctive fact. For example, a linear spring has a flat frequency response to relative displacements between its terminals; this has a counterpart for the vehicle's behaviour which was identified earlier in this paper. In that sense, a non arbitrary range of passive networks can be designed using springs and dampers only to 'relax' the longitudinal stiffness at certain frequencies. However, the possibilities are reduced in the design of convenient configurations. A wider freedom on the design of passive suspensions using simple mechanical elements properties was given by the introduction of the inerter concept.

An inerter is a two-terminal mechanical device analogous to an ungrounded capacitor in an electric circuit, according to the force-current analogy, as described by Smith in [3]. It develops a linear force at its terminals which is proportional to the relative acceleration across them. It was termed by Chen et al. [4] to be 'the missing mechanical element' required to complete the referred analogy with electric networks using resistors, inductors and capacitors only, for which arbitrary passive impedances can be synthesised. In this manner, the inerter extends the possibilities in the synthesis of mechanical impedances and equivalently allows the formulation of arbitrary frequency characteristics with the unique constraint being on positivity requirements [3].

In this study, simple layouts using springs, dampers and inerters are examined. The candidate layouts basically consider the introduction of a novel mechanical device in the longitudinal plane with different stiffness according to the excitation frequency, augmenting the longitudinal stiffness already provided by the primary suspensions. Those are represented in Fig. 6, for which the parameter $b$ is the inertance property of the inerter, with units given in kilograms. $c$, $k$, and $k_x$ stand for normal damping and stiffness design parameters. The passive forces applied on the wheelsets and the bogie are characterised by the candidate layouts complex mechanical admittance $\mathrm{Y}_{pn}$(see [3]) as follows

TABLE II
COMPLEX ADMITTANCE OF THE CANDIDATE LAYOUTS IN FIG. 6

| Layout | Complex Admittance, $\mathrm{Y}_{pn}(s)$ |
|---|---|
| S0 | $\frac{k_x}{s}$ |
| S1 | $\frac{c}{c/k\ s+1}$ |
| S2 | $\frac{k_x}{s}+\frac{c}{c/k\ s+1}$ |
| S3 | $\frac{b\ s}{b/k\ s^2+b/c\ s+1}$ |
| S4 | $\frac{k_x}{s}+\frac{b\ s}{b/k\ s^2+b/c\ s+1}$ |

$$\hat{F}_{pn,i}=\mathrm{Y}_{pn}s\left(\theta_b-\theta_{w,i}\right) \tag{12}$$

The complex admittance of every layout is given in Table II. For every passive layout, the controllable canonical form was obtained in $A_{pn}$, $B_{pn}$, $C_{pn}$, $D_{pn}$, which is common to the two subsystems generating the longitudinal forces $F_{pn1}$ and $F_{pn2}$ in response to $\dot{\theta}_b-\dot{\theta}_{w1}$ and $\dot{\theta}_b-\dot{\theta}_{w2}$, respectively, and with states vectors $x_{pn1}$ and $x_{pn2}$ .

Although this reduced selection of passive structures does not allow to generalise on the effect of the inerter in passive longitudinal suspensions combined with active yaw control, it identifies the potential of the inerter in this proposed synergy.

## VI. Optimisation of parameters and performance assessment

Once the structure of the controllers has been established, both active and passive, a multi-objective optimisation problem was formulated on the closed-loop system represented in the state-space as

$$\begin{aligned}\dot{x}_{cl}&=\mathcal{A}x_{cl}+\mathcal{B}_\eta\eta\\ y_{cl}&=\mathcal{C}x_{cl}\end{aligned} \tag{13}$$

for the augmented state vector

$$x_{cl}=\left[x^T\middle|x_{\tau1}^T\middle|x_{\tau2}^T\middle|x_{pn1}^T\middle|x_{pn2}^T\right]^T, \tag{14}$$

and the output vector $y_{cl}=y_o$ re-written accordingly. The closed-loop system's matrices are defined as

$$\begin{aligned}\mathcal{A}&=\left[\begin{array}{c|c}A+B\,\Lambda_D^uC_m & B\,\Lambda_C^u\\ \hline \mathcal{A}_{21} & \Lambda_A^u\end{array}\right],\\ \mathcal{B}&=\left[\begin{array}{c|c|c|c}B_\eta^T & 0 & 0 & 0\end{array}\right]^T,\text{and}\\ \mathcal{C}&=\left[\begin{array}{c|c|c|c}C_o & 0 & 0 & 0\end{array}\right],\end{aligned}$$

with

$$\begin{aligned}\Lambda_A^u =& \text{diag}\left(A_\tau,\, A_\tau,\, A_{pn},\, A_{pn}\right)\\ \Lambda_C^u =& \text{diag}\left(C_\tau,\, C_\tau,\, C_{pn},\, C_{pn}\right)\\ \Lambda_D^u =& \text{diag}\left(D_\tau,\, D_\tau,\, D_{pn},\, D_{pn}\right),\end{aligned}$$

and

$$\mathcal{A}_{21}=\left[\, C^T_{m(1,*)}B^T_\tau \middle| C^T_{m(2,*)}B^T_\tau \middle| C^T_{m(3,*)}B^T_{pn} \middle| C^T_{m(4,*)}B^T_{pn} \,\right]^T.$$

The "zero" entries in the matrix definitions are zero vectors/matrices of appropriate dimension, and $C^T_{m(i,*)}$ corresponds to the $i$-th row of the matrix $C_m$ in (9).

In the stability problem devised for optimisation, two additional design objectives compromise the optimum stability: the minimisation of the active control gain and the minimisation of the fixed parallel stiffness $k_x$ for the layouts S0, S2 and S4. With this, one aims to determine whether or not the use of passive suspensions with inerters allows the reduction of the control gain and to improve the vehicle's performance while curving. The objective for an optimum stability was defined as the maximisation of the least damping ratio among the kinematic modes of the vehicle at a particular travelling speed of V=55ms$^{-1}$ (approx. 200km/h).

The Matlab® genetic algorithms (GA) toolbox was utilised to solve the trade-off emerging from this multiple goals formulation. The tuning parameters in the problem were: the control gain, $K_u$, the cut-off frequency of the high-pass filter, $f_c$, and the stiffness, damping and inertance parameters according to each individual candidate layout. Reasonable values for the physical constraints on the parameters were supplied to the algorithm. Because the optimum stability definition for the nominal speed does not necessarily account for lower speeds stability, a penalty was included in the stability cost function based on dismissing the parameter set for which the vehicle was unstable at the particular speed of 5ms$^{-1}$. Even though it does not avoid instability for all the speeds below the nominal, it does provide certain level of control on the stability along the evaluated range of speeds without significantly affecting the optimal tuning for the nominal speed. Indeed, with this procedure, levels of instability –possibly unrealistic– occur only for very low speeds which are transitional for a high-speed train running at normal conditions.

### A. Optimal stability

For the stability control design, the vehicle was considered to travel on a straight track, i.e. the curved track radius $R_i \rightarrow \infty$, and consequently also zero cant angle, $\theta_{c,i}$, for $i$=1, 2 (radius and cant angle measured at the front and rear wheelsets positions). The 3D plot in Fig. 9 shows the best population attained with genetic algorithms for those candidate layouts including $k_x$. It evidences the conflict between the three objectives defined in the study. The 3D plot reveals how the inerter simplifies the optimisation problem resulting with longitudinal stiffness values, $k_x$, between $0 - 2\times10^6$Nm$^{-1}$, and control gain values, $K_u$, between $(10-20)\times10^6$. Conversely, for the suspensions S0 and S1 the algorithm encountered different settings providing the same stability level with greater variability in the components parameters values. Decisions on the optimisation results are compiled in Table III, indicating also the best value for the least damping ratio, $\zeta_c$, at the design speed. The choice of the best set of parameters was arbitrarily done on the highest stability index value, $\zeta_c$. For those suspensions without the inerter the optimum set was chosen to be the one with the highest level of stability and lowest stiffness. For S3 and S4 the best stability resulted for a single set of parameters in every case, thus those were the chosen for comparisons. Because the values of $k_x$ and $K_u$ are reasonable, this method of choosing the best settings focused mostly on the degree of stability. Achievements are contrasted with the default passive configuration in Fig. 3 (equivalent to S0 with $k_x = 0$) with active stability control.

TABLE III
PARAMETERS VALUES FROM THE OPTIMISATION

| **Configuration** | $\zeta_c$ [%] | **Active Optimal parameters** | **Passive Optimal parameters** |
|---|---|---|---|
| Default Active | 20.6 | $K_u = 1.37\times10^7$<br>$f_c = 0.001$ Hz | N/A |
| Active and S0 | 20.6 | $K_u = 2.28\times10^7$<br>$f_c = 0.70$ Hz | $k_x = 6.39\times10^6$ Nm$^{-1}$ |
| Active and S1 | 20.7 | $K_u = 1.57\times10^7$<br>$f_c = 0.03$ Hz | $k_x = 0$,<br>$c = 6.42\times10^5$ Nsm$^{-1}$,<br>$k = 2.20\times10^6$ Nm$^{-1}$ |
| Active and S2 | 20.8 | $K_u = 4.94\times10^7$<br>$f_c = 0.76$ Hz | $k_x = 7.16\times10^6$ Nm$^{-1}$,<br>$c = 58.83\times10^5$ Nsm$^{-1}$,<br>$k = 2.55\times10^6$ Nm$^{-1}$ |
| Active and S3 | 21.2 | $K_u = 1.89\times10^7$<br>$f_c = 0.34$ Hz | $k_x = 0$,<br>$c = 6.13\times10^5$ Nsm$^{-1}$,<br>$b = 9.98\times10^4$ kg,<br>$k = 2.55\times10^6$ Nm$^{-1}$ |
| Active and S4 | 23.2 | $K_u = 1.91\times10^7$<br>$f_c = 0.28$ Hz | $k_x = 0.78\times10^6$ Nm$^{-1}$,<br>$c = 5.83\times10^5$ Nsm$^{-1}$,<br>$b = 6.84\times10^5$ kg,<br>$k = 2.77\times10^6$ Nm$^{-1}$ |

A classification of the candidate structures in Fig. 6 was done in two groups, A and B, for the presentation of the results: group A comprising novel devices without a fixed stiffness in parallel, i.e. S1 and S3, and group B consisting of novel devices with additional stiffness in parallel, i.e. S0, S2, and S4. The plots for $\zeta_c$ versus travelling speed with the optimum tuning obtained for the nominal speed $V$ are depicted in Fig. 7 and Fig. 8, providing also a comparison with the stability curve for the passive conventional system. The passive conventional setting is for a steering linkage stiffness of $k_x = 3.666\times10^7$ Nm$^{-1}$, guaranteeing the bogie stability, and $\tau_{u1}$ and $\tau_{u2}$ equal to zero.

From Fig. 7–8, improved stability achieved with all the configurations including active control can be observed. Particularly, those with inerters were found to provide, at some

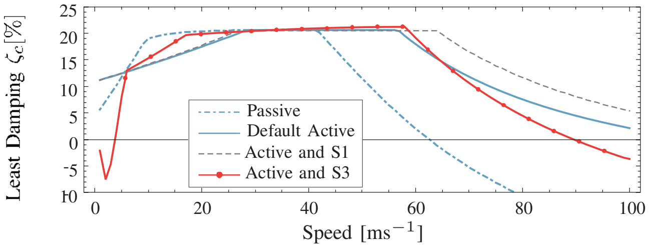

Fig. 7. Least damping ratio for the kinematic modes vs. speed (group A).

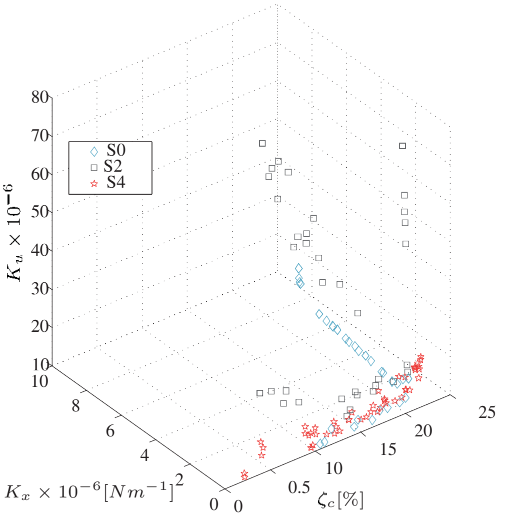

Fig. 9. Conflict 3D plot obtained from multi-objective optimisation for the active control combined with layouts in group B.

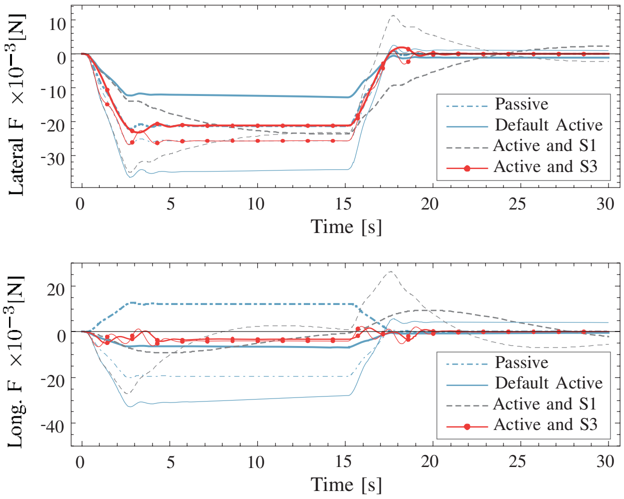

Fig. 10. Creep forces: Top- Lateral, Bottom- Longitudinal (group A).

extent, a better improvement on the vehicle's stability at the nominal speed over the other configurations: about 3% with S3, and 12.6% with S4 compared with achievements with S0. Also for low speeds better stability is attained in contrast with the configurations using the "relaxed suspensions" S1 and S3, albeit the irrelevant instability obtained for speeds below 5ms$^{-1}$. For speeds above the design speed, the other configurations result with better stability. In this regard, other exercises were done on optimising for higher speeds and the tendency is to obtain a slightly better stability with S3 and S4 for the design speed in contrast to the results for the structures without the inerter.

### B. Curving

With the optimum sets of parameters in Table III, curving behaviour in the time domain was also assessed. For this end, a track radius of 1000m and a cant angle of 6° were assumed, with a transition time of 3 seconds for a nominal travelling speed of V=55ms$^{-1}$ as in Jiang et al.'s paper [12].

The system excited by these transitional inputs develops longitudinal and lateral forces as displayed in Fig. 10 and Fig. 11, with applied control torques as shown in Fig. 12 and Fig. 13. In Figs. 10-13, bold curves correspond to the front wheelset responses, while normal curves are for the rear wheelset. If one refers back to the complex admittance of the layouts in Fig. 6 (i.e. Table II) and the parameter values from the optimisation (Table III), one can find that the strength of the layouts S3 and S4 is the better attenuation of the low frequency content of the relative displacements between wheelsets and bogie in the development of the resultant passive forces. S3 and S4, i.e. the structures with an inerter, provide an attenuation of +40dB/dec in contrast with the +20dB/dec provided by S1 and S2, and the all-pass characteristic of S0. It causes the longitudinal suspensions to behave even softer while curving, and with a flat stiffness for high frequency components, e.g. track irregularities. The filter effect of every suspension system is encountered at the following cut-off frequencies: 3.4 rads$^{-1}$ for S1, 0.4 rads$^{-1}$ for S2, 5.1 rads$^{-1}$ for S3, and 2 rads$^{-1}$ for S4. It reveals lowered cut-off frequencies for the structures with a fixed stiffness placed in parallel to the softer structures (or equivalently, frequency-dependent stiffness).

Results from the optimisation disclose that the active control technique based on absolute position of the wheelsets feedback can be further improved by feeding back the position of the wheelsets relative to the bogie position with adequate compensation. Analysing the simulations for the creep forces

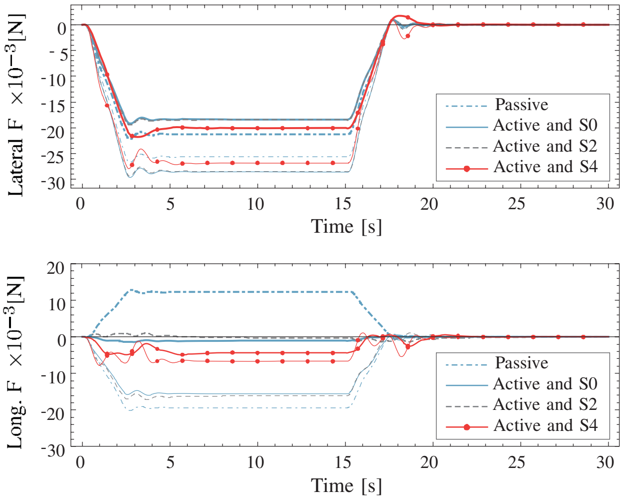

Fig. 11. Creep forces: Top- Lateral, Bottom- Longitudinal (group B).

and the active torques, the following benefits were obtained:

- a difference between the front and rear lateral creep forces for both S3 and S4 conveniently close to that obtained with the pure passive stabilisation configuration (for which $\zeta_c$ is approximately 7% only);
- a significant and favourable reduction of the front and rear longitudinal creep forces for both S3 and S4, when compared with those configurations without inerter, and
- lower active torque for S3, while higher for S4 –although perhaps better damped.

At higher nominal speeds, e.g. 83 ms$^{-1}$ (300km/h), suspensions as S1 and S3 will not guarantee a high degree of stability; results are not included here for brevity. In those cases, a fixed stiffness is needed for all the frequencies and therefore S2 and S4 are more appropriate. In fact, Fig. 10 and Fig. 12 show that even at 55 ms$^{-1}$, S1 is not adequate.

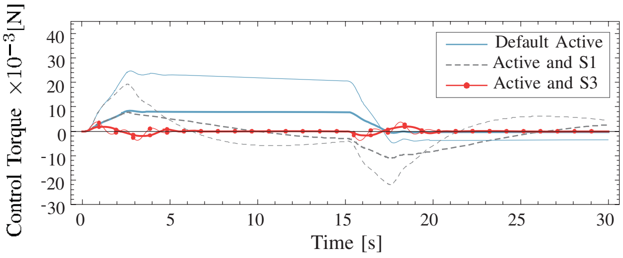

Fig. 12. Time-response for the applied control torque (group A).

## VII. Conclusion

Including inerters into the longitudinal suspensions simplifies the issues arising in stability control of a railway vehicle using absolute stiffness. A best compromise was achieved for the three objectives formulated: maximum stability for the nominal travelling speed, and reduction of the longitudinal stiffness and the control gain via GA optimisation. Time domain simulation results illustrated the usefulness of adding the inerter to the active control solution, i.e. some improvement in the wheelsets stability was attained while also longitudinal and lateral creep forces are reduced. This study presented possibilities of enhancing railway suspension behaviour via active control integrated with a novel mechanical element, the inerter.

*Abstract*—**This paper proposes a multi-objective trajectory optimization method to be used in the planning of environmentally efficient commercial aircraft trajectories. The problem of finding environmentally efficient trajectories is treated as an optimal control problem that is solved by applying a direct method of trajectory optimisation. The method involves an inverse trajectory parameterisation technique, methods for the calculation of environmental objectives, and the use of a multi-objective version of the Differential Evolution algorithm. The principal benefit of the method relative to previous work is that it allows the fast generation of Pareto optimal fronts between several competing objectives. This allows the decision maker to make informed decisions about potential trade-offs between different environmental goals.**

## I. Introduction

Over the last decade global passenger air traffic has increased by more than 45%, with similar levels of growth projected for the coming decade [1]. It has long been recognised that aviation benefits society, as a generator of wealth, and as an enabler to the exchange of ideas and culture between nations. However, increasing levels of air traffic will continue to impact the environment, with rising levels of aircraft emissions and higher numbers of people exposed to significant levels of aircraft noise [2].

The Advisory Council for Aviation Research in Europe (ACARE) is a group of representatives from the European commission, member states, industry and academia tasked with influencing the direction of European aviation research and development. The council, recognising the impact of aviation on the environment, has proposed to meet the challenges of sustainable aviation through the application of research and technology. To achieve this, it has created a strategic agenda for European aviation research with associated goals to be achieved by the year 2020. The environmental targets proposed by ACARE are (from a 2000 baseline) [3]

- Reduce fuel consumption and carbon dioxide (CO2) emissions by 50% per passenger kilometre.
- Reduce NOx emissions by 80%.
- Reduce perceived noise by 50% .

Of the targets, ACARE has proposed in its roadmap that 5-10% of the CO2 reduction be achieved through improved aircraft operations and air traffic management. This target is in line with the Single European Sky Air Traffic Management Research (SESAR) programme goal of reducing Air Traffic Management (ATM) related CO2 emissions by 10% per flight (from a 2005 baseline) [4]. Although no quantitative targets have been set for ATM related noise reduction, both initiatives recognise the role that improving aircraft operations has to play in reducing noise impact on communities around airports.

A particular focus of Air Traffic Management research related to delivering the ACARE goals is the design and delivery of trajectories that minimise environmental impact, referred to as green trajectories. Green trajectories, in the form of Continuous Descent Approaches (CDA), have already shown promise in delivering emissions and noise reductions to airport terminal areas [5]. The planning and optimization of green trajectories has been the subject of a number of theoretical studies. The Sourdine project, using expert analysis, developed a series of recommended noise abatement procedures for airport arrival and departures [6]. The trajectories were optimized to reduce noise under the flight-path for representative medium narrow-body and large wide-body aircraft. Simulations subsequently showed that large scale adoption of the Sourdine procedures could lead to significant reductions in noise footprints relative to conventional trajectories, although runway rates were adversely affected [7], [8]. Visser et al [9], [10] posed the problems of finding green arrival and departure trajectories as optimal control problems. This work used the direct collocation technique proposed by Hargreaves and Paris [11] to calculate optimal trajectories in terms of fuel burn and awakenings. Hebly et al [12] also used a collocation method and a weighted-sum cost function based on fuel burn and awakenings to optimise a Required Navigation (RNAV) departure procedure. Prats et al [13], again using a collocation method, recognised that the calculation of green trajectories can require the consideration of several conflicting optimisation criteria. To account for this, a lexiographic method for multi-objective optimisation was implemented. For the method, a hierarchy of importance for the objectives was established prior to the simulation. In this case, the method finds the minimum for the first objective and then seeks reductions in subsequent objectives providing

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

they do not increase the values of the objectives higher in the hierarchy. What results is a single Pareto optimal point that lies at the extreme of the first objective in the hierarchy.

When multiple conflicting objectives exist for an optimization problem, a single Pareto optimal point, or the minimum of a single objective, offer the Decision Maker (DM) very little information about potential tradeoffs between the optimization objectives. In environmental trajectory optimization, it is usually desirable to have multiple Pareto optimal points, where the tradeoffs in objectives, such as noise and fuel burn, can be assessed relative to each other.

The aim of this paper then is to solve the general multi-objective trajectory optimization problem for several types of environmental objectives, and to find the Pareto optimal set between minimised objectives. To do this, it is proposed to convert the optimal control problem to a Non Linear Programming (NLP) problem using a direct method of trajectory optimization that can be combined with aircraft emission and noise methods for the calculation of objectives. It is then proposed to solve the NLP problem for a Pareto optimal set using a stochastic evolutionary algorithm as the NLP solver. It is intended that the proposed method be useful to air traffic route designers and to airline flight planners as an approach that can be used to predict and optimize the environmental impact of commercial aircraft trajectory operations.

## II. Problem

Stated generally, the multi-objective trajectory optimization problem can be stated as the problem of minimising an array of scalar objective functions

$$\min_{\mathbf{z},\mathbf{u}}[f_1(\mathbf{z},\mathbf{u}), f_2(\mathbf{z},\mathbf{u}), \ldots, f_q(\mathbf{z},\mathbf{u})]^T \tag{1}$$

where, in this work, the aircraft states are $\mathbf{z} = [x(t), y(t), h(t), v(t), \gamma(t), \chi(t)]^T$, the aircraft position is $\mathbf{r} = [x(t), y(t), h(t)]^T$, $v(t)$ is the airspeed, $\gamma(t)$ is the flight path angle and where $\chi(t)$ is the heading angle. The aircraft controls are then $\mathbf{u} = [T(t), n(t), \phi(t)]^T$ where $T(t)$ is thrust, $n(t)$ is load factor and $\phi(t)$ is the bank angle. The individual objectives of the array are then minimised subject to the inequality constraints to be satisfied

$$\mathbf{c}_i(\mathbf{z},\mathbf{u}) \leq 0 \tag{2}$$

When solving a multiobjective optimization problem, where n is the number of objectives, the objective vector $\mathbf{s}^*$ is Pareto optimal, if there does not exist another objective vector $\mathbf{s} \in S$ where $s_i \leq s_i^*$ for all $i = \{1, \ldots, n\}$ and where $s_j^* < s_j$ for at least one index of $j$, $j \in \{1, \ldots, n\}$. A Pareto front is a set of Pareto optimal solutions. A set is Pareto optimal if each solution in the set is Pareto optimal. For conflicting objectives, the Pareto optimal set should identify the extremes of the objectives, most fuel efficient and shortest path for instance, and allow for tradeoffs between objectives to be examined. This facilitates the search for solutions that offer the best balance between objectives.

## III. Transcription

To solve the general optimal control problem it may be converted to a finite dimensional numerical optimization problem. Methods for transcription to a numerical problem are classified in Betts [14] as indirect and direct. Indirect methods involve forming the Hamiltonian of the system, estimating the costate variables, and finding a root of the two point boundary value problem. Direct methods involve discretising the optimal control problem and solving for the states and controls at a series of dividing nodes. Direct methods are preferred for this work because they do not require the definition of costate variables or constrained arcs and are therefore easier to apply to the problem.

Direct collocation methods use polynomials to parameterise the states and controls of the aircraft. Hargreaves and Paris [11] used piecewise cubic polynomials, while Fahroo et al [15], [16] and Benson et al [17] have used orthogonal polynomials with several different forms of collocation points. A significant drawback of collocation methods however, is that they can require large numbers of varied parameters. When applied to problems with large numbers of Air Traffic Control (ATC) constraints on aircraft position, speeds and rates of climb/descent, collocation methods may be very slow to evolve, first from infeasible to feasible solutions and then from feasible to a point along the global Pareto front. Yakimenko proposed an inverse method where the position states of the aircraft and their derivatives are parameterised using 7th degree polynomials [18]. Controls are then determined by inverting the state equations. The method significantly reduces the number of optimization variables required by analytically determining the polynomial coefficients from the prescribed states and controls at the boundaries ($t = 0$ and $t = t_f$). Instead of parameterising by time, Yakimenko adopted Taranenko's method of parameterising the polynomials by $\tau$, creating a virtual arc $\tau \in [0, \tau_f]$. The relationship between time $t$ and $\tau$ is defined as $\lambda = d\tau/dt$. The use of the relationship parameter $\lambda$ allows the definition of aircraft velocity using a separate reference function, enabling the creation of a virtual speed profile along the trajectory path of the aircraft. The method, termed the Inverse Dynamics in the Virtual Domain (IDVD) method, is a fast trajectory optimization method and has been considered for real time implementation [18], [19]. The IDVD method was adopted for this work because the small number of varied parameters allowed the Differential Evolution (DE) algorithm used in this work to quickly evolve decision vectors through the differential mutation and crossover mechanisms. The DE algorithm was chosen because it had the potential, when combined with the IDVD method, to efficiently converge on detailed global Pareto fronts.

For the IDVD method, the flat earth Cartesian coordinates $r_j (j = 1, 2, 3)$ and their derivatives are parameterised from the reference function (3) and its derivatives,

$$r(\tau)_j = \sum_{k=0}^{7} \frac{a_j k \tau^k}{\max(1, k(k-1))} \tag{3}$$

The coefficients of the polynomials are determined analytically from the coordinates and their derivatives at the boundaries ($\tau = 0$ and $\tau = \tau_f$) by making the coefficients the subjects of the following set of linear equations:

$$\begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 1 & \tau_f & \frac{\tau_f^2}{2} & \frac{\tau_f^3}{6} & \frac{\tau_f^4}{12} & \frac{\tau_f^5}{20} & \frac{\tau_f^6}{30} & \frac{\tau_f^7}{42} \\ 0 & 1 & \tau_f & \frac{\tau_f^2}{2} & \frac{\tau_f^3}{3} & \frac{\tau_f^4}{4} & \frac{\tau_f^5}{5} & \frac{\tau_f^6}{6} \\ 0 & 0 & 1 & \tau_f & \tau_f^2 & \tau_f^3 & \tau_f^4 & \tau_f^5 \\ 0 & 0 & 0 & 1 & 2\tau & 3\tau^2 & 4\tau^3 & 5\tau^4 \end{bmatrix} \begin{bmatrix} a_{j0} \\ a_{j1} \\ a_{j2} \\ a_{j3} \\ a_{j4} \\ a_{j5} \\ a_{j6} \\ a_{j7} \end{bmatrix} = \begin{bmatrix} r_{j0} \\ r'_{j0} \\ r''_{j0} \\ r'''_{j0} \\ r_{jf} \\ r'_{jf} \\ r''_{jf} \\ r'''_{jf} \end{bmatrix} \tag{4}$$

To modify the polynomials, the variables iterated by the solver are then $\Xi = [x'''_{0,f}, y'''_{0,f}, h'''_{0,f}, v''_{0,f}, \tau_f]$. To transform the polynomials to the system dynamics, a point mass model is used. Therefore the state and controls are determined by inverting the following equations:

$$\begin{aligned} \dot{x} &= v \cos\gamma \cos\chi, & \dot{v} &= \frac{T - D}{m} - g \sin\gamma \\ \dot{y} &= v \sin\chi \cos\gamma, & \dot{\chi} &= \frac{gn \sin\phi}{v \cos\gamma} \\ \dot{h} &= v \sin\gamma, & \dot{\gamma} &= \frac{g}{v}(ncos\phi - \cos\gamma) \end{aligned} \tag{5}$$

The drag $D$ is modelled with the aid of the BADA drag polars [20], aircraft mass is $m$, $g$ is gravitational acceleration and $n$ is the load factor. Conversions between the virtual and time domain are achieved by:

$$\begin{gathered} \dot{r} = \lambda r'; \quad \ddot{r} = \lambda(r''\lambda + r'\lambda') \\ \dddot{r} = \lambda^3 r''' + 3\lambda^2 \lambda' r'' + (\lambda^2 + \lambda\lambda'^2) r' \end{gathered} \tag{6}$$

Once the state and control histories are determined from $\tau_o$ to $\tau_f$, the following constraints are applied to ensure that they lie between defined limits determined with the aid of the BADA database [20]:

$$\begin{gathered} T \in [T_{min}, T_{max}] \quad n \in [n_{min}, n_{max}] \quad |\phi| \le |\phi_{max}| \\ v \in [1.2 v_{stall}, v_{max}] \quad \dot{v} \in [\dot{v}_{min}, \dot{v}_{max}] \quad \gamma \in [\gamma_{min}, \gamma_{max}] \end{gathered}$$

For the BADA parameters, Eurocontrol compensate for inaccuracies in the parameter estimation process by defining limits for both aircraft thrust and acceleration.

## IV. Waypoint Constraints

For commercial aircraft trajectory optimization, constraints imposed by the operating environment must be considered. Calculated trajectories must be able to adhere to ATC constraints imposed by airspace sectorization, procedures and traffic flow corridors. Typically, operating environment and procedural restrictions manifest as constraints on the height, speed or path of the flight, or some combination of the three. Therefore a simple five dimensional constraints model is developed.

Waypoint fixes are defined by the user in 2 dimensions as $\mathbf{W}_r = [W_x, W_y]$. The aircraft's trajectory path can then be constrained to fly over the 2D fix. For each waypoint fix, the minimum distance between the trajectory path and the fix position is calculated as a 2D distance $d_{min}$, with a corresponding minimum time $t_{d_{min}}$,

$$d_{min} := \min_{t \in [t_0, t_f]} d(t) \;\text{ where }\; d(t) = \|r_{2D}(t) - \mathbf{W}_r\|$$

$$t_{d_{min}} := \min t \;\; s.t. \;\; d(t) = d_{min}$$

The aircraft is then constrained to fly within a distance radius of the centre point of the fix, where $\hat{d}$ is the upper constraint on $d_{min}$,

$$\mathbf{c}_1(d_{min}) = d_{min} - \hat{d}$$

The aircraft can also be constrained to cross the fix at a specified height, speed and arrival time. The cross above constraints, $\underline{h}, \underline{v}, \underline{t}$, and cross below constraints, $\overline{h}, \overline{v}, \overline{t}$, constrain the minimum and maximum heights, speeds and time of the aircraft crossing the waypoint. The minimum and maximum can be constrained simultaneously to create height,speed and time windows at the waypoint.

$$\mathbf{c}_2(\mathbf{h}, \mathbf{v}, \mathbf{t}, t_{d_{min}}) = \begin{bmatrix} h(t_{d_{min}}) - \overline{h}_{t_{min}} \\ \underline{h}_{t_{min}} - h(t_{d_{min}}) \\ v(t_{d_{min}}) - \overline{v}_{t_{min}} \\ \underline{v}_{t_{min}} - v(t_{d_{min}}) \\ t_{d_{min}} - \overline{t}_{min} \\ \underline{t}_{min} - t_{d_{min}} \end{bmatrix}$$

## V. Environmental models

For the calculation of civil aircraft noise impact local to airports, the most commonly used method in the field is the Noise Power Distance (NPD) method [21]. The NPD method utilises, for a number of noise metrics, tables of empirical data that relate the noise level calculated on the ground to the power utilised by the aircraft and the distance from the aircraft to the noise assessment point. Specifically, the noise level at a point is calculated as

$$noise\,level = f_n(P(t), d(t), \boldsymbol{\beta}), \quad \forall t \in [t_o, t_f] \tag{7}$$

where $P(t)$ is power, $d(t)$ is slant distance between the aircraft and the assessment point, $\boldsymbol{\beta}$ is a set of segment level correction terms, and $t_o$ and $t_f$ are respectively the start and end times of the trajectory. Power, in this instance, is corrected net thrust. The noise model chosen for use in this work is the Integrated Noise Model (INM). INM is a model developed by the Federal Aviation Administration (FAA) to assess the impact of civil aircraft noise on communities local to airports. INM version 7 [22] is fully compatible with ECAC Doc 29, [21] guidance that provides a standardized methodology for the computation of noise contours around civil airports. INM is able to calculate several types of aircraft noise impact metrics, including the maximum A-weighted sound pressure level $L_{Amax}$, the single event exposure metrics Sound Exposure Level $(SEL)$ and The Effective Perceived Noise Level $(EPNL)$. INM also allows the calculation of noise metric contours that can be used to calculate population exposures and awakenings.

For the calculation of aircraft emissions, the emissions CO2, water vapor (H2O) and sulphur oxides (SOx) are calculated using direct multipliers on fuel burn, such that their rate of emissions is:

$$\dot{e}(t) = f_e(F(t), \boldsymbol{\alpha}) \tag{8}$$

where $F(t)$ is the rate of fuel burn and $\boldsymbol{\alpha}$ is a set of fuel burn multipliers. For the work presented in this document, rate of fuel burn is calculated using the BADA fuel flow model [20], where $F(t)$ is a function of thrust and the thrust specific fuel consumption factor $\eta$ such that:

$$F(t) = f_F(P(t), \eta) \tag{9}$$

The emissions for hydrocarbons (HC), carbon (CO), and oxides of nitrogen (NOx) are calculated using the Boeing Fuel Flow Methodology (BFFM) [23]. The ICAO emissions databank contains empirical information for certified engines that relate fuel burn to emissions indices at 4 different engine thrust settings. The BFFM offers a procedure for correcting the data for atmospheric conditions and for interpolating the data to calculate emissions of HC, CO, and NOx from fuel flow such that their rate of emissions is:

$$\dot{e}(t)_{BFFM} = f_{BFFM}(F(t), \mathbf{EI}) \tag{10}$$

where EI is a set of of emissions indices.

## VI. Stochastic solver

NLP algorithms can be applied in the iterative solution of a wide array of optimization problems. NLP algorithms can be generally classified as direct search (no derivatives), gradient search or stochastic. Derivative based gradient solvers require the definition or estimation of the derivatives of the objective function, while derivative free optimisers compare only the objective function value. To reach a global optimum it helps if gradient and derivative free optimisers are initialised where the objectives and constraints are convex. Stochastic solvers however tend to find it easier to escape local minima. Like derivative free algorithms, stochastic algorithms compare only objective values between iterations but use probability functions in guiding the search for the optimum solution. More details on stochastic optimization methods can be found in [24]. Evolutionary algorithms are a popular type of stochastic method and are well suited to solving multi objective optimization problems. Evolutionary algorithms, at each step of an optimization, maintain a population of solutions. This, allows the algorithms to simultaneously explore different parts of the solution space to identify decision vectors that provide the minimum for each objective and also the Pareto optimal points that form a front between the minimums.

The stochastic solver chosen for this work was Differential Evolution [25]. The DE algorithm utilises the mechanism of differential mutation. Differential mutation is a self adaptive mechanism where 3 population vectors are randomly selected from the parent generation and the scaled difference between 2 of the vectors is added to the third. The DE algorithm has proved to be a simple yet effective method for handling global optimization problems [26]. DE requires only 3 configuration parameters for calibration and has shown promising results when used with the inverse dynamics method chosen for use in this research. Drury [27] tested the performance of the Inverse Dynamics method with a number of popular Non Linear Programming (NLP) algorithms. For 2000 different sets of boundary values, the DE algorithm achieved a convergence of 99.8% with a relative optimality score of 94%, outperforming all of the other NLP algorithms. A multiobjective variant of DE is defined in [25] where Lampinen's dominance based method for constrained optimization [28] is used to drive solutions towards a Pareto front. Madavan [29] subsequently showed that multiobjective DE could be supplemented with a nondominated sorting procedure and the crowding distance metric developed by Deb et al [30] for the Nondominated Sorting Genetic Algorithm (NSGAII). The result was a fast and powerful method that combined the self organising mechanism of differential mutation with the elitism and the diversity preservation of the NSGAII algorithm.

### A. Main

The variant of DE chosen for this work was DE/rand/1/Bin [25]. The algorithm initialises by generating a population of random individuals between the user specified upper $b_U$ and lower $b_L$ parameter bounds. For each individual in this population, a candidate vector is created that is the algebraic combination of 3 parent vectors, further modified by crossover between the candidate and the target vectors. Each candidate vector is placed in an offspring population. Once a candidate population has been generated that is the same length as the parent population, it is appended to the parent population. The combined population is then sorted into fronts using nondominated sorting. For the production of the new population for the next generation, the size of the combined population is reduced to the initial population size by truncation. Each solution in the solution set is sorted into fronts $(F)$ depending on the number of other solutions in the set each is dominated by. All fronts from the first nondominated front $(F_1)$ upwards , whose combined length is less than or equal to the initial population size are preserved for the next generation. The individuals in the final front are sorted according to their crowding distance value. Individuals with large crowding distance values are moved toward the start of the front and the individuals with

Algorithm 1 A fast, self-adaptive, elitist, diversity preserving, multi-objective evolutionary algorithm

```
$G = 1$                                                First generation
$P = \emptyset$                                        Initialise initial population
for $i := 1$ to $NP$                                   Create $NP$ real valued vectors
    $\mathbf{p}_i = \emptyset$                         Initialise population vector
    for $j := 1$ to D                                  Each population vector contains $D$ real parameters
        $x_{j,i,G} = rand(0,1)(b_{j,U} - b_{k,L}) + b_{j,L}$   Create parameters within bounds
        $\mathbf{p}_i = \cup\{x_{j,i,G}\}$             Add the parameter to the population vector
    end
    $P = \cup\{\mathbf{p}_i\}$                         Add the population to the set of populations
end

while $G < G_{max}$                                    While current generation is less than final generation
        $Q = \emptyset$                                Initialise offspring population
        for each $\mathbf{p}_{i,G} \in P_G$            For each population vector in the population
        $r_1, r_2, r_3 \in \{1, ..., NP\}$             Select 3 random indexes
        $F_S \in [0,1]$                                Scale factor
        $\mathbf{v}_{i,G} = \mathbf{p}_{r_1,G} + F_S(\mathbf{p}_{r_2,G} - \mathbf{p}_{r_3,G})$   Create mutant population with Differential mutation
        $CR \in [0,1]$                                 DE crossover parameter $CR$
        $k \in \{1, ..., D\}$                          Random parameter index
        $\mathbf{q}_i = \emptyset$                     Initialise candidate vector
        for each $x_{j,G} \in \mathbf{p}_{i,G}$        For each parameter in the vector
            $r = rand(0,1)$
            if $r <= CR \vee j == k$                   Crossover between parent and the mutant vectors
                $u_{j,G} = v_{j,G}$
            else
                $u_{j,G} = x_{j,G}$
            end
            $\mathbf{q}_{i,G} \cup \{u_{j,G}\}$        Add parameter to candidate vector
        end
        $Q_G \cup \{\mathbf{q}_{j,G}\}$                Add candidate vector to offspring population
        end
        $R_G = P_G \cup \{Q_G\}$                       Combine parent and offspring population
        $F = fast\ nondominated\ sort(R_G)$
        $P_{G+1} = \emptyset\ and\ l := 1$             All nondominated fronts of $R_G$
        while $|P_{G+1}| + |F_l| \leq |P_G|$           Until the new population $P_{G+1}$ is filled
                $crowding\ distance\ assignment(F_l)$  Calculate the crowding distance in $F_l$
                $P_{G+1} = P_G \cup \{F_l\}$           Include the $l^{th}$ nondominated front in the new population
                $l = l + 1$                            Check the next front for inclusion
        end
        $sort(F_l : F_{end}, \prec)$                   Sort final front in descending order using domination
        $P_{G+1} = P_{G+1} \cup F_L[1 : (N - |P_{G+1}|)]$   Truncate final front if required
        $G = G + 1$                                    Increment generation counter
end
```

small crowding distance values are moved towards the rear. If inclusion of the final front results on a population size greater than the initial population size, then the final front is truncated. This ensures that the solutions in the final front with the greatest solution diversity are retained for the next generation.

### B. Nondominated Sorting

In general, for 2 feasible solutions where $\mathbf{p}, \mathbf{q} \in S$, $\mathbf{p}$ dominates $\mathbf{q}$ $(\mathbf{p} \prec \mathbf{q})$ if $\forall k : f_k(\mathbf{p}) \leq f_k(\mathbf{q}) \wedge \exists k : f_k(\mathbf{p}) < f_k(\mathbf{q})$ Nondominated sorting involves using domination to rank each solution into fronts that are sets of solutions with equal dominance ranking. Solutions that are not dominated by any other solutions are assigned to the first front $F_1$, Solutions that are dominated by 1 other individual will appear on the next front $F_2$, and so on until all solutions are assigned to the appropriate front.

### C. Crowding Distance

The crowding distance metric is used to measure the distance along the same nondominated front from one solution to the 2 adjacent solutions. For each objective function, the greatest and smallest objective values are assigned an infinite crowding value, preserving the boundary value individuals. For each intermediate individual, its proximity to other individuals is determined by taking the normalised difference between the solutions either side of that solution. When this measure is summed over all individual's objective functions, a measure of the closeness between solutions is reached.

### D. Selection

Unlike many Evolutionary Algorithms, where parent and child populations are compared to each other for fitness, for the NSGA-II method, the parent and child populations are appended to each other, and all selection occurs within the same population. Fitter individuals as determined by their nondomination rank and crowding distance are moved to the front of the population, while less fit individuals are moved to the back of the population and may be subjected to truncation. As shown in Algorithm 2, domination is determined by the constraints, rank, and crowding distance of each individual. In Algorithm 2, the solution $\mathbf{i}$ dominates the solution $\mathbf{j}$ if both are feasible and $\mathbf{i}$ has either a lower nondominated rank ($rank$) or has a greater crowding distance value ($distance$) at the same nondominated rank. If $\mathbf{i}$ is feasible and $\mathbf{j}$ is infeasible then $\mathbf{i}$ dominates. If both solutions are infeasible, then the individual with the lowest overall constraint violation dominates.

Algorithm 2 Selection

$$\zeta(\mathbf{i}) = \sum_{k}^{m} max[0, g_k(\mathbf{i})]$$

$$\zeta(\mathbf{j}) = \sum_{k}^{m} max[0, g_k(\mathbf{j})]$$

$$\mathbf{i} \prec \mathbf{j} \;\; \textit{if} \begin{cases} \begin{cases} \zeta(\mathbf{i}) \leq 0 \wedge \zeta(\mathbf{j}) \leq 0 \\ \wedge \\ i_{rank} < j_{rank} \\ \vee \\ [i_{rank} = j_{rank}] \wedge [i_{distance} > j_{distance}] \end{cases} \\ \vee \\ \begin{cases} \zeta(\mathbf{i}) \leq 0 \\ \wedge \\ \zeta(\mathbf{j}) > 0 \end{cases} \\ \vee \\ \begin{cases} \zeta(\mathbf{i}) > 0 \\ \wedge \\ \zeta(\mathbf{i}) \;\; < \zeta(\mathbf{j}) \end{cases} \end{cases}$$

## VII. Results

A departing aircraft scenario was created to demonstrate the multi objective trajectory optimization method. In the scenario, a commercial aircraft is required to climb from an initial climb point below 500ft at the west of a large population centre, to an en-route connection point lying at 20,000ft on the far side of the population centre. The commercial aircraft simulated was the medium narrow-body Airbus A321 aircraft with twin International Aero Engine V2530 engines. The population was artificially created for the scenario, and consisted of 1.5 million people evenly distributed over an area of 45000 hectares. In addition to the constraints from Section III, the bank angle $\phi$ and the minimum climb gradient below 1000ft were constrained to $0(rad)$ and $12\%$ respectively. For the first scenario the objectives chosen were the greenhouse gas Carbon Dioxide and the population enclosed within the 70 dB(A) Sound Equivalent Level footprint contour. SEL was used here as it forms the basic 'building block' of the Lden (Day-Evening-Night Average Sound Level) and Ldn (Day-Night Average Sound Level) contour calculations used to asses the community impact of aircraft noise.

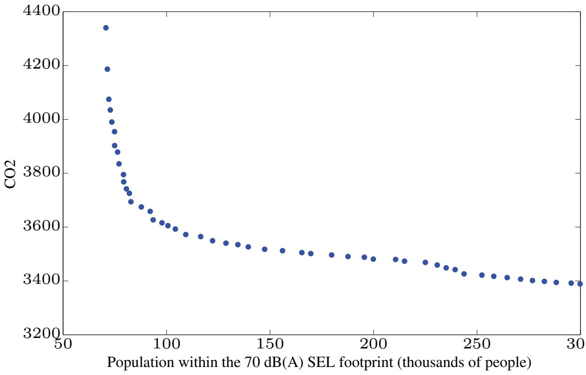

Fig. 1. Pareto front between CO2 emissions and the population within the 70dB(A) footprint

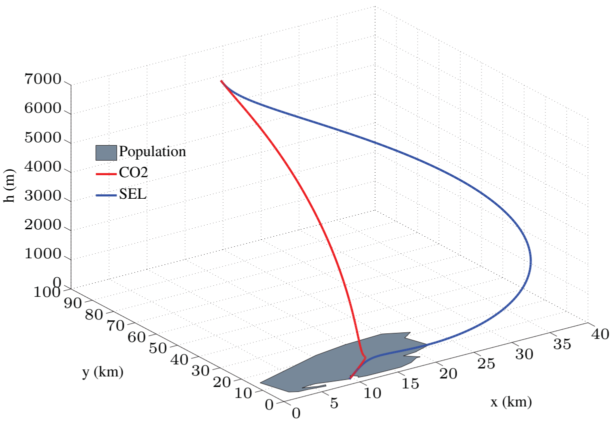

Fig. 2. Minimum noise and CO2 trajectories

Fig. 1 shows a Pareto front between the minimums of the two objectives. It can be seen from the front that there is a trade-off of approximately 900kg of CO2 between the most CO2 optimal trajectory and the most noise optimal trajectory. Similarly there is a trade-off of approximately 300,000 exposed people between the most noise optimal trajectory and the most CO2 optimal trajectory. Fig. 2 shows the trajectories for the two minimums. The aircraft trajectory for the minimum CO2 objective, after climbing out to 1000ft takes a direct route over the population area to the target end point, minimising excess track miles, fuel burn and therefore CO2. The trajectory for the minimum noise objective, initially progresses directly to the east, avoiding over-flying the majority of the population area and therefore minimising the population exposed to noise. It can be seen from Fig. 2 and from Fig. 3 that the noise optimised trajectory climbs to a height of 1500ft where it reduces thrust and accelerates to zero flap speed while passing over a population region near to the airport. On clearing the population region, the aircraft is turned to the target end point while thrust is increased gradually to maximum climb thrust and the aircraft accelerates to en-route climb speed. The trajectory produced mimics closely the Sourdine close-in noise abatement procedure as both involve an initial climb at full thrust followed by acceleration at reduced thrust and a gradual power increase.

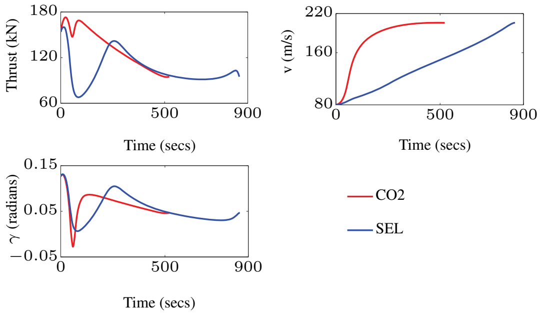

Fig. 3. Thrust, speed and flight path angle histories for the minimum noise and CO2 trajectories

A second scenario was created to examine the trade-offs between minimising for noise near to the airport and minimising for noise farther away from the airport. Boundary values remained as in the first scenario, however, all solution trajectories were constrained via the constraints in Section IV to lie along a common $x, y$ ground path shown in Fig. 4.

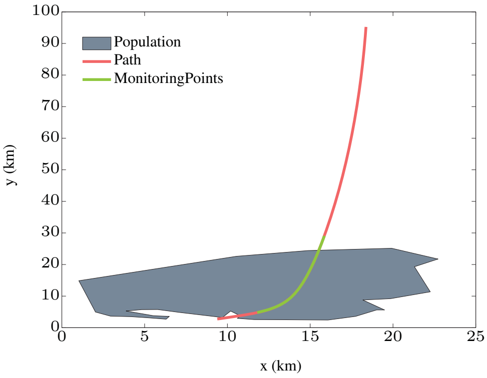

Fig. 4. Constrained $x, y$ path with noise monitoring region

All improvements in objectives were therefore achieved through changes to the vertical trajectory. A region of noise monitoring points, shown in green in Fig. 4, were then placed at 1000m intervals from a distance of 3000m to 30,000 metres from start of roll. The region of 3000m to 15000m was defined as the close-in region and the region of 15,000 to 30,000 metres was defined as the far region. Two objectives were then the subject of the optimization, Average EPNL in the close-in region, and average EPNL in the far region. Fig. 5 shows the Pareto front between the average EPNL in the near region and average EPNL in the far region. It can be seen that there is a 2-3 EPNdB average EPNL tradeoff between optimising trajectories for the different regions.

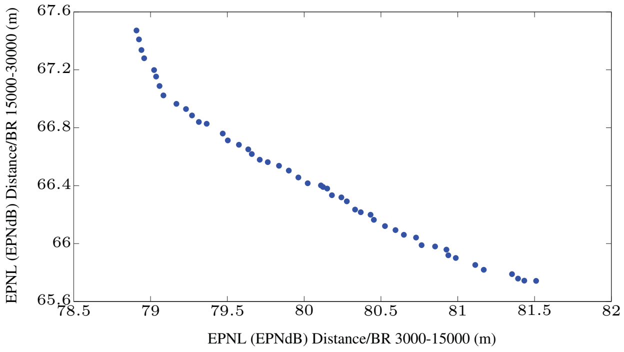

Fig. 5. Pareto front between close-in and far region average EPNL

It can be seen from Fig. 6 and from Fig. 7 that the near region optimization causes the aircraft to cutback its thrust and to assume a shallower flight path angle climb sooner than the far region optimization. As can be seen in Fig. 8, this results in a reduction in EPNL noise levels along the trajectory centreline at distances running from 3000 to 11000 metres. By contrast the far region optimization results in the aircraft climbing as high as possible using maximum thrust and flight path angle prior to the beginning of the far region. Once the far region is reached, the aircraft reduces thrust and climb angle, but the greater altitude attained allows the aircraft to fly higher over the far region increasing the noise attenuation distance and reducing noise levels on the ground. Once the far region has been passed, thrust is increase to accelerate the aircraft to enroute speed. Fig. 8, shows the corresponding higher close-region noise levels and lower far region noise levels that result from this trajectory.

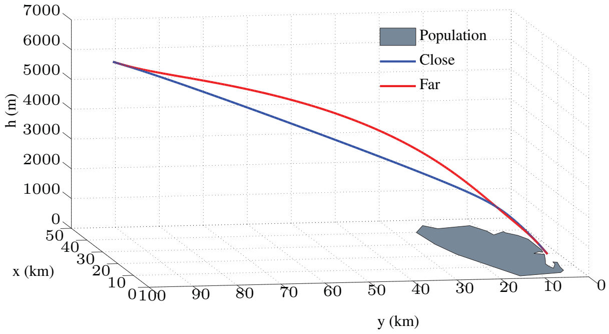

Fig. 6. Minimum close-in noise and far region noise trajectories

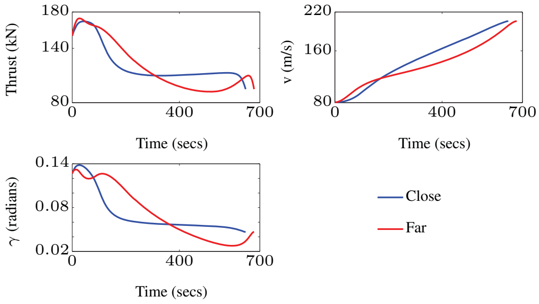

Fig. 7. Thrust, speed and flight path angle histories for the minimum close-in and far noise trajectories

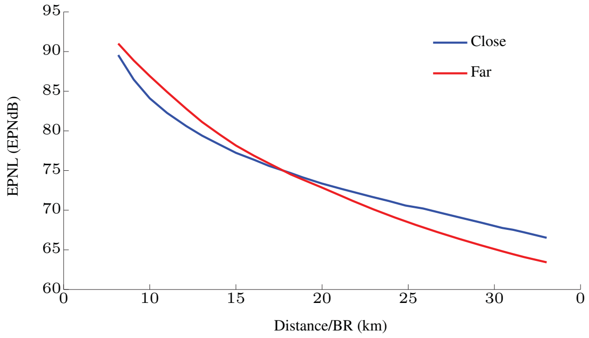

Fig. 8. Minimum close-in noise and far region noise trajectories

## VIII. Conclusion

As can be seen from Section VII, under many circumstances, there is no one trajectory that minimises all environmental costs. Therefore when planning environmentally efficient trajectories, the trade-offs between the objectives must be considered. This work has proposed a multi-objective trajectory optimisation method that may be used to analyse the trade-offs between environmental objectives that arise when operating commercial aircraft in different ways. The work assumes the availability of an advanced Flight Management System (FMS) with auto-throttle capable of tracking the detailed trajectory solutions. However, each trajectory may be segmented into a smaller number of operational steps that would be suitable for a pilot to execute. Further work will involve the automated analysis of the Pareto fronts so that certain solutions from the front can be recommended to the user to aid their decision making. This is intended to be especially useful when analysing Pareto fronts between more than two objectives.

## Acknowledgment

This work was completed thanks to funding support from Cranfield university. The authors would also like to thank Ken Lai from Cranfield University, Peter Hullah from Eurocontrol and Rick Drury from Flight Applications Limited for their help and guidance.

***Abstract*—Self-optimizing control (SOC) is a powerful tool to select controlled variables (CVs) so that when these variables are maintained at constant set-points, the entire process operation is automatically optimal or near optimal (self-optimizing) in spite of the presence of various uncertainties. Over a decade development, many SOC theories and methods have been developed to select optimal CVs. However, all these methods are based on local linearization of the process model at a nominally optimal operating point, hence referred to as local methods.**

**Due to the nature of locality, existing SOC methods may cause a large performance loss when the feasible operation region is large and the process is highly nonlinear. In this paper, we propose a global approach to select optimal CVs for nonlinear processes so that the average loss over the entire feasible operation region is minimized. Firstly, the globally average loss minimization problem is formulated and a toy example is solved analytically to explain the difference between the global approach and other local methods. For more complex processes where an analytical solution is not tractable, a numerical approach is proposed to minimize the average loss globally. In the new approach, optimal CV selection is found by solving a regression problem to approximate the necessary conditions of optimality of the objective function. A case study on an exothermic reactor demonstrates the effectiveness of the new approach.**

## I. Introduction

Traditionally, CVs are selected from a list of available or inferred measurements based on heuristic experiences and understanding of the whole process from an engineering perspective. For example, the variables related to safety regulations and product qualities usually need to be actively controlled and they are naturally chosen as CVs, thus consuming most of the process degrees of freedom (DOF). In many cases, these active constraints will dominate the process operation. However, for processes with extra DOF more than active constraints, self-optimizing control (SOC) [1] showed that the remain DOF can be used for optimization purpose by selecting appropriate CVs. When the selected CVs are maintained at predetermined constant set-points, the entire process operation is automatically optimal or near optimal (self-optimizing) in spite of the presence of various uncertainties, disturbances and measurement errors.

Over a decade development, many SOC theories and methods have been developed to select optimal CVs. Halvorsen et al. [2] derived simple singular value rule and local exact method for CV selection. Recent works have been engaged in finding proper combination matrix $H$ of measurements as CVs to reduce the economic cost. Kariwala [3] minimized the local worst-case loss via singular value and eigenvalue decompositions. Later Kariwala et al. [4] derived optimal $H$ with average loss minimization. Alstad and Skogestad [5] presented a null space method to minimize the loss caused by disturbances. Furthermore, Alstad et al. [6] extended null space method using extra measurements to minimize the loss caused by implementation error. Hori and Skogestad [7] compared maximum gain rule and local exact method and found the former one should be used with care for ill-conditioned plants. All these SOC methods were derived based on linearization of the process model around a normally optimal operating point, hence are referred to as local methods. This means the CVs selected by using these methods may only be optimal in a small neighborhood around the nominal point.

To address the locality issue, this paper aims to select CVs for nonlinear processes to be globally optimal by minimizing the average loss across the entire operation region. The remaining of this paper is organized as follows: Section II briefly reviews the local SOC methods, and Section III presents the formulation of globally average loss minimization problem for CV selection, together with a toy example to explain the difference between the global approach and existing local approaches. In Section IV, a CV selection procedure through regression for more general processes is proposed. The effectiveness of proposed solution is further demonstrated through an exothermic reactor case study in Section V. Finally, Section VI concludes the work together with some suggestions for future works.

## II. A Brief Review of Local Methods based Self-Optimizing Control

Consider a generalized static optimization problem for continuous processes, which is given as

$$\begin{aligned} &\min_u J(u,d) \qquad (1)\\ &\text{s.t. } g(u,d) \le 0 \end{aligned}$$

with available measurements

$$y = f(u,d) \qquad (2)$$

where $J$ is the scalar objective function; $u \in \mathbb{R}^{n_u}$, $d \in \mathbb{R}^{n_d}$ and $y \in \mathbb{R}^{n_y}$ are manipulated, disturbance and measurement variables, respectively; $g : \mathbb{R}^{n_u \times n_d} \Rightarrow \mathbb{R}^{n_g}$ and $f : \mathbb{R}^{n_u \times n_d} \Rightarrow \mathbb{R}^{n_y}$ are the operational constraints and measurement equations, respectively.

Let $c$ represent the CVs with set-points at $c_s$. SOC [1] demonstrated that if $c$ are properly selected, then when these variables are perfectly maintained at their optimal values, $c_s = c_{opt}(d)$ in the presence of disturbance, $d$, manipulated variables, $u$ will approach to their optimal values $u_{opt}(d)$ through feedback control without re-optimizing $c_s$. To select CV properly, let measurements $y$ at the nominal point be linearized as

$$y = G_y u + G_{yd} W_d d + W_n n \tag{3}$$

where $G_y$ and $G_{yd}$ are the steady state gain matrices of $y$ with respect to $u$ and $d$, respectively; $n$ is the implementation error due to measurement noise and/or control errors associated with individual measurement; $W_d$ and $W_n$ are diagonal matrices representing magnitudes of $d$ and $n$ respectively.

The selected CVs as linear combinations of full measurements set $y$ can be represented as

$$c = Hy \tag{4}$$

where $H$ is the combination matrix with full row rank of $n_u$ to square the control system. Especially, zero columns in $H$ imply a subset of full y is unused. The worst case loss [2] and the average loss [4] in objective function due to maintaining CVs at constant set-points for uniformly distributed $d$ and $n$ are given in (5) and (6), respectively.

$$L_{\text{wc}} = \frac{1}{2}\sigma^2_{\max}(M) \tag{5}$$

$$L_{\text{av}} = \frac{1}{6(n_d + n_y)}\|M\|^2_F \tag{6}$$

where $\sigma_{\max}(\cdot)$ and $\|\cdot\|_F$ are the maximum singular value and Frobenius norm of a matrix respectively; $M = \left[J_{uu}^{1/2}\left(J_{uu}^{-1}J_{ud} - G^{-1}G_d\right)W_d \quad J_{uu}^{1/2}G^{-1}HW_n\right]$ with $G = HG_y$ and $G_d = HG_{yd}$. Here, $J_{uu} = \partial^2 J/\partial u^2$ and $J_{ud} = \partial^2 J/(\partial u \partial d)$ are the diagonal and off-diagonal Hessian matrices of $J$ evaluated at the nominal point.

CV selection is then characterized as minimizing (5) or (6) with respect to $H$. Recently, several explicit expressions for $H$ have been reported [5], [3], [4], [6]. For example, if $n_y = n_u + n_d$, the combination matrix $H$ according to null space method proposed by Alstad and coworkers [5], [6] can be selected as

$$H = \left[J_{uu}^{1/2} \quad J_{uu}^{-1/2}J_{ud}\right]\left[G_y \quad G_{yd}\right]^{-1} \tag{7}$$

## III. Selection of Globally Optimal Controlled Variables

### A. Formulation

In the existing SOC theory, the CV selection problem is solved by assuming measurements in (2) are linearized in (3). This assumption restricts the solution to be local. To avoid this locality, the linear model assumption is discarded in the new global formulation to be presented below. Furthermore, in general, CVs can be either linear (as shown in (4)) or nonlinear combinations of all or a subset of available measurements. Therefore, in this work, the CVs are parameterized by $w \in \mathbb{R}^{n_w}$ as follows.

$$c = \phi(y, w) \tag{8}$$

For simplicity but without loss of generality, it is assumed that $c_s = 0$.

Let the entire operating range defined by the disturbance $d \in \mathcal{D}$ and all possible measurement noise represented by $n \in \mathcal{N}$. It is assumed that $d$ and $n$ are statistically independent. The minimum cost of the optimization problem in (1) is a function of $d$, $J_{\text{opt}}(d)$, while the actual cost when $c = 0$ is a function of $d$ and $n$ denoted as $J_w(d, n)$. Then, the operation loss in terms of the cost function for $c = 0$ with specific $d$ and $n$ is $L_w(d, n) = J_w(d, n) - J_{\text{opt}}(d)$, whilst the average loss across the entire operation range is a function of design parameters, $w$ as follows.

$$\begin{aligned} L_{\text{gav}}(w) &= E[L_w(d,n)] && (9)\\ &= \int_{n\in\mathcal{N}, d\in\mathcal{D}} \rho(d)\rho(n)L_w(d,n)\mathrm{d}n\mathrm{d}d && (10)\end{aligned}$$

where $E[\cdot]$ and $\rho(\cdot)$ represent the expected value and the probability density of a random variable, respectively.

Then, the globally optimal CVs can be selected by designing $w$ to solve the following optimization problem

$$\begin{aligned} &\min_w L_{\text{gav}}(w) && (11)\\ &\text{s.t. } y = f(u, d) + n\\ &\quad\;\; 0 = \phi(w, y)\\ &\quad\;\; d \in \mathcal{D}\\ &\quad\;\; n \in \mathcal{N}\end{aligned}$$

The optimization problem in (11) is generally suitable for various $\mathcal{D}$, $\mathcal{N}$ and nonlinear combination, $\phi$.

It was shown in [8] that local SOC methods essentially capture necessary conditions of optimality (NCO) locally at the nominal point with a straight line as CV. The aim of this work is to search other curves as CVs, which have better average performance across the whole region. The differences of these methods are illustrated in Figure 1, where $c_{\text{loc}}$ is the CV obtained by local SOC method, $c_{\text{gav}}$ is the globally optimal CV. As shown in Figure 1(a), the vertical axis is the NCO value when $c = 0$, where the desired value is 0. The curve of NCO for $c_{\text{loc}}$ can only be maintained at the nominal point, $d = d^\star$, whereas the deviation goes large as the operation point drifts far away from the nominal point. The curve of NCO for $c_{\text{gav}}$ approaches the zero line more closely in an average sense to minimize the overall loss, which can be quantified by the area surrounded by the curve of $L$ and $d$ axis in the disturbance range $[\underline{d}, \bar{d}]$, as shown in Figure 1(b).

From Figure 1, it is clear that the price to gain better average performance across the entire region is the slightly increased loss around the nominal operating point. To help understanding of the general formulation, a toy example is to be solved as follows.

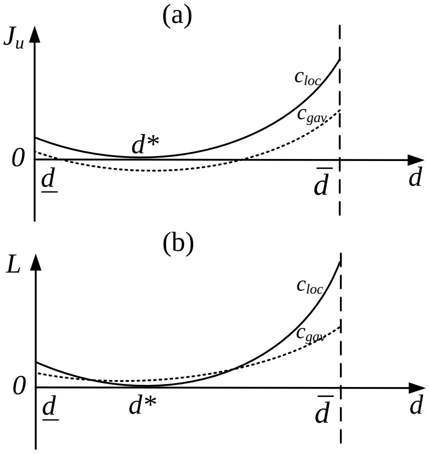

Fig. 1. Comparison of local SOC and globally optimal CV: (a) NCO against $d$; (b) Loss function $L$ against $d$

### *B. A toy example*

To illustrate the proposed new framework for globally optimal CVs selection, consider a problem to minimize the objective function

$$J = \frac{1}{2}(u-d)^2 \tag{12}$$

where both $u$ and $d$ are scalars. Two measurements are available as follows.

$$y_1 = u \tag{13}$$

$$y_2 = \frac{1}{4}u^2 + d \tag{14}$$

The nominal disturbance is $d^* = 0$. Correspondingly, the optimal point is then defined by $u^* = 0$, where $J^* = 0$, $y_1^* = 0$ and $y_2^* = 0$. The possible variation of $d$ is uniformly distributed between $-1$ and 1, *i.e.* $d \in \begin{bmatrix}-1 & 1\end{bmatrix}$.

It is clear that $u_{\text{opt}}(d) = d$ and correspondingly, $J_{\text{opt}}(d) = 0$. Therefore, for a non-optimal input, $u$, the loss, $L(u,d) = J(u,d) - J_{\text{opt}}(d) = J(u,d)$.

Firstly, the local SOC approach of null space method proposed in [5], [6] is applied to the problem. Since, $J_{uu} = 1$, $J_{ud} = -1$, $G_y = \begin{bmatrix}1 & 0\end{bmatrix}^T$ and $G_{yd} = \begin{bmatrix}0 & 1\end{bmatrix}^T$, the local optimal CV is then obtained using (7), which also minimizes the average loss locally for this problem[4]

$$c_{\text{lav}} = y_1 - y_2 \tag{15}$$

To maintain $c_{\text{lav}} = 0$ through feedback, the corresponding input has two solutions. The one satisfies the nominal operating condition, $u^* = 0$ is

$$u_{\text{lav}} = 2 - 2\sqrt{1-d} \tag{16}$$

Accordingly, the loss is then

$$L_{\text{lav}}(d) = \frac{1}{2}(2 - 2\sqrt{1-d} - d)^2$$

Hence, the expectation of the loss over the entire range is

$$\begin{aligned} E[L_{\text{lav}}(d)] &= \frac{1}{2}\int_{-1}^{1}\frac{1}{2}\left[8(1-d) + d^2 - 4(2-d)\sqrt{1-d}\right]\mathrm{d}d \\ &= 0.0183 \end{aligned}$$

Next, the global CV selection problem in (11) is to be solved for the toy example. For simplicity, consider the CV to be a linear combination of measurements. It can be parameterized as

$$c_{\text{gav}} = \phi(w,y) = y_1 + w_1 y_2 + w_2 \tag{17}$$

When $c_{\text{gav}} = 0$, the corresponding input, which is most close to $u^* = 0$ is

$$u_{\text{gav}} = \frac{2}{w_1}\left(-1 + \sqrt{1 - w_1(w_2 + dw_1)}\right) \tag{18}$$

Inserting (18) into (10) and solve it for optimization problem (11), we obtain the following results using Matlab Symbolic Math and Optimization Toolboxes:

$$\begin{aligned} w_1 &= -0.9231 \\ w_2 &= 0.0705 \end{aligned}$$

with the minimized average loss

$$\min_{w} L_{\text{gav}}(w) = 0.00278 \tag{19}$$

The result shows that the minimum global loss is much less than the local counterpart even though CVs of both methods are linear with the same number of parameters. The globally optimal linear CV is

$$c_{\text{gav}} = y_1 - 0.9231 y_2 + 0.0705 \tag{20}$$

which minimizes the average loss over the entire disturbance space.

## IV. A Regression Approach for Globally Optimal CV Selection

The toy example is solved analytically through finding the relationships between the loss expectation $E[L]$ and the CV parameters, $w$. However, finding analytical solution may not be tractable for general self-optimizing control problems. Therefore, it is necessary to develop a numerically effective approach to solve the globally optimal CV selection problem. In the following, we propose a regression approach to approximate the NCO of the optimization problem using CVs so that when these CVs are perfectly controlled at zero, the loss is proportional to the regression error. More specifically, let $u_w$ the control input corresponding to $c_w = \phi(w,y,n) = 0$. Then, the cost function $J(u,d)$ at a specific $d$ can be represented as the Taylor expansion around $u_w$,

$$J(u,d) = J_w + \eta_w^T \Delta u + 0.5\Delta u^T S_w \Delta u \tag{21}$$

where $\Delta u = u - u_w$, $J_w = J(u_w, d)$,

$$\eta_w = \left.\frac{\partial J(u,d)}{\partial u}\right|_{u=u_w} \tag{22}$$

and

$$S_w = \left.\frac{\partial \eta(u,d)}{\partial u}\right|_{u=u_w} \tag{23}$$

The gradient function can also be expanded similarly.

$$\eta(u,d) = \eta_w + S_w \Delta u \tag{24}$$

At the optimal point, $u_{\rm opt}(d)$, the above expansion becomes

$$J(u_{\rm opt}, d) = J_w + \eta_w^T \Delta u_{\rm opt} + 0.5 \Delta u_{\rm opt}^T S_w \Delta u_{\rm opt} \tag{25}$$

where $\Delta u_{\rm opt} = u_{\rm opt} - u_w$. Equivalently,

$$\begin{aligned} L_w(d,n) &= J_w - J(u_{\rm opt}, d) \\ &= -\eta_w^T \Delta u_{\rm opt} - 0.5 \Delta u_{\rm opt}^T S_w \Delta u_{\rm opt} \end{aligned} \tag{26}$$

Furthermore, at the optimal point, the NCO is

$$\eta(u_{\rm opt}, d) = \eta_w + S_w \Delta u_{\rm opt} = 0$$

Therefore,

$$\Delta u_{\rm opt} = -S_w^{-1} \eta_w \tag{27}$$

This leads to

$$L_w(d,n) = 0.5 \eta_w^T S_w^{-1} \eta_w \tag{28}$$

Note, a similar result on the loss has been derived in [9], however, for local loss around the nominally optimal point, whilst the result derived in (28) is globally valid.

Although loss derived in (28) can be directly used in (9) for global CV selection, the requirement of $S_w$ at each $d$ and $n$ is prohibitive. However, if CVs are represented as a summation of the NCO and an approximation error as follows,

$$c_w = \eta_w - \epsilon_w \tag{29}$$

then the approximation error, $\epsilon_w = \eta_w$ because $c_w = 0$ is perfectly controlled. Therefore, an upper bound of the global loss can be derived using the approximation error,

$$L_w(d,n) \le 0.5 M \|\epsilon_w\|_2^2 \tag{30}$$

where

$$M = \max_{d \in \mathcal{D}, n \in \mathcal{N}} \bar{\lambda}(S_w) \tag{31}$$

with $\bar{\lambda}(\cdot)$ denoting the maximum eigenvalue of a matrix.

To simplify the optimization problem in (11) further, the continuous operating region specified by $\mathcal{D}$ and $\mathcal{N}$ is discretized in $N$ sampling points, $d_i \in \mathcal{D}$ and $n_i \in \mathcal{N}$ for $i = 1, \ldots, N$. To avoid solving the perfect CV control equation, $\phi(w, y) = 0$, $u$ is also sampled at $N$ points within a feasible range, $\underline{u} \le u_i \le \bar{u}$, accordingly. With these three independent variable samples, the gradient, $\eta_i = \eta(u_i, d_i)$, $y_i = y(u_i, d_i) + n_i$ can be calculated from the process model. Then the following regression problem is to be solved in order to determine the optimal CV parameters,

$$\min_w \frac{1}{2} (\phi(w, y_i) - \eta_i)^T (\phi(w, y_i) - \eta_i) \tag{32}$$

This is a nonlinear least squares problem. The famous Levenberg-Marquardt algorithm [10] is available to solve this problem efficiently. Meanwhile, there are many nonlinear model structures are available in the literature as well, which can be adopted for $\phi(w, y)$, such as the polynomial and Gaussian kernel models. For simplicity, only linear regression is considered in the formulation bellow, for which an analytical solution can be derived.

The general form of linear $\phi(w, y)$ is given as follows.

$$c_w = Hy + b \tag{33}$$

with the parameter vector, $w = \begin{bmatrix} {\rm vec}(H)^T & b^T \end{bmatrix}^T$, where $H \in \mathbb{R}^{n_u \times n_y}$, $b \in \mathbb{R}^{n_u}$ and ${\rm vec}(\cdot)$ represents a matrix to be arranged in a vector.

Using the linear combination CVs given in (33), $n_u$ CVs can be calculated independently for each CV to approximate one of elements in the gradient vector, $\eta$. Therefore, for simplicity, in the following development, it is assumed that $n_u = 1$.

Denote

$$\eta = \begin{bmatrix} \eta_1 & \cdots & \eta_N \end{bmatrix}^T \tag{34}$$

$$Y = \begin{bmatrix} y_1 & \cdots & y_N \\ 1 & \cdots & 1 \end{bmatrix}^T \tag{35}$$

$$w = \begin{bmatrix} H & b \end{bmatrix}^T \tag{36}$$

Then the regression problem (32) is equivalent to a linear regression problem

$$\varepsilon = \min_w \frac{1}{2} (Yw - \eta)^T (Yw - \eta) \tag{37}$$

The least squares solution to the problem can be analytically obtained as

$$w_{\rm opt} = (Y^T Y)^{-1} Y^T \eta \tag{38}$$

The corresponding minimum total regression cost is

$$\varepsilon = \frac{1}{2} \eta^T (I - Y(Y^T Y)^{-1} Y^T) \eta \tag{39}$$

The corresponding global average loss by adopting this linear combination CV can be bounded by $L_{\rm gav} \le M\varepsilon$. Note although above solution is derived for linear combinations as CV, it can be easily extended to polynomial form by expanding matrix $Y$ with higher order terms, as illustrated in case studies below.

## V. Case Studies

### A. Toy example continued

Applying proposed regression method above, the variation ranges for $u$ and $d$ ($u, d \in \begin{bmatrix} -1 & 1 \end{bmatrix}$) are both discretized into 10 parts equally resulting total $N = 11^2 = 121$ sample points. At each sampling point, the measurements and gradient $J_u$ are calculated, then we obtained the matrix $Y$ and vector $\eta$. A linear LS regression is simply performed using (38), which results in the following CV

$$c_{w1} = y_1 - 0.9809 y_2 + 0.09809 \tag{40}$$

To calculate the average loss, the control input for $c_w$ is found to be

$$u_{w1} = 2.039 - 2.0389\sqrt{1.0962 - 0.9621 d} \tag{41}$$

Inserting (41) into (12) and (10) to yield the expectation of loss calculated as

$$E[L_{w1}(d)] = 0.00375 \tag{42}$$

The average loss for $c_{w1}$ has been significantly reduced as compared with local method and is only slightly bigger than optimal 0.00278, which is analytically searched in Section III. The convenience of proposed regression method is that it directly determines $w$ via numerical approach, avoiding the requirement of representing input $u$ in terms of $d$ and $w$, which is inevitable and hard to access in analytical way. To demonstrate the powerful usage of proposed method, a second order polynomial regression is further performed by adding terms $y_1y_2$, $y_1^2$ and $y_2^2$ into $Y$, the CV is found to be

$$c_{w2} = y_1 - y_2 + 0y_1y_2 + 0.25y_1^2 + 0y_2^2 + 0 \tag{43}$$

The corresponding control input $u_{w2}$ and the expected loss are interestingly found to be $u_{w2} = d$ and $\min_w L_{w2}(d) = 0$, respectively. It means that the process can achieve perfect self-optimizing control under any disturbance! Note, if we specify a quadratic form of $\phi(y, w)$ in the first place and solve it analytically, the solution process will be very complicated and almost prohibitive.

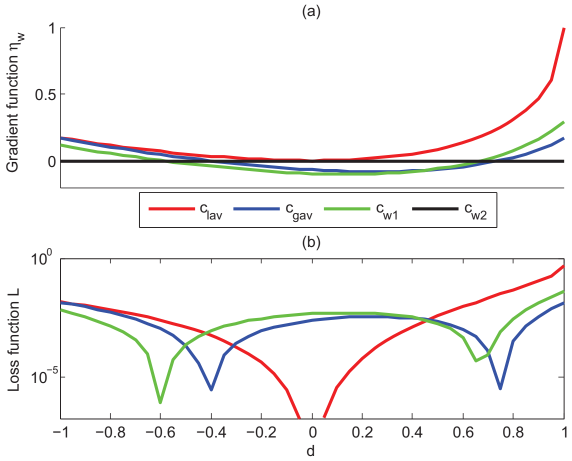

Fig. 2. Comparisons for different CVs for the toy example: (a) gradient function $\eta_w$ against $d$; (b) Loss function $L$ against $d$

Figure 2 (a) and (b) show the loss performances of various CVs when they are perfectly controlled at set-points 0. Compared with $c_{\text{lav}}$, globally optimal $c_{\text{gav}}$ is able to steer the gradient $\eta_w$ closer to 0 and minimize the loss over the entire disturbance range. $c_{w1}$ is suboptimal but its shape is approximately similar to $c_{\text{gav}}$, hence the loss is only slightly bigger. Moreover, $c_{w2}$ achieves perfect self-optimizing control and its curves overlap with desired 0 horizon line in the figures (not shown in semi-logarithmic plot (b)). Although for this problem $c_{w2}$ can also be derived through arrangements for model equations by eliminating $u$ and $d$, this may be hardly possible for other more complex problems, whereas regression method provides a very simple and efficient alternative, as illustrated in the reactor case study below.

### B. Exothermic Reactor

Self-optimizing control for the exothermic reactor has been previously studied by several researchers [3], [9], [11]. The reactant A is fed into a continuous stirred-tank reactor (CSTR) and undergoes a reversible exothermic reaction in the CSTR. The inlet temperature, concentrations of A and product B in the feed are denoted as $T_i$, $C_{Ai}$ and $C_{Bi}$ respectively, the outlet temperature, concentrations of unreacted A and product B in the outlet stream are denoted as $T$, $C_A$ and $C_B$ respectively. The schematic of exothermic reactor process is shown in Figure 3.

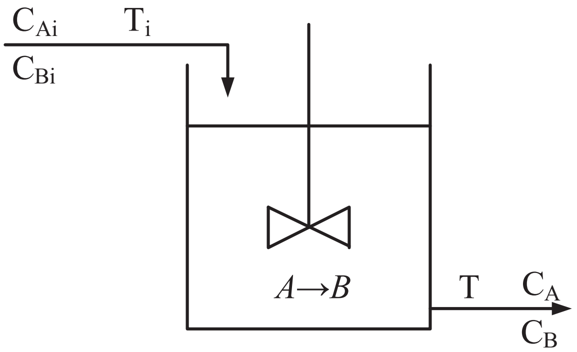

Fig. 3. Exothermic reactor process

The first principle models are composed of differential equations for mass and energy balances

$$\frac{dC_A}{dt} = \frac{1}{\tau}(C_{Ai} - C_A) - r \tag{44}$$

$$\frac{dC_B}{dt} = \frac{1}{\tau}(C_{Bi} - C_B) + r \tag{45}$$

$$\frac{dT}{dt} = \frac{1}{\tau}(T - T_i) + 5r \tag{46}$$

where $\tau = 60$s is the residence time, and $r$ is the rate of reaction which is dependent on process variables

$$r = 5000e^{-\frac{10000}{1.987T}}C_A - 10^5e^{-\frac{15000}{1.987T}}C_B \tag{47}$$

The classifications for manipulated variable, available measured variables and disturbances are given as

$$u = [T_i] \tag{48}$$

$$y = [C_A \quad C_B \quad T \quad T_i]^T \tag{49}$$

$$d = [C_{Ai} \quad C_{Bi}]^T \tag{50}$$

The anticipated noises for measured variables are ±0.01 mol/L for concentrations $C_A$ and $C_B$, ±0.5K for temperatures $T$ and $T_i$. The allowable sets for disturbances are considered as $0.5 \leq C_{Ai} \leq 1.5$ and $0 \leq C_{Bi} \leq 0.5$.

The operational objective of exothermic reactor process is to maximize the economic profit, which is equivalent to minimizing a cost function

$$J = -20090C_B + (0.1657T_i)^2 \tag{51}$$

where the first term of $J$ is the negative profit of product $B$ and the latter represents the cost of heating the input stream. The nominal values for process variables are given in Table 1. The operational degree of freedom for this case is 1, so only 1 CV is to be selected to square the control system.

TABLE I
PROCESS VARIABLES AND NOMINAL VALUES

| Variable | Physical description | Nominal value | Unit |
|---|---|---|---|
| $C_A$ | Outlet A concentration | 0.498 | $\mathrm{mol} \cdot \mathrm{L}^{-1}$ |
| $C_B$ | Outlet B concentration | 0.502 | $\mathrm{mol} \cdot \mathrm{L}^{-1}$ |
| $T$ | Outlet steam temperature | 426.803 | K |
| $T_i$ | Inlet steam temperature | 424.292 | K |
| $C_{Ai}$ | Inlet A concentration | 1.0 | $\mathrm{mol} \cdot \mathrm{L}^{-1}$ |
| $C_{Bi}$ | Inlet B concentration | 0 | $\mathrm{mol} \cdot \mathrm{L}^{-1}$ |
| $J$ | Economic objective | $-5149.3$ | \$ |

For this example, an analytical CV solution to minimize the globally overall loss is not available. Alternatively, the regression approach is use to select the optimal CV. Samples for regression are collected as follows: the possible variation range of each independent variable ( $C_{Ai}$, $C_{Bi}$ and $T_i$) is discretized equally into 10 parts, therefore, $11^3$ points of data are generated. Each point of data contains four measured variables and $dJ/du$, which is calculated using input perturbations and finite differences. The variation ranges for disturbances are defined earlier, the range for $T_i$ is considered as $\begin{bmatrix}380\mathrm{K} & 450\mathrm{K}\end{bmatrix}$, which is determined from later observations that the majority of optimum $u$ falls into this interval.

Least square regression is performed straightforward to get a combination model as CV with measurements as predictors. A linear and second order polynomial regression result in the following CVs,

$$c_1 = -772.2 - 184.3y_1 + 152.0y_2 - 7.4y_3 + 9.3y_4 \tag{52}$$

$$\begin{aligned} c_2 = {} & 1131.0 + 324.3y_1 - 1298.8y_2 - 105.5y_3 + 100.3y_4 \qquad (53) \\ & + 12.0y_1y_2 - 44.7y_1y_3 + 43.3y_1y_4 + 15.6y_2y_3 \\ & - 12.0y_2y_4 + 81.2y_1^2 - 30.5y_2^2 + 3.4y_4^2 \end{aligned}$$

with an $R^2$ regression index of 0.9464 and 0.9997, respectively. As a comparison, the methods proposed by Kariwala et al. [4] to minimize average local loss and Alstad et al. [6] using extended null space method are also applied to current example. These CVs are

$$\begin{aligned} c_{\mathrm{Kariwala}} = {} & 0.76y_1 - 0.65y_2 - 6.58 \times 10^{-5}y_3 \qquad (54) \\ & - 0.0051y_4 + 2.15 \\ c_{\mathrm{Alstad}} = {} & -171.76y_1 + 145.23y_2 + 0.0083y_3 \qquad (55) \\ & + 1.15y_4 - 479.18 \end{aligned}$$

A Monte Carlo experiment for 100 set of randomly generated disturbances within expected ranges is conducted and the results are shown in Table 2. The results in Table 2 show that self-optimizing performance can be significantly improved by using proposed method. Compared to $c_{\mathrm{Kariwala}}$ and $c_{\mathrm{Alstad}}$, the average losses (11.57 and 10.21) are furthermore effectively reduced by $c_1$ and $c_2$ (3.07 and 0.0896) because proposed method minimize the loss globally in the entire operation region.

TABLE II
AVERAGE ECONOMIC LOSSES WITH DIFFERENT COMBINATION CV

| CV | Average loss | Maximum loss | Standard deviation |
|---|---|---|---|
| $c_1$ | 3.07 | 15.39 | 3.26 |
| $c_2$ | 0.0896 | 0.97 | 0.15 |
| $c_{\mathrm{Kariwala}}$ | 11.57 | 52.78 | 12.11 |
| $c_{\mathrm{Alstad}}$ | 10.21 | 71.33 | 14.76 |

## VI. CONCLUSIONS

This paper presented a formulation for selecting CVs with globally average loss minimization in the context of SOC. A toy example is provided to illustrate the procedure of selecting globally optimal CVs for self-optimizing control. Compared with existing local SOC methods, which are only accurate in small neighborhood around the nominal point, new approach is advantageous that the global loss is minimized in an average sense. To circumvent the difficulty for solving the complicated and maybe non-convex optimization problem, a numerical solution is proposed alternatively to find optimal CVs, which is based on least squares regression to approximate the NCOs. The usage and effectiveness of the numerical method are demonstrated by the toy example and a more realistic exothermic reactor case study. The later shows that the loss over the entire operating range is significantly reduced comparing with the results obtained before using local SOC approaches.

*Abstract*—**For selection of controlled variables (CVs) in self-optimizing control, various criteria have been proposed in the literature. These criteria are derived based on local linearization of the process model and the necessary conditions of optimality (NCO) at a nominally optimal operating point. Recently, a novel CV selection framework has been proposed by Ye et al. [1] by converting the CV selection problem into a regression problem to approximate the NCO globally over the entire operation region. In this approach, linear combinations of a subset of available measurements are used as CVs. The subset selection problem is combinatorial in nature redering the application of the globally optimal CV selection method to large-scale processes difficult. In this work, an efficient branch and bound (BAB) algorithm is developed to handle the computational complexity associated with the selection of globally optimal CVs. The proposed BAB algorithm identifies the best measurement subset such that the regression error in approximating NCO is minimized. This algorithm is applicable to the general regression problem. The efficiency and effectiveness of the proposed BAB algorithm is demonstrated through a binary disdillation column case study.**

## I. Introduction

The selection of controlled variables (CVs) from available measurements is an important task during the design of control systems. For CV selection, several methods have been proposed in the literature. Skogestad [2] introduced the concept of self-optimizing control for selection of CVs based on process economics. In this approach, CVs are selected such that in presence of disturbances, the loss incurred in implementing the operational policy by holding the selected CVs at constant setpoints is minimal, as compared to the use of an online optimizer. The advantages of self-optimizing control approach for CV selection has been demonstrated through several case studies; see *e.g.* [3] for an overview.

The choice of CVs based on the general non-linear formulation of self-optimizing control requires solving large-dimensional non-convex optimization problems [2]. To quickly pre-screen alternatives, exact local methods with worst-case [4] and average loss minimization [5] have been proposed. These local methods are useful for selecting a subset or linear combinations of available measurements as CVs, where the latter approach provides lower losses. Recently, explicit solutions to the problem of finding locally optimal measurement combinations have been proposed [6], [5], [7]. Hu *et al.* [8] have proposed a local method to explicitly handle the input and output constraints during CV selection.

The available CV selection criteria are derived based on local linearization of the process model. Recently, a globally optimal CV selection framework has been proposed by Ye *et al.* [1], [9]. In this framework, the CV synthesis problem is converted into a regression problem using CVs as measurement combinations to approximate the Necessary Conditions of Optimality (NCO) globally over the entire operation region. It has been proven that the average loss is globally minimized when the regression error is minimal over the entire operation region and the measurement combinations as CVs are perfectly controlled at zero. A number of linear and nonlinear regression models have been proposed to approximate the NCO. Case studies showed that all these models are able to significantly reduce the loss, as compared to using CVs designed by using existing local methods.

In general, CV selection is a combinatorial problem. For selection of individual measurements as CVs, a number of efficient branch and bound (BAB) approaches, called bidirectional BAB (B$^3$), have been developed for various local criteria to address the combinatorial issue [18], [10], [11]. These BAB algorithms are not required for the selection of individual measurements as globally optimal CVs, as the selection is not combinatorial any more because approximations of individual gradients are not correlated and can be solved separately. However, to select measurement combinations, the combinatorial difficulty still exists for the global CV selection problem.

It is known that the use of combinations of a few measurements as CVs often provide similar loss as the case where combinations of all available measurements are used [6], [5], [7], [9]. Though the former approach results in control structures with lower complexity, it gives rise to a combinatorial optimization problem involving selection of measurements, whose combinations can be used as CVs. For local self-optimizing control methods, partially bidirectional BAB (PB$^3$) methods have been proposed to solve this combinatorial problem efficienctly [10], [11]. In this work, the framework is further extended to measurement subset selection for synthesis of globally optimal CVs chosen as linear combinations of measurements. It is proven that the selection criterion is equivalent to a quadratic problem, for which a standard BAB algorithm [12] exists. The standard algorithm is improved into a downwards BAB algorithm. The efficiency and effectiveness of the proposed BAB algorithm is demonstrated through a distillation case study [13].

## II. Local Methods for Self-Optimizing Control

Consider that the steady-state economics of the plant is characterized by the scalar objective function $J(u, d)$, where $u \in \mathbb{R}^{n_u}$ and $d \in \mathbb{R}^{n_d}$ are inputs and disturbances, respectively. The optimal operation policy is to update $u$ according to $d$, which usually requires the use of an online optimizer. For this case, let the optimal value of the objective function be denoted as $J_{\text{opt}}(d)$. A simpler strategy involves indirect adjustment of $u$ using a feedback controller. In this case, the feedback controller manipulates $u$ to hold the CVs $c$ close to their specified setpoints. Here, in addition to $d$, $J$ is also affected by the error $e$ in implementing the constant setpoint policy, which results due to uncertainty and measurement noise. The suboptimal objective functional value under the second strategy is denoted as $J_c(e, d)$. Then, the worst-case and average losses due to the use of the suboptimal strategy are given as

$$\begin{aligned} \text{Worst-case loss} &= \max_{e\in\mathcal{E}} \max_{d\in\mathcal{D}} \left(J_{\text{opt}}(d) - J_c(e, d)\right) && (1) \\ \text{Average loss} &= E[J_{\text{opt}}(d) - J_c(e, d)] && (2) \\ & && (3) \end{aligned}$$

where $\mathcal{D}$ and $\mathcal{E}$ represent the sets of allowable disturbances and implementation errors, respectively, and $E$ is the expectation operator. Self-optimizing control is said to occur, when we can achieve an acceptable loss by holding the CVs close to their setpoints without the need to reoptimize when disturbances occur [2]. Based on this concept, the appropriate CVs can be selected by comparing the losses for different alternatives.

As mentioned earlier, the use of nonlinear formulation of self-optimizing control is difficult. Hence, some local methods were developed to estimate the losses defined in (1) and (2) by linearising the process model around the normally optimal operating point as follows:

$$y = G^y\, u + G^y_d\, W_d\, d + W_e\, e \tag{4}$$

where $y \in \mathbb{R}^{n_y}$ denotes the process measurements and $e \in \mathbb{R}^{n_y}$ denotes the implementation error, which results due to measurement and control errors. Here, the diagonal matrices $W_d$ and $W_e$ contain the expected magnitudes of disturbances and implementation error, respectively. The CVs $c \in \mathbb{R}^{n_u}$ are given as

$$c = H\, y = G\, u + G_d\, W_d\, d + H\, W_e\, e \tag{5}$$

where $H$ is a selection or combination matrix and

$$G = H\, G^y, \quad G_d = H\, G^y_d \tag{6}$$

It is assumed that $G \in \mathbb{R}^{n_u \times n_u}$ is invertible. This assumption is necessary for integral control. When $d$ and $e$ are assumed to be uniformly distributed over the set

$$\left\| \begin{bmatrix} d^T & e^T \end{bmatrix}^T \right\|_2 \leq 1 \tag{7}$$

the local worst-case and average losses are given as [4], [5]:

$$\begin{aligned} L_{\text{worst}}(H) &= 0.5\bar{\sigma}^2 \left( J_{uu}^{1/2} (H\, G^y)^{-1} H\, Y \right) && (8) \\ L_{\text{average}}(H) &= \frac{1}{6(n_y + n_d)} \left\| J_{uu}^{1/2} (H\, G^y)^{-1} H\, Y \right\|_F^2 && (9) \end{aligned}$$

where $\bar{\sigma}$ and $\|\cdot\|_F$ denote the maximum singular value and Frobenius norm, respectively, and

$$Y = \begin{bmatrix} (G^y\, J_{uu}^{-1}\, J_{ud} - G^y_d)\, W_d & W_e \end{bmatrix} \tag{10}$$

with $J_{uu} = \frac{\partial^2 J}{\partial u^2}$ and $J_{ud} = \frac{\partial^2 J}{\partial u \partial d}$, evaluated at the nominal operating point. In comparison with worst-case loss, the selection of CVs is preferred through minimization of average loss, as the worst-case may not occur frequently in practice [5].

When individual measurements are selected as CVs, $H$ can be considered to be a selection matrix. Instead of using individual measurements, it is possible to use combinations of measurements as CVs. For this case, Alstad et al. [7] has recently proposed an explicit expression for $H$, which minimizes the $L_{\text{average}}$ in (9) and is given as

$$H^T = (YY^T)^{-1} G^y ((G^y)^T (YY^T)^{-1} G^y)^{-1} J_{uu}^{1/2} \tag{11}$$

As shown by Kariwala et al. [5], the $H$ in (11) also minimizes $L_{\text{worst}}$ in (8). The locally optimal combinations of all the available measurements, which can be used as CVs can be found using (11).

## III. Globally Optimal Method

The local methods [4], [5] are based on linearization around the nominally optimal operating point. Therefore, the identified CVs are only locally optimal. To derive globally optimal solution CVs, it is assumed that the NCO is approximated by CVs and the CVs are perfectly controlled at zero. Then, the loss, $L(d)$ for a particular disturbances $d$, due to the approximation error, $\epsilon(d)$ can be expressed as [1], [9]:

$$L(d) = 0.5\epsilon(d)^T H(d)^{-1} \epsilon(d) \tag{12}$$

where $H(d)$ is the reduced Hessian of the cost function evaluated at point where the CV, $c(d)$ is perfectly controlled corresponding to particular disturbance, $d$, whilst $\epsilon(d) = g(d) - c(d)$, where $g(d)$ is the reduced gradient evaluated at the same point.

The average loss over the entire operation region, $D$ can be represented as,

$$\bar{L} = E_{d\in D} L(d) \approx \frac{1}{2N} \sum_{i=1}^{N} \epsilon(d_i)^T H(d_i)^{-1} \epsilon(d_i) \tag{13}$$

where $d_i \in D$, $i = 1, \ldots, N$ are $N$ samples of disturbances in $D$ and $E$ is the expectation operator.

According to (13), the loss minimization is equivalent to a least squares regression problem to minimize the weighted residual, $H^{-1/2}\epsilon$. However, due to the difficulty and reliability to evaluate the reduced Hessian for every $d_i \in D$, $H(d_i)$ can be replaced by a constant matrix, *e.g.* the identity matrix or $H$ evaluated at nominal value of $d$. Then the regression problem can be set up as discussed next.

Let the entire operation region be sampled by $N$ points for independent variables (input and disturbance), $u = \begin{bmatrix} u_1 & \cdots & u_N \end{bmatrix}$ and $d = \begin{bmatrix} d_1 & \cdots & d_N \end{bmatrix}$. The corresponding measurement values and the reduced gradient values are $y = \begin{bmatrix} y_1 & \cdots & y_N \end{bmatrix}$ and $g = \begin{bmatrix} g_1 & \cdots & g_N \end{bmatrix}$, respectively. The CV is parameterized by $\theta$ at each sampling point as:

$$c_i = f_\theta(y_i), \ i = 1, \ldots, N \tag{14}$$

where $f_\theta(\cdot)$ is the parameterized regression function of measurements, which can be either linear or nonlinear, such as polynomial or Gaussian. Then the optimal CV, $c^* = f_{\theta^*}(y)$ is determined by adjusting $\theta$ to minimize the regression error $\epsilon = f_\theta(y_i) - g_i$ as follows:

$$\min_\theta \ \frac{1}{2N} \sum_{i=1}^{N} (f_\theta(y_i) - g_i)^T H^{-1} (f_\theta(y_i) - g_i) \tag{15}$$

For linear regression, $f_\theta(y) = \theta y$, *i.e.* $g = \theta y + \epsilon$. Then the regression problem in (15) can be solved analytically; see Section IV-B for details. In principle, it is possible to parametrize the CVs in terms of all the available measurements. Control systems with lower complexity can be obtained by using a subset of available measurements to parametrize the CVs, which often provides similar loss as the case where CVs are chosen to be functions of all the available measurements [6], [5], [7], [9]. The selection of the subset of measurements is a combinatorial optimization problem, which makes the application of this method difficult to large-scale processes. The BAB framework used to overcome this difficulty is presented in the next section.

## IV. Branch and bound method

### A. General principle

Let $X_r = \{x_i | i = 1, 2, \cdots, r\}$, be an $r$-element set. A subset selection problem with the selection criterion $\phi$ involves finding the optimal solution, $X_n^*$, such that

$$\phi(X_n^*) = \max_{X_n \subset X_r} \phi(X_n) \tag{16}$$

For this problem, the number of alternatives is $\mathcal{C}_r^n = \frac{r!}{(r-n)!n!}$, which grows very quickly with $r$ and $n$ rendering exhaustive search unviable. A BAB approach can provide globally optimal solution for the subset selection problem in (16) without exhaustive search. In this approach, the original problem (node) is divided (branched) into several non-overlapping subproblems (sub-nodes). If any of the $n$-element solution of a sub-problem cannot lead to the optimal solution, the sub-problem is not evaluated further (pruned), else it is branched again. The pruning of sub-problems allows the BAB approach to gain efficiency in comparison with exhaustive search.

The available BAB methods for subset selection can be classified as downwards [12], [14], [15], [16], [17] and upwards [18], [10], [11] BAB methods based on the search direction. For the regression problem associated with globally optimal CV selection, the downwards BAB approach is applicable and is discussed next. The reader is referred to [12], [14], [17] for details on downwards BAB method.

In a downwards BAB approach, each node is represented by $X_s = F_f \cup C_c$, where $s = f + c$ and, $F_f$ and $C_c$ denote the fixed and candidate sets, respectively. Here, the subscript denote the size of the set. The relationship between the fixed and candidate sets of a node and its $i^{\text{th}}$ sub-node (branching rule) is given as follows:

$$F_{f_i}^i = F_f \cup \{x_1, \cdots, x_{i-1}\}; \ C_{c_i}^i = C_c \setminus \{x_1, \cdots, x_i\} \tag{17}$$

where $F_{f_i}^i$ and $C_{c_i}^i$ denote the fixed and candidate sets of the $i^{\text{th}}$ sub-node and $i = 1, 2, \cdots, n - f + 1$. An example of the solution tree obtained by recursively applying the branching rule in (17) is shown in Figure 1. For the root node in this solution tree, we have $F_f = \emptyset$ and $C_c = X_r$. The label of the nodes denote the element being removed from $X_s$. The solution tree has $\mathcal{C}_n^r$ terminal nodes, which represent different $n$-element subsets of $X_r$.

To describe the pruning principle, let $\mathcal{X}$ denote the ensemble of all $n$-element subsets, which can be obtained using (17), *i.e.*

$$\mathcal{X} = \{F_f \cup C_c / X_{f+c-n} | X_{f+c-n} \in C_c\} \tag{18}$$

and $\underline{\phi}(F_f \cup C_c)$ be the upper bound on $\phi$ computed over all elements of $\mathcal{X}$, *i.e.*

$$\underline{\phi}(F_f \cup C_c) = \max_{X_n \in \mathcal{X}} \phi(X_n) \tag{19}$$

Assume that $B$ is a lower bound of the globally optimal criterion, *i.e.* $B \leq \phi(X_n^*)$. Then,

$$\phi(X_n) < \phi(X_n^*) \quad \forall X_n \in \mathcal{X}, \quad \text{if} \ \ \underline{\phi}(F_f \cup C_c) < B \tag{20}$$

Hence, any $X_n \in \mathcal{X}$ cannot be optimal and can be pruned without further evaluation, if $\underline{\phi}(F_f \cup C_c) < B$.

Although pruning of nodes using (20) results in an efficient BAB algorithm, further efficiency can be gained by performing pruning on the sub-nodes directly. This happens as the lower bounds for different sub-nodes are related and can be computed together from $\underline{\phi}(F_f \cup C_c)$ resulting in computational efficiency. For $x_i \in C_c$, the $i^{\text{th}}$ sub-node can be pruned if

$$\underline{\phi}(F_f \cup C_c / x_i) < B \tag{21}$$

For a BAB method involving pruning of sub-nodes, branching needs to be carried on sub-node level as well, which requires choosing a decision element to branch upon. Here, the decision element is selected as the element with largest $\underline{\phi}(F_f \cup C_c / x_i)$ among all $x_i \in C_c$ (best-first search).

### B. Application to CV Selection using Regression

The linear regression model is given as:

$$b = A\theta + \epsilon \tag{22}$$

where $b$ are the observations or measurements, matrix $A$ contains the regressors, $\theta$ are the unknown parameters and $\epsilon$ is the noise. Under the assumption that $\epsilon$ is independently

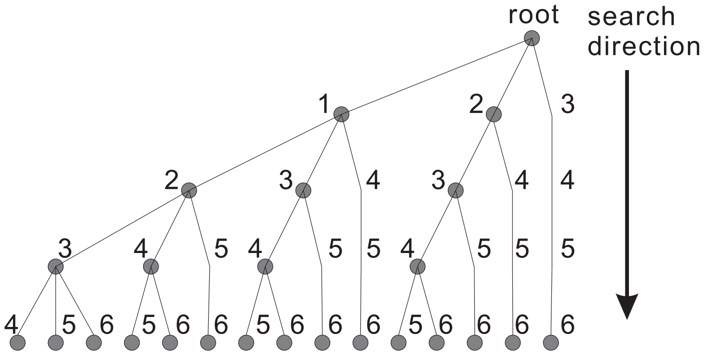

Fig. 1. Solution tree for selecting 2 out of 6 elements

and identically distributed (i.i.d.), it is well known that the unbiased estimate of $\theta$ is given as; see *e.g.* [19],

$$\hat{\theta} = \left(A^T A\right)^{-1} A^T b \tag{23}$$

With the estimate of $\theta$ given in (23), the predicted values of observations are $\hat{b} = A\hat{\theta} = A\left(A^T A\right)^{-1} A^T b$ and the prediction error $e$ is given as

$$e = b - \hat{b} = Pb \tag{24}$$

where $P = \left(I - A\left(A^T A\right)^{-1} A^T\right)$. Then, sums of squares of errors (SSE) can be computed as

$$SSE = e^T e = b^T P^T P b = b^T P b \tag{25}$$

where the last identity follows as $P$ is an idempotent matrix [19]. The SSE can be further expressed as

$$SSE = b^T b - b^T A\left(A^T A\right)^{-1} A^T b \tag{26}$$

As the first term in (26) is constant, the variables can be selected by minimizing SSE or equivalently maximizing $b^T A\left(A^T A\right)^{-1} A^T b$. Let us define $y = A^T b$ and $C = A^T A$. Now, the subset selection can be performed by solving the following optimization problem:

$$\max_{X_n \subset X_r} \phi(X_n) = \mathbf{y}_{X_n}^T (\mathbf{C}_{X_n, X_n})^{-1} \mathbf{y}_{X_n} \tag{27}$$

where $X_r = \{1, 2, \cdots, r\}$, $\mathbf{y}_{X_n}$ denotes the elements of $\mathbf{y}$ with indices in $X_n$ and $\mathbf{C}_{X_n, X_n}$ represents the principal submatrix of $\mathbf{C}$ with rows and columns indexed by $X_n$. Note that a similar combinatorial optimization problem is considered in [20], where the objective function instead needs to be minimized.

The use of BAB for solving the optimization problem in (27) requires an upper bound on the selection criteria, calculated over the ensemble $\mathcal{X}$ in (18). This upper bound is derived in the next proposition.

***Proposition 1:*** Consider a node with fixed set $F_f$ and candidate set $C_c$. For $\mathcal{X}$ in (18),

$$\phi(F_f \cup C_c) \geq \max_{X_n \in \mathcal{X}} \phi(X_n) \tag{28}$$

Proposition 1 implies that the non-optimal nodes can be pruned using $\phi(F_f \cup C_c)$ as the upper bound. To gain further efficiency by pruning the sub-nodes directly, we relate the selection criteria of a node with its sub-nodes in the next proposition.

***Proposition 2:*** Consider a node with fixed set $F_f$ and candidate set $C_c$. Let $S = F_f \cup C_c$. For $x_i \in C_c$, $i = 1, 2, \cdots, c$,

$$\phi(S \setminus x_i) = \phi(S) - \alpha_i^2 / \delta_i \tag{29}$$

where

$$\alpha_i \quad = \quad \mathbf{z}_i^T \mathbf{y}_S \tag{30}$$

whilst $\mathbf{z}_i^T$ and $\delta_i$ are the $i$th row and $(i, i)$th element of $\mathbf{C}_{S,S}^{-1}$ respectively.

The evaluation of (29) requires inversion of only one matrix $\mathbf{C}_{S,S}$, which is the same for all $x_i \in C_c$. Thus, the use of (29) to obtain the selection criteria for all sub-nodes together is computationally more efficient than directly evaluating the selection criteria for every node. In summary, the following BAB algorithm can be used for subset selection for regression.

***Algorithm 1:*** Initialize $f = 0$, $F_f = \emptyset$, $C_c = X_r$, $\phi(F_f) = 0$ and $B = 0$. Call the following recursive algorithm:

1) If $\phi(F_f \cup C_c) > B$, prune the current node and return, else perform the following steps.
2) Calculate $\alpha_i$ in (30) $\forall i \in C_c$. Prune the subsets with $\phi(F_f \cup C_c) - \alpha_i^2 < B$.
3) If $f = n$ or $f + c = n$, go to next step. Otherwise, generate the $c$ sub-nodes according to the branching rule in (17) and call the recursive algorithm in Step 1 for each sub-node. Return to the caller after the execution of the loop finishes.
4) Find $J_{\max} = \phi(F_f \cup C_c) - \max_{i \in C_c} \alpha_i^2$. If $J_{\max} > B$, update $B = J_{\max}$. Return to the caller.

## V. Binary Distillation Column Case Study

To evaluate the efficiency of proposed BAB algorithm for selecting globally optimal CVs, we test the performance of BAB algorithm on a binary distillation column [13]. All tests are conducted on a PC running Windows 7 SP1 with Intel Core i3-2100 3.10GHz processor, 8GB RAM using Matlab R2011a.

The objective is to minimize the relative steady-state deviations of the distillate ($z^L_{\text{top}}$) and bottoms ($z^H_{\text{btm}}$) compositions from their nominal values, *i.e.*

$$J = \left( \frac{z^H_{\text{top}} - z^H_{\text{top,s}}}{z^H_{\text{top,s}}} \right)^2 + \left( \frac{z^L_{\text{btm}} - z^L_{\text{btm,s}}}{z^L_{\text{btm,s}}} \right)^2 \tag{31}$$

where the superscripts $L$ and $H$ refer to the light and heavy components and the nominal steady-state values are $z^H_{\text{top,s}} = z^L_{\text{btm,s}} = 0.01$ (99% purity). The distillation column has 4 manipulated variables: reflux flow rate ($L$), vapor boilup ($V$), distillate flow rate ($D$) and bottoms flow rate ($B$). Because the levels of top condenser and bottom reboiler need to be stabilized, which consumes two degrees of freedom. We select $D$ and $B$ to control the levels, which is also referred as LV configuration for distillation column control, therefore, two degrees of freedom are remained for composition control. The main disturbances are feed flow rate ($F$), feed composition ($z_F$) and vapor fraction of feed ($q_F$), which are allowed to vary between $1 \pm 0.2$, $0.5 \pm 0.1$ and $1 \pm 0.1$, respectively. The top and bottom compositions are not measured online and thus two CV's needs to be identified for indirect control of the compositions. It is considered that the temperatures on 41 trays ($y_1, \ldots, y_{41}$, counting from bottom to top) are measured with an accuracy of $\pm 0.5°$C, whose combinations can be used as CVs for implementation of self-optimizing control strategy.

Data samples for NCO regression are generated as follows: each independent variable is evenly divided into 5 parts within its variation range. The variation range for disturbances are defined earlier. Variation range for reflux flow rate $L$ is chosen as $1 \pm 10\%$ at its nominal value and vapor boilup V is bounded within $(L-(1-q_F)F, L+q_F F)$ in order to let $0 < B,D < F$. For each scenario, temperatures at each tray are calculated and the two NCO components $J_L$ and $J_V$, which refer to the gradient of $J$ with respect to $L$ and $V$, respectively, are also obtained using finite difference method. Therefore, $6^5 = 7776$ samples are collected for regression. Because the number of candidate measurements for regression is large, we apply proposed BAB algorithm to choose an appropriate subset and determine globally optimal CVs. Similar computation performances are observed for regressing $J_L$ and $J_V$, as summarized in Figure 2.

Figure 2 (a) and (b) show that using full set of measurements as predictors for NCOs is not necessary. When $n > 5$, the SSE can only be slightly reduced. A trade-off between SSE, which is directly related to the overall economic loss, and the number of measurements used has to be made. Therefore, we can choose $n = 6$ and get CV models for self-optimizing control of this column. Figure 2 (c), (d), (e) and (f) show the computation time and number of node evaluations and demonstrate the usefulness and effectiveness of proposed BAB algorithm. Brute force cannot handle such a large problem, whereas proposed BAB algorithm solves it successfully. It takes about 1260s to complete all the selection tasks, which is reasonable for off-line computing. Largest computation time is seen for $n = 15$, which takes about 100s for selecting 15 out of 41 measurements. Overall, proposed algorithm is practically appealing, as the algorithm makes it possible to reduce the overall operation cost and meanwhile, reduces the investment for hardware sensors (*e.g.* temperature sensors for the column).

Furthermore, the economic losses associated with the CVs obtained by using the proposed BAB algorithm are evaluated and compared with those associated with CVs obtained in previous work [11] through local self-optimizing control. It is found that $n = 6$ results in a good trade-off between self-optimizing performance and investment cost of sensors, where both CVs are designed using 6 measurements.

The self-optimizing method using local average criterion [5] is adopted for comparison. To derive the CVs, linear model and Hessian matrices at the nominal point are obtained through finite difference. We also choose $n = 6$ and apply the PB$^3$ algorithm [11], [22] to get the best measurement subset.

A Monte Carlo experiment with 100 sets of randomly generated disturbances within their allowable ranges is used. The feedback control actions are implemented to maintain CVs at 0 and objective function $J$ is calculated, whose optimal value is expected to be 0. The average and maximal objective costs for regression method are 2.222 and 82.766, respectively, while the average and maximal objective costs for local method are 170.411 and 1577.474, respectively. This is because that the distillation process is strongly nonlinear, therefore, local method fails to characterize the process in wider operation range, whereas the regression method is advantageous in this respect resulting in significantly enhanced self-optimizing performance.

## VI. Conclusions

In the context of self-optimizing control, a novel branch and bound (BAB) algorithm is proposed for selecting globally optimal controlled variables (CVs) based on the method of regression for necessary conditions of optimality. The BAB algorithm aims to identify the best measurement set to minimize the sums of squares of errors (SSE) and use the set to construct the optimal CVs. Numerical tests using a practical binary distillation column case study show the efciency and effectiveness of this algorithm. It is pointed out that the proposed algorithm is applicable to the general linear regression problem as well as other statistical problems. The proposed downwards algorithm is efficient for problems where a few among many candidate variables need to be discarded. However, for problems where a few variables needs to be selected from many candidate variables, the computational expense incurred by the algorithm is still large. To this end, upwards and bidirectional BAB algorithms are currently being developed and will be presented in an extended paper.

***Abstract*—We consider the control structure design for a heat exchanger network (HEN), where a stream is split into parallel lines which are heated individually before they are merged together again. The objective is to find a control structure which maximizes the final temperature. We consider two scenarios, where (Scenario 1) the flow rates and the heat transfer coefficients are considered as disturbances, and (Scenario 2) where the hot stream temperatures are treated as additional disturbances. In both scenarios it is found that controlling linear measurement combinations gives very good performance, and that including flow measurements in the combinations gives little advantage over using only combinations of temperature measurements.**

***Index Terms*—Control structure selection, Self-optimizing control, Heat exchanger networks, Optimization**

## I. Introduction

With growing markets and limited natural resources, it is increasingly necessary to use the available resources in the best possible way. In many cases, this can be directly translated into re-using energy. Important tools for re-using energy are heat exchanger networks (HENs), which are operated such that a maximum amount of energy is transferred from one set of process streams to another.

It has been shown in [1], [2], that if there are no stream splits in the heat exchanger network, then optimal operation of the HEN can be considered and modelled as a linear program (LP), where the optimal operation point is always at constraints. In particular this means that the available degrees of freedom should be used for

1) keeping required target temperatures at their setpoints
2) meeting active constraints (i.e. fully opening or closing of some bypasses and utilities)

Since the stream parameters such as temperatures and flow rates change under operation, the task of achieving optimal operation can be re-formulated as finding the set of active constraints corresponding to the current operating conditions.

However, when streams are split, the optimal operating point will generally no longer be at constraints; and the optimal split will not remain constant because of disturbances such as changing temperatures of the streams, changing flow rates, or change of heat transfer properties due to fouling.

One approach for adjusting the split optimally is to periodically solve a numerical optimization problem to find the optimal setpoint values for some set of controlled variables (real-time optimization (RTO)) [3]. A good choice of controlled variables (CVs) will reduce the necessity to update the setpoints, while a poor choice will require frequent setpoint updates to remain close to optimality.

The RTO approach relies heavily on a good process model and the ability to solve the optimization problem online. Furthermore it is necessary to obtain good estimates of the model parameters. All these factors render the online-optimization approach relatively expensive.

Therefore, it is desirable to find controlled variables, which do not have to be updated often. A control structure which, in spite of varying disturbances, gives an acceptable loss without the need to adjust the setpoints for the controlled variables is called “self-optimizing” [4]. In such a control structure the setpoints of the controlled variables need to be updated very infrequently, or not even at all. For a recent overview of available methods for control structure design using the self-optimizing control ideas, we refer to [5] and the literature cited therein.

The contribution of this work is to study the effect of different self-optimizing control structures for a HEN with stream split, and in particular to evaluate the necessity of relative expensive flow measurements. Our paper is structured such that in the next section we present some basic concepts for finding self-optimizing variables. In Section III we introduce the heat exchanger network, and Section IV contains the simulation scenarios and results. Our paper is closed with a discussion and conclusions in Section V.

## II. Controlled variable selection

In this paper we apply local controlled variable selection procedures from self-optimizing control [4], [6], [7]. We assume that optimal operation corresponds to minimizing a scalar cost function, and for local optimality around the nominal optimum, it can be approximated [8] as

$$\min_{\Delta u} J(\Delta u, \Delta d) := [\Delta u^T \; \Delta d^T] \begin{bmatrix} J_{uu} & J_{ud} \\ J_{ud}^T & J_{dd} \end{bmatrix} \begin{bmatrix} \Delta u \\ \Delta d \end{bmatrix}. \tag{1}$$

Here, $J$ is the scalar approximation of the nonlinear cost function, $\Delta u \in \mathbb{R}^{n_u}$ and $\Delta d \in \mathbb{R}^{n_d}$ denote the inputs and the disturbances in deviation variables, respectively. $J_{uu} = \frac{\partial^2 J}{\partial u^2}$ denotes the positive definite Hessian of the cost function with respect to the degrees of freedom $u$, and $J_{ud} = \frac{\partial^2 J}{\partial u \partial d}$, $J_{dd} = \frac{\partial^2 J}{\partial d^2}$ denote second order partial derivatives with respect to $[u, d]^T$ and $[d, d]^T$, respectively.

The model is linearized around the nominal optimum, such that

$$\Delta y = G^y \Delta u + G^y_d \Delta d + \Delta n^y, \tag{2}$$

where $\Delta y$ denotes the $n_y$-dimensional measurement vector, $G^y = \frac{\partial y}{\partial u}$ and $G^y_d = \frac{\partial y}{\partial d}$ are gain matrices of appropriate sizes, evaluated at the nominal operating point. Finally, $\Delta n^y \in \mathbb{R}^{n_y}$ denotes the measurement noise or implementation error.

### A. Exact local method

The goal is to find a set of controlled variables (CV)

$$\Delta c = H \Delta y, \tag{3}$$

where $\Delta c \in \mathbb{R}^{n_u}$, and $H$ is a measurement selection or combination matrix of size $n_u \times n_y$, such that controlling the CVs at constant setpoints, $\Delta c = 0$, results in acceptable loss

$$L = J(H, \Delta d, \Delta n^y) - J_{opt}(d) \tag{4}$$

in spite of varying disturbances $\Delta d$ and noise $\Delta n^y$. In [6] it is shown that solving the convex optimization problem

$$\begin{aligned} &\min_H ||HY||_F \\ &\text{s.t.} \\ &HG^y = J_{uu}^{1/2} \end{aligned} \tag{5}$$

leads to a $H$ which locally minimizes the average and worst case loss. Here $||\cdot||_F$ denotes the Frobenius norm,

$$Y = [FW_d \quad W_{n^y}] \tag{6}$$

denotes the augmented optimal sensitivity matrix where $F = \partial y^{opt} / \partial d$, and the matrices $W_d$ and $W_{n^y}$ denote diagonal scaling matrices of appropriate dimensions, with

$$\Delta d = W_d d' \quad \text{and} \quad \Delta n^y = W_{n^y} n^{y'}, \tag{7}$$

such that

$$\left|\left| [d' \, n^{y'}]^T \right|\right|_2 \leq 1. \tag{8}$$

The local average loss resulting from a given control structure represented by $H$ can be evaluated using ([6], [7])[1]

$$L = \frac{1}{2} \left|\left| J_{uu}^{1/2} (HG^y)^{-1} HY \right|\right|_F^2 \tag{9}$$

**Remark 1.** *The matrices $F = \frac{\partial y^{opt}}{\partial d}$ and $G^y$ can be obtained by re-optimizing the process and a finite difference approximation, or as done in this work, by using the efficient sensitivity calculation routines in sIPOPT [9]. The software provides the sensitivity of the KKT solution with respect to parameters (disturbances d). As sIPOPT re-uses the matrix factorizations from the NLP solver IPOPT [10], the sensitivities are obtained by a simple backsolve. Similarily, the inverse of the reduced Hessian $J_{uu}$ can be easily obtained from sIPOPT.*

### B. Null-space methods

If there is no noise, and we have sufficient independent measurements ($n_y \geq n_u + n_d$), then H may be chosen in the left null space of $F$. In this case we have $HF = 0$, and since $W_{n^y} = 0$, we also have that $HY = 0$. Hence the local loss from (9) is zero. In practice, however, there will always be measurement noise ($W_{n^y} \neq 0$), and the CVs obtained from the null space method will cause a loss, which can be unacceptably high. Alstad et al. [6] present the extended null-space method, which selects $H$ in the null-space of $F$ (optimal disturbance rejection), and uses the remaining degrees of freedom to minimize the effect of noise. We, however, aim at minimizing the combined effect of disturbances and noise. Therefore, we use Eq. (5) for determining candidates for controlled variables.

### C. Selecting subsets of measurements

The above expressions for optimal measurement combinations are valid for controlled variables $c$ which contain a given set of measurements $y$. However in practice it is often desirable to use subsets of the available measurements, because the performance does not improve significantly beyond including a certain number of measurements, while installation and maintenance costs increase.

For finding the best subsets of measurements, branch-and-bound methods have been developed [11], [12], [13]. Recently [14] proposed a method to implement certain structural constraints on $H$.

In this paper we will not dwell on the available methods, but rather investigate some sets of controlled variables for a HEN with a stream split. For finding sets of measurements, we use the freely available software `b3av.m` [13] for MATLAB™.

## III. Heat exchanger network

### A. Process description

We consider the HEN in Fig. 1, where a feed stream with temperature $T_0$ and heat capacity $w_0$ is split into 6 lines, which are heated independently before they are merged again. The structure of this HEN is the same as the structure of the HEN for feed pre-heating of the crude oil distillation unit at the Mongstad refinery in Norway. The objective is to adjust the feed split such that the end temperature is maximized,

$$\min J = -T_{end}. \tag{10}$$

This corresponds to minimizing the energy required for the crude oil distillation unit. The heat exchanger network has 30 measurable temperatures and 14 flows. Thus, the potentially

[1] Our definition of the average loss is slightly different from [7], where it is defined as $L = \frac{1}{6(n_y+n_d)} \left|\left| J_{uu}^{1/2} (HG^y)^{-1} HY \right|\right|_F^2$. Although this definition is formally correct, one may reduce the loss arbitrarily by adding (unused) measurements, $n_y \to \infty$. To avoid this, we define the average loss as in (9).

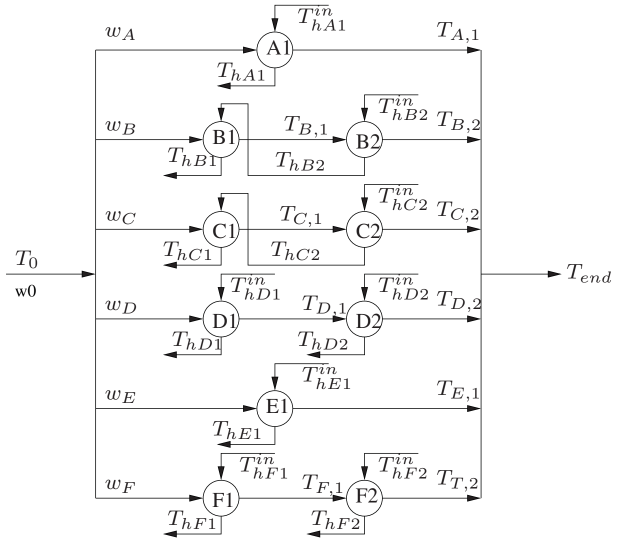

Fig. 1. Heat exchanger network

available measurement vector is

$$\begin{aligned} y = \big[ & T_0, T_{end}, T_{1A}, T_{h1A}, T^{in}_{h1A}, \\ & T_{2B}, T_{1B}, T_{h1B}, T_{h2B}, T^{in}_{h2B}, \\ & T_{2C}, T_{1C}, T_{h1C}, T_{h2C}, T^{in}_{h2C}, \\ & T_{2D}, T_{1D}, T_{h1D}, T_{h2D}, T^{in}_{12D}, T^{in}_{h2D}, \\ & T_{1E}, T_{h1E}, T^{in}_{h1E}, \\ & T_{2F}, T_{1F}, T_{h1F}, T_{h2F}, T^{in}_{h1F}, T^{in}_{h2F}, \\ & w_A, w_{h1A}, w_B, w_{h2B}, w_C, w_{h2C}, \\ & w_D, w_{h1D}, w_{h2D}, w_E, w_{h1E}, w_F, w_{h1F}, w_{h2F} \big]. \end{aligned} \tag{11}$$

We assume that all temperature measurements have an uncertainty (noise) of +/-1$°C$, that is $W_{n^{y_T}} = 1°C \; \mathrm{I}_{30\times30}$, where $\mathrm{I}_{30\times30}$ denotes the identity matrix of dimension 30 × 30.

The flow measurements are assumed to have an uncertainty of 2% of the nominal value, resulting in $W_{n^{y_w}} = diag(0.64, 0.96, 0.92, 1.85, 0.48, 0.72, 0.59, 2.37, 0.68, 0.77, 1.60, 1.11, 0.94, 3.50)$ kW/K. The resulting overall noise weighting matrix is

$$W_{n^y} = \begin{bmatrix} W_{n^{y_T}} & 0 \\ 0 & W_{n^{y_w}} \end{bmatrix}. \tag{12}$$

### B. Heat exchanger network model

The heat exchangers are modelled with simple energy balances. We present the model of the heat exchanger in the first line (A) in detail here; the heat exchangers on the other lines are modelled analogously. The main assumptions are incompressible fluids and constant specific heat capacities in all flows.

The energy balance around the cold and hot sides give

$$Q_{A1} = w_A(T_{A,1} - T_0) = w_{hA1}(T^{in}_{hA1} - T_{hA1}), \tag{13}$$

where $Q_{A1}$ denotes the heat, $w_A = m_A c_P$ is the heat capacity flow rate (product of the mass flow rate $m_{A,1}$ and the specific heat capacity $c_P$) of stream A, $w_{hA1}$ is the heat capacity flow rate of the hot stream $hA1$, and $T^{in}_X$ and $T_X$ denote the temperatures of stream $X$ at the inlet and outlet of the heat exchanger, respectively.

The transfered heat is calculated as

$$Q_{A1} = UA_{A1}\Delta T_{lm}, \tag{14}$$

where the logarithmic temperature difference is calculated using the Underwood approximation [15]:

$$(\Delta T_{lm})^{1/3} = \frac{1}{2}[(\Delta T_1)^{1/3} + (\Delta T_2)^{1/3}] \tag{15}$$

where $\Delta T_1 = T^{in}_{hA1} - T_{A,1}$ and $\Delta T_2 = T_{h,A1} - T_0$ denote the temperature differences on the two sides of the heat exchanger. This approximation is very close to the logarithmic mean temperature, while it has better numerical properties. In particular, it is still defined when $\Delta T_1 = \Delta T_2$, while the exact logarithmic mean temperature is not, which can cause problems during the optimization.

An energy balance around the mixer gives

$$T_{end} = \frac{1}{w_0} \sum_{i=A,B,\ldots,F} w_i T_i, \tag{16}$$

and a mass balance around the splitter:

$$w_0 = \sum_{i=A,B,\ldots,F} w_i. \tag{17}$$

### C. Degrees of freedom analysis and nominal optimum

Under operation, the hot flow rates and temperatures are given, as well as the feed temperature $T_0$. Since the total feed flow rate is fixed, the flow in 5 of 6 lines can be set freely. The sixth flow is given from the law of mass conservation. Thus, there are 5 degrees of freedom, and we need to find $n_c = 5$ controlled variables. The nominal parameter values are listed in Table I, and the corresponding optimal measurement values are given in Table II.

## IV. Simulation Scenarios

We consider two scenarios: In Scenario 1, the varying disturbances are assumed to be only the flow rates of the feed and the hot streams, and the heat transfer $UA$ in all heat exchangers. In Scenario 2 the temperatures of incoming streams are considered as additional disturbances.

For both scenarios, we consider different choices of CVs, including single measurements and selected measurement combinations. Their performance is compared in terms of the average loss $L$ calculated from equation (9).

### A. Scenario 1. Flow rate and heat transfer disturbances

The flow and heat transfer disturbances for Scenario 1 are given together with their numerical values in Table III. In the next sections, we consider the performance of some selected control structures.

TABLE I
NOMINAL PARAMETER VALUES

| Symbol | Value | Unit | Description |
|---|---|---|---|
| $T_0$ | 133 | °C | Feed temperature |
| $w_0$ | 225 | kW/K | Feed heat capacity |
| $T_{h1A}^{in}$ | 300 | °C | Hot stream 1A temperature |
| $w_{h1A}$ | 48 | kW/K | Hot stream 1A heat capacity |
| $UA_{A1}$ | 131 | kW/K | Heat transfer coefficient times area A1 |
| $wh1B$ | 92.5 | kW/K | Hot stream 1B heat capacity |
| $UA_{B1}$ | 102.7 | kW/K | Heat transfer coefficient times area B1 |
| $T_{h2B}^{in}$ | 270.3 | °C | Hot stream 2B temperature |
| $UA_{B2}$ | 88.64 | kW/K | Heat transfer coefficient times area B2 |
| $wh1C$ | 35.8 | kW/K | Heat capacity stream 1C |
| $UA_{C1}$ | 84 | kW/K | Heat transfer coefficient times area C1 |
| $T_{h2C}^{in}$ | 245 | °C | Hot stream 2C temperature |
| $UA_{C2}$ | 133.6 | kW/K | Heat transfer coefficient times area C2 |
| $T_{12D}^{in}$ | 226 | °C | Hot stream 1D temperature |
| $w_{h1D}$ | 118.5 | kW/K | Heat capacity stream 1D |
| $UA_{D1}$ | 132.8 | kW/K | Heat transfer coefficient times area D1 |
| $T_{h2D}^{in}$ | 273.8 | °C | Hot stream 2D temperature |
| $w_{h2D}$ | 33.9 | kW/K | Heat capacity stream 2D |
| $UA_{D2}$ | 41.6 | kW/K | Heat transfer coefficient times area D2 |
| $T_{h1E}^{in}$ | 256.4 | °C | Hot stream 1E temperature |
| $w_{h1E}$ | 79.9 | kW/K | Heat capacity stream 1E |
| $UA_{E1}$ | 190.9 | kW/K | Heat transfer coefficient times area E1 |
| $T_{h1F}^{in}$ | 203 | °C | Hot stream 1F temperature |
| $w_{h1F}$ | 47.2 | kW/K | Heat capacity stream 1F |
| $UA_{F1}$ | 49.4 | kW/K | Heat transfer coefficient times area 1F |
| $T_{h2F}^{in}$ | 248 | °C | Hot stream 2F temperature |
| $w_{h2F}$ | 175.1 | kW/K | Heat capacity stream 2F |
| $UA_{F2}$ | 224.1 | kW/K | Heat transfer coefficient times area 2F |

TABLE II
NOMINAL OPTIMAL MEASUREMENT VALUES

| Variable | Value | Variable | Value |
|---|---|---|---|
| $T_{end}$ | 255.676 °C | $T_{h2D}$ | 247.350 °C |
| $T_{1A}$ | 283.102 °C | $T_{1E}$ | 251.430 °C |
| $T_{h1A}$ | 200.358 °C | $T_{h1E}$ | 199.429 °C |
| $T_{2B}$ | 261.281 °C | $T_{2F}$ | 244.393 °C |
| $T_{1B}$ | 231.824 °C | $T_{1F}$ | 164.622 °C |
| $T_{h1B}$ | 206.632 °C | $T_{h1F}$ | 165.818 °C |
| $T_{h2B}$ | 255.680 °C | $T_{h2F}$ | 222.716 °C |
| $T_{2C}$ | 243.184 °C | $w_A$ | 31.8637 kW/K |
| $T_{1C}$ | 213.075 °C | $w_B$ | 45.9091 kW/K |
| $T_{h1C}$ | 171.672 °C | $w_C$ | 23.8251 kW/K |
| $T_{h2C}$ | 224.962 °C | $w_D$ | 29.4667 kW/K |
| $T_{2D}$ | 254.175 °C | $w_E$ | 38.4364 kW/K |
| $T_{1D}$ | 223.745 °C | $w_F$ | 55.4990 kW/K |
| $T_{h1D}$ | 203.435 °C | | |

*1) Open loop operation:* Simply leaving the split at the nominal optimal values results in an average loss of

$$L_{OL1} = 0.3147°C \tag{18}$$

Although this value is quite low, it may be reduced further by controlling the right variables.

*2) Controlling a combination of all measurements:*

*a) Exact local method:* Using a combination $c = Hy$ of all measurements $y$, for our scenario the average loss is

$$L_{All1} = 0.0284°C \tag{19}$$

This is the locally best loss that can be achieved in this scenario using a linear measurement combination.

TABLE III
FLOW AND HEAT TRANSFER DISTURBANCES WITH MAGNITUDES FOR SCENARIO 1

| Variable | Weighting in $W_d$ | Description |
|---|---|---|
| $w_0$ | 11.25 kW/K | Feed heat capacity |
| $w_{h1A}$ | 2.40 kW/K | Hot stream 1A heat capacity |
| $UA_{A1}$ | 13.10 kW/K | Heat transfer coefficient times area A1 |
| $UA_{B1}$ | 10.20 kW/K | Heat transfer coefficient times area B1 |
| $w_{h2B}$ | 4.60 kW/K | Hot stream 2B heat capacity |
| $UA_{B2}$ | 8.90 kW/K | Heat transfer coefficient times area B2 |
| $UA_{C1}$ | 8.40 kW/K | Heat transfer coefficient times area C1 |
| $w_{h2C}$ | 1.80 kW/K | Hot stream 2C heat capacity |
| $UA_{C2}$ | 13.40 kW/K | Heat transfer coefficient times area C2 |
| $w_{h1D}$ | 5.90 kW/K | Heat capacity stream 1D |
| $UA_{D1}$ | 13.30 kW/K | Heat transfer coefficient times area D1 |
| $w_{h2D}$ | 1.70 kW/K | Heat capacity stream 2D |
| $UA_{D2}$ | 4.20 kW/K | Heat transfer coefficient times area D2 |
| $w_{h1E}$ | 4.00 kW/K | Heat capacity stream 1E |
| $UA_{E1}$ | 19.10 kW/K | Heat transfer coefficient times area E1 |
| $w_{h1F}$ | 2.40 kW/K | Heat capacity stream 1F |
| $UA_{F1}$ | 4.90 kW/K | Heat transfer coefficient times area 1F |
| $w_{h2F}$ | 8.80 kW/K | Heat capacity stream 2F |
| $UA_{F2}$ | 22.40 kW/K | Heat transfer coefficient times area 2F |

*b) Null space method:* If we neglect the noise and select $H$ in the left null space of $F$, the performance of the plant with noise is dependent on which basis vectors of the null space are chosen for $H$. For two different sets of basis vectors $H_1$ and $H_2$ we have

$$\begin{aligned} L_{All1}^{NullSpace}(H_1) &= 19.1711°C \\ L_{All1}^{NullSpace}(H_2) &= 2.0702°C \end{aligned} \tag{20}$$

The loss is very different for different choices of basis vectors of the left null space of $F$. If there was no noise, $W_d = 0$, we would have $L_{All1}^{NullSpace}(H_1) = L_{All1}^{NullSpace}(H_2) = 0$. We do not further consider the issue of selecting the best basis vectors using the extended null-space method [6], because this is beyond the scope of this paper, and because the exact local method (Eq. (5)) selects the best (optimal) $H$ in presence of noise and disturbances.

*3) Using subsets of measurements:* The average loss when using different subsets of measurements in linear variable combinations is shown in blue in Fig. 2. The largest reduction in the loss comes when increasing the number of measurements from 5 to 6. The reason for this is that the disturbances may enter the plant in all 6 lines. When using only 5 measurements from 5 lines, the disturbance in the 6th line is not detected. Adding a 6th measurement from the remaining line makes it possible to detect disturbances affecting this line, too, and therefore reduces the loss significantly.

Above a certain number of measurements the loss does not significantly decrease further. From Fig. 2 it is evident that the loss decreases very little for more measurements than 15, and above 20 measurements the decrease in loss is hardly observable[2]. The loss is very low for this scenario, and in

[2] It decreases slightly for some more measurements, but for the last 9 measurements it is completely flat. These last 9 measurements are the inlet temperatures of the feed and the hot streams, which are assumed to be constant. Thus they do not provide any further information for disturbance rejection in Scenario 1.

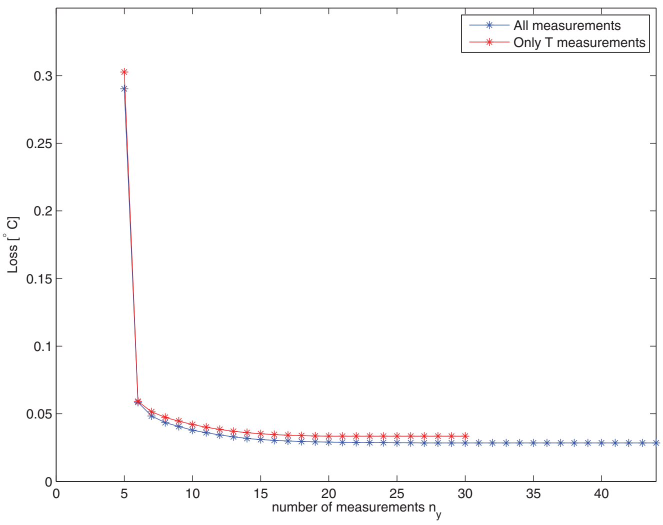

Fig. 2. Scenario 1 (Flow rate and $UA$ disturbances): Loss for best combinations of different number of measurements $n_y$

most practical cases, open loop operation will be sufficient. However, if one wants to optimize performance further, it does not seem reasonable invest in measurement equipment for more than 10-15 measurements.

*a) Only temperature measurements:* Typically, not all measurements are equally capital intensive. E.g. temperature measurements are generally much cheaper than flow measurements. Therefore we next consider cases with different sets of temperature measurements. The relationship between the average loss and the number of temperature measurements included in the CVs is given in red in Fig. 2. The trend is very similar to when flow measurements are used, too. After a sharp initial decrease, the curve flattens out quickly. The average loss resulting from using all temperature measurements is

$$L_{AllT1} = 0.0335°C. \tag{21}$$

This is only little higher than when using all measurements, including flows. Note that also here, the constant inlet temperatures do not contribute to minimizing the loss.

*b) Only specific temperature measurements:* In many practical cases we may have that the outlet temperatures of the cold streams are measured, i.e.

$$y = [T_{1A}, T_{1B}, T_{2B}, T_{1C}, T_{2C}, T_{1D}, T_{2D}, T_{1E}, T_{1F}, T_{2F}]^T \tag{22}$$

In this case the average loss using a linear combination is

$$L_{outTemp1} = 0.0639°C \tag{23}$$

*c) Single temperature measurements:* The simplest strategy (beside open loop operation) is to control as many single temperatures as there are degrees of freedom. The best set gives a loss of

$$L_{Single\,T1} = 0.3027°C \tag{24}$$

TABLE IV
TEMPERATURE DISTURBANCES WITH MAGNITUDES FOR SCENARIO 2

| Variable | Weighting in $W_d$ | Description |
|---|---|---|
| $T0$ | $13.0°C$ | Feed temperature |
| $T^{in}_{h1A}$ | $30.0°C$ | Hot stream 1A temperature |
| $T^{in}_{h2B}$ | $27.0°C$ | Hot stream 2B temperature |
| $T^{in}_{h2C}$ | $24.5°C$ | Hot stream 2C temperature |
| $T^{in}_{12D}$ | $22.6°C$ | Hot stream 1D temperature |
| $T^{in}_{h2D}$ | $27.4°C$ | Hot stream 2D temperature |
| $T^{in}_{h1E}$ | $25.6°C$ | Hot stream 1E temperature |
| $T^{in}_{h1F}$ | $20.3°C$ | Hot stream 1F temperature |
| $T^{in}_{h2F}$ | $24.8°C$ | Hot stream 2F temperature |

with the measurements

$$y = [T_{1A}, T_{2B}, T_{h2C}, T_{2D}, T_{1E}]^T. \tag{25}$$

### *B. Scenario 2. Flow, heat transfer, and temperature disturbances*

In this more general scenario, in addition to varying flow rates and heat transfer coefficients, as in the previous section, we assume that the stream temperatures are also varying in the ranges given in Table IV. We proceed as in the previous section with considering the different cases with different measurements involved.

*1) Open loop operation:* Operating the heat exchanger in open loop with the nominal values for the splits, results in a quite high average loss of

$$L_{OL2} = 2.2836°C. \tag{26}$$

*2) Controlling a combination of all measurements:*

*a) Exact local method:* Using all available measurements, the exact local method gives an average loss of

$$L_{All2} = 0.0318°C. \tag{27}$$

which is just a little bit higher than the loss in Scenario 1.

*b) Null space method:* If we neglect the noise and select $H$ in the left null space of $F$, such that $HF = 0$, the actual loss with noise is again dependent on the choice of basis vectors for $H$. Two examples are

$$\begin{aligned} L^{NullSpace}_{All1}(H_1) &= 19.1711°C \\ L^{NullSpace}_{All1}(H_2) &= 2.0702°C \end{aligned} \tag{28}$$

The loss is the same as in Scenario 1, since the same columns of the null space have been selected, and the left null space for Scenario 1 is contained in the null space for Scenario 2.

*3) Using subsets of measurements:* Plotting the number of measurements used in the controlled variable versus the loss, Figure 3 in blue, indicates that it is not necessary to include all measurements, since the loss is not reduced significantly when including more than 10 measurements. Moreover, we find that above 10 measurements including flow measurements does not give any significant advantage in terms of loss over using only temperature measurements.

*a) Only temperature measurements:* Using only temperatures, the best combination results in a very small a loss of

$$L_{AllT2} = 0.0438°C. \tag{29}$$

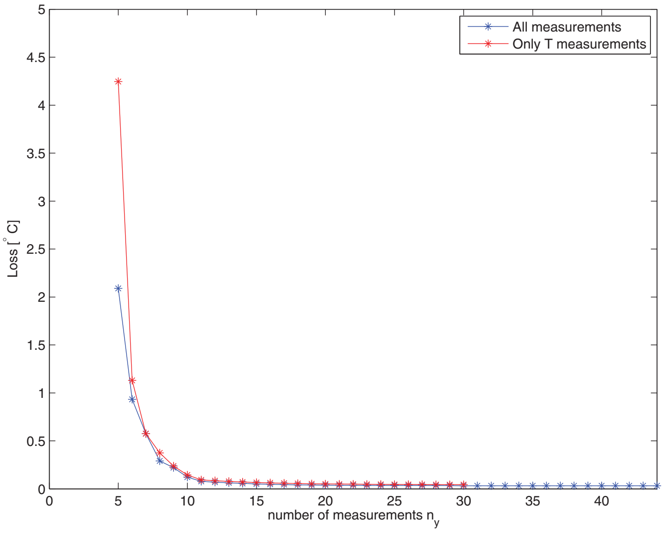

Fig. 3. Scenario 2 (Flow rate, Temperature and $UA$ disturbances): Loss for best combinations of different number of measurements $n_y$

*b) Only specific temperatures measurements:* Using only the outlet temperatures of the cold streams, as in Eq. (22) gives a loss of

$$L_{outTemp2} = 16.9079°C, \tag{30}$$

which is very high. However, if we add some disturbance measurements, namely the stream inlet temperatures,

$$\begin{aligned} y =[&T_0, T_{1A}, T_{h1A}^{in}, T_{2B}, T_{h2B}^{in}, T_{2C}, T_{h2C}^{in}, T_{2D}, T_{1D}, \\ &T_{h1D}^{in}, T_{h2D}^{in}, T_{1E}, T_{h1E}^{in}, T_{2F}, T_{1F}, T_{h1F}^{in}, T_{h2F}^{in}] \end{aligned} \tag{31}$$

the loss is reduced to

$$L_{outTemp2a} = 0.0961°C \tag{32}$$

Thus, measuring the disturbances (the stream inlet temperatures) reduces the loss orders of magnitudes.

*c) Single temperature measurements:* Controlling single temperature measurements, leads to a loss of

$$L_{SingleT2} = 4.2459°C \tag{33}$$

with the measurement set

$$y = [T_{h1A}, T_{1B}, T_{1C}, T_{2D}, T_{h1E}] \tag{34}$$

## V. Discussion and Conclusions

This HEN case study shows clearly that the control structure design has a strong impact on the performance. Especially in cryogenic processes and systems which process large quantities, like refineries, improving the average end temperature just 0.5-1°C leads to significant economics savings.

Although the disturbances in Scenario 1 are included in Scenario 2, we treated Scenario 1 separately, because it shows that the stream inlet temperatures are the disturbances, which have the strongest effect on the loss. If it could be guaranteed that the inlet temperatures remain constant (Scenario 1), then keeping the splits constant would most likely be sufficient.

The situation changes dramatically if the stream inlet temperatures are varying (Scenario 2). Here an open loop policy causes high loss, and controlling single measurements performs even worse. In this case, however, controlling good temperature measurement combinations can reduce the loss up to around 2 orders of magnitude.

The relationship between the number of measurements used and the loss, Fig. 2 and 3, shows that including flow measurements does not reduce the loss significantly, provided enough temperature measurements are available. Controlling combinations of about 10 or more temperature measurements results in a very small loss.

The null space method, which gives zero loss without noise, has been shown to give very poor performance, sometimes even worse than open loop operation, because the loss is dependent on which set of null space basis vectors is chosen as $H$. Thus, this case study clearly demonstrates how necessary it is to take noise into account when finding $H$.

*Abstract*— **This paper presents a study on the plantwide control of a benchmark pulping process. Control structure determination was based on Relative Gain Array (RGA) and Relative Disturbance Gain (RGD) analysis. RGA and RDG were calculated based process a multiple-input multiple-output (MIMO) process transfer model identified from open-loop tests. Both static and dynamic RGA and RDG were calculated and analysed. These analyses confirmed the setting provided by the authors of the Benchmark, based on static RGA. Controllers in the individual control loops were tuned using Internal Model Control (IMC) tuning methodologies and the best set of controller parameters was chosen by evaluating the control system performance for set-point tracking and disturbance rejection in terms of the Integral of Absolute Error (IAE), setting time, time constant and percentage of overshoot. The Kappa factor, a key quality variable, was controlled by PI controllers combined with Smith-predictors and tuned with IMC. PI-only controllers tuned using IMC were used to control the secondary variables. With Smith predictors larger controller gains and smaller reset times can be used leading to faster control response. The proposed control strategy is successfully implemented on the benchmark simulation.**

## I. INTRODUCTION

In a pulp mill, the main objective is to produce pulp of a certain Kappa number (measurement of lignin content) and brightness (traditional measurement of blue reflectance) using the minimum energy resources, utilities and chemicals. Castro and Doyle [1] presented a detailed control study of the fiberline of a pulp mill process. The process model consists of a set of equations with approximately 5000 states to capture the dynamics of the main unit operations: pulp digester, oxygen reactor, bleach towers, washers, and storage tanks. Heuristic methods were used to determine the primary control variables and relative gain array (RGA) analysis was performed to obtain the input-output pairings for decentralized control. The performance of model predictive control and decentralized single-input single-output control were compared, finding that the MPC offers a better framework when controlling the digester but no big differences between both techniques were found when controlling the bleach plant.

Vanbrugghe et al. [2] recalculated the RGA of the bleach plant and proposed a real-time optimization algorithm based on a modified version of an IMC-based optimization method. The performance was improved by on-line estimation of the process parameters and the total cost of the bleaching section was reduced by 10.6%. In 2004, Castro and Doyle [3] introduced a benchmark problem of a pulping process, including both the fiber line and the chemical recovery sections. The complete details of the pulp mill process were given, as well as the control objectives, modes of operation, process constraints, measurements and costs. The dynamic model, including the source/binary code of all the unit operations was made available to the process control academic community as a benchmark for its use in process system engineering studies. The benchmark also provides code for different controller structures, such as PID and MPC, including other decentralized advanced tools like feedforward controllers and Smith predictors.

Since its introduction, RGA has been a very important tool for determining the best input-output parings for decentralized control. However, there are many control practitioners who doubt about its usefulness in some control applications because it does not include the effects of disturbances. Stanley et al. [4] proposed a new measurement, called relative disturbance gain (RDG) in order to include disturbances when selecting the input-output pairings. There is not an explicit study of RGD in the bleach plant supporting and confirming the proposed input-output pairings obtained using RGA or dynamic RGA. It should be therefore necessary to demonstrate that the input-output pairings given by Castro and Doyle [1] are suitable in the bleach plant in terms of disturbance rejection performance.

The paper is organized as follows. Section II presents the benchmark simulated bleach plant. Control structure selection using RGA and RDG analysis is presented in Section III. Section IV gives the control system performance. Some concluding remarks are presented in Section IV.

## II. THE BLEACH PLANT

The main objective of the bleach plant is to remove lignin from the pulp and to obtain an appropriate brightness coefficient. This objective is achieved by using bleach towers, where the pulp is mixed together with oxidizing chemicals

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

which make the lignin to be soluble in water. Fig. 1 shows a schematic of the bleaching plant [3].

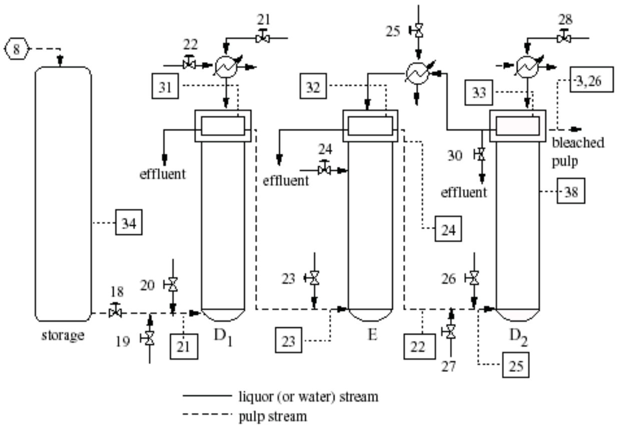

Fig. 1. Bleach plant flowsheet

After storage, the pulp is subjected to three bleach stages. The bleach towers are vertical cylindrical vessels. The pulp moves vertically in plug flow. Each tower has auxiliary equipment such as a chemical mixer, a washer and a seal tank.

The washer is mounted in the bleach tower exit and it is used to eliminate dissolved chemicals from the pulp. It is a rotary drum washer, where clear water or recycled washer effluent coming from the following bleach tower is used to eliminate dissolved chemicals. The pulp enters in the rotating drum under vacuum. The outer surface of the drum is at higher pressure than its internal part, so the pulp enters in the drum through its porous surface. This causes the formation of a mat of pulp in the surface of the drum. Then, wash showers are used to remove further dissolved solids which may still in the pulp. Additional water is mixed together with the pulp to achieve the desired consistency. The temperature of this water is controlled with heat exchangers. The seal tank acts as storage or buffer for compensating variations in the composition of the liquor. The first and third bleach towers use chlorine dioxide as chemical agent to remove lignin from the pulp while the second uses sodium hydroxide.

The benchmark bleach plant has 11 controlled variables (CV), 14 possible manipulated variables (MV) and 10 potential disturbances (DV). Tables I, II and III show, respectively, the controlled, manipulated and disturbance variables.

TABLE I.
CONTROLLED VARIABLES OF THE BLEACH PLANT

| CV | Description | CV | Description |
|---|---|---|---|
| 21 | Temperature of bleach tower $D_1$ | 31 | Washer 5 dilution factor |
| 22 | Bleach tower E Kappa no. | 32 | Washer 6 dilution factor |
| 23 | Temperature of bleach tower E | 33 | Washer 7 dilution factor |
| 24 | E washer $[OH^-]$ | 34 | Storage volume |
| 25 | Temperature of bleach tower $D_2$ | 38 | $D_2$ tower volume |
| 26 | $D_2$ tower brightness | | |

Controlled variables CV22 and CV26 are considered to be the quality variables of the bleach plant, so special care must be taken when designing a control system for these variables. Variable CV24 is not a quality variable, but it has a big influence in variable CV26. These three variables are assumed to be the primary controlled variables of the bleach plant. The rest of the controlled variables are the secondary controlled variables of the process.

| 20 | $D_1$ $ClO_2$ flow | 27 | $D_2$ caustic flow |
| 21 | $D_1$ wash water flow | 28 | $D_2$ wash water flow |
| 22 | $D_1$ steam flow | 30 | Split fraction 4 |
| 23 | E caustic flow | 38 | $D_2$ exit flow |

## III. CONTROL STRUCTURE SELECTION

The RGA technique was developed by Bristol [5] and has become the most important technique for measuring interaction and a very useful tool for decentralized control design. It is a valuable technique for the selection of manipulated-controlled variable pairings and it can also be used to predict the behaviour of controlled responses [6]. Grosdidier et al. [7] provided a derivation of the properties of the RGA. Additional properties were presented by Hovd and Skogestad [8], who extend the rules to the frequency domain.

The RGA methodology requires the steady-state gains of the process to determine the best set of input-output pairings. The presence of the storage tank and the $D_2$ bleach tower makes the process to be open-loop unstable. This is caused by the integrating nature of level systems. Before proceeding with the open-loop tests, two loops were closed to control the level of these two vessels. The manipulated variable selected to control the level of the storage tank was the storage exit flow. The manipulated variable chosen to control the level of the $D_2$ bleach tower was the $D_2$ exit flow. In order to avoid excessive variations of these two manipulated variables, two proportional-only controllers with default settings were used to perform this task. After removing these two input-output variables from the steady-state gain matrix, twelve candidate manipulated variables were available to control the remaining nine output variables. The generalization of the RGA for non-square plants was used to perform the RGA analysis. Then, the RGA, $\Lambda$, is given by:

$$\Lambda = H * \left(H^T\right)^{-1} \tag{1}$$

where * represents element by element multiplication.

The gain matrix $G$ can be decomposed, using singular value decomposition, as:

$$G = UDV^T \tag{2}$$

where $U$ and $V$ are orthogonal matrices and $D$ is a diagonal matrix containing only the positive singular values. In Eq(1), $H$ is the pseudo-inverse of matrix $G$. It was observed that the sum of terms of the columns related to manipulated variables “MV24”, “MV19” and “MV19” were much lower than one, so these variables were removed from the RGA to obtain a square matrix. The resulted RGA is presented in Fig. 2. Due to the sequential nature of the bleach plant, the RGA is almost a diagonal matrix. All diagonal terms are close to one and off-diagonal terms are negligible.

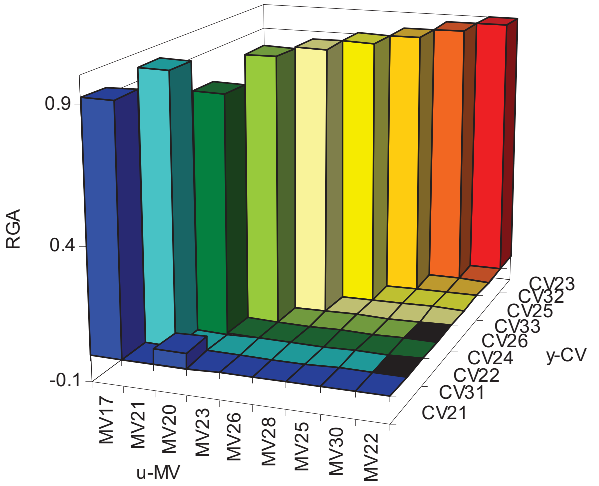

Fig. 2. Relative Gain Array of the bleach plant

After approximating the open-loop responses with continuous first-order-plus-time-delay transfer functions, the RGA was calculated as a function of frequency to find if the pairings calculated using static RGA are still appropriate from a dynamic point of view. All diagonal terms of the RGA remain closed to one in the whole frequency range, which indicates the proposed set of input-output pairings is also suitable from the dynamic point of view. Fig. 3 shows the first three diagonal elements of the dynamic RGA.

Since its introduction, RGA has been widely used in industry to configure multi-loop control systems [9]. McAvoy [10] has shown that there is a strong link between the RGA and the stability and design of a control loop. However, the RGA has been the subject of controversy [11]. Some engineers think that it does not have any use while others strongly rely on it.

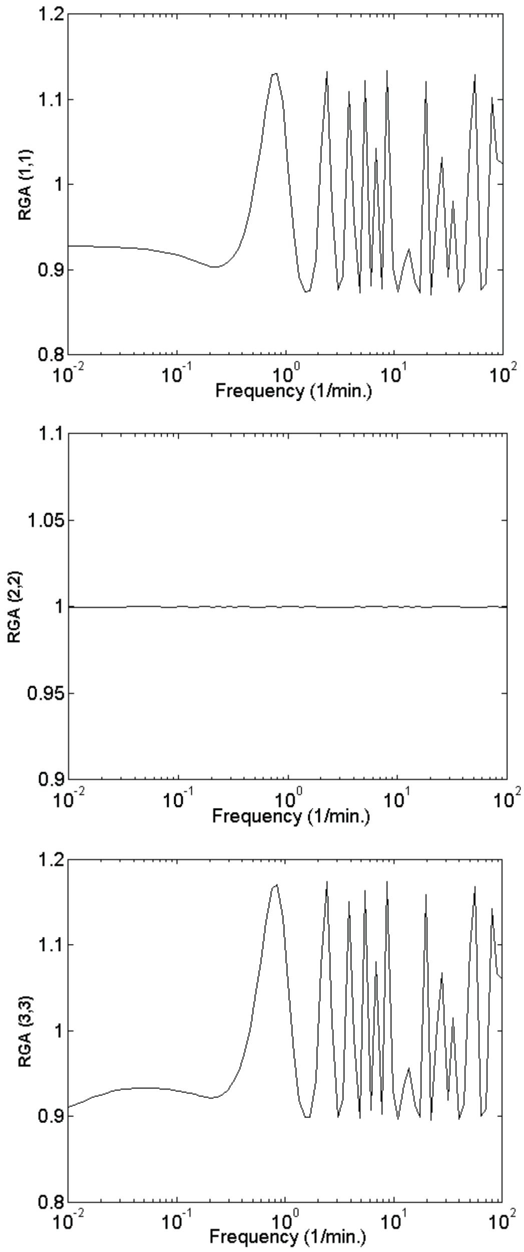

Fig. 3. The first three diagonal terms of the dynamic RGA

RGA is generally considered having two main disadvantages. Firstly, RGA is calculated from steady-state data only and therefore dynamic interactions may cause it to provide wrong conclusions. This problem was overcome by introducing dynamic interaction measures [12], [13]. Secondly, RGA is independent of load disturbances affecting the control loop. Stanley et al. [4] defined RDG in order to include disturbances in the analysis of the control loop performance. RGD is similar to RGA in the sense that it involves the ratio of two different steady-state gains: perfect control gains to open-loop gains. RDG can be calculated from steady-state information only but it can also be extended to take into account dynamic interactions. For simplicity, the definition of the RDG is presented for a 2×2 system. The extension for an $n \times n$ case is straightforward. The steady-state gain matrix for a 2×2 system including the gains of a load disturbance, $d$, is:

$$\begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = \begin{bmatrix} K_{11} & K_{12} & K_{F1} \\ K_{21} & K_{22} & K_{F2} \end{bmatrix} \begin{bmatrix} m_1 \\ m_2 \\ d \end{bmatrix} \qquad (3)$$

The RGD, $\beta_1$, is defined as the ratio of changes in the controller output that is required to bring $x_1$ back to its desired set-point when the load disturbance, $d$, is introduced into the system under two situations: multi-loop control and single loop control. Mathematically, $\beta_1$ is defined as a ratio of two gains:

$$\beta_1 = \frac{\left.\dfrac{\partial m_1}{\partial d}\right|_{x_1, x_2}}{\left.\dfrac{\partial m_1}{\partial d}\right|_{x_1, m_2}} \qquad (4)$$

Thus, $\beta_i$ can also be interpreted as a comparison between multi-loop control and ideal decoupled control. This means that if $\beta_i > 1$, then the controller effort within a multi-loop environment is bigger than the one required for a SISO system and therefore a decoupler is recommended. A small value of the RDG means that the controller output does not have to move too far from its steady-state to compensate the effects of the load disturbance. Mathematically, multi-loop control is preferred when [4]:

$$|\beta_1| + |\beta_2| < 2 \qquad (5)$$

From the ten possible load disturbances, it was observed that just five play a significant role in the process. These load disturbances are DV14, DV16, DV18, DV19 and DV22. Each of the load disturbances DV18, DV19 and DV22 only affects one controlled variable CV25, CV26 and CV25 respectively. The load disturbance DV14 affects the controlled variables CV22 and CV26 while the load disturbance DV16 affects the controlled variables CV24 and CV26. Therefore, the RDG analysis only makes sense when studying the disturbance variables DV14 and DV16. Fig. 4 shows the effects of the disturbance variable DV16 on controlled variables CV24 and CV26 in terms of RDG. Fig. 5 gives the RDG terms related to disturbance DV14. As observed, the sum of RDG does not surpass considerably the upper limit in the whole frequency range. This means the control loop pairings obtained using RGA are appropriate for disturbance rejection is this process.

## IV. Control Performance

The primary variables were controlled by a combination of Kappa Factor control with conventional feedback control while the secondary outputs using only PI controllers. The Kappa Factor control is a particular controller used in Pulp Mills especially designed for disturbance rejection. Its operation together with PI controllers allows free-offset set-point tracking. Essentially, the Kappa factor can be understood as the ratio between lignin content in the pulp and the chemical agent entering the bleach tower. The general equations of the Kappa Factor are defined as [2]:

$$K_f = a_n K_{in}^n + a_{n-1} K_{in}^{n-1} + \ldots + a_1 K_{in} + a_0 \qquad (6)$$

$$F_x = K_f F_p C_p K_{in} / X \qquad (7)$$

where $K_f$, $F_x$, $X$, $F_p$, $C_p$ and $K_{in}$ are, respectively, the Kappa factor, chemical flow rate (manipulated variable), chemical composition, pulp flow rate, pulp consistency and pulp upstream Kappa no. The product of variables $K_f$, $C_p$ and $F_P$ determines the amount of lignin entering the bleach tower. Coefficients $a_0$ to $a_n$ define a polynomial of order $n$ which expresses the functionality between the Kappa Factor and the incoming Kappa no. Based on industrial experience it is possible to determine this functionality.

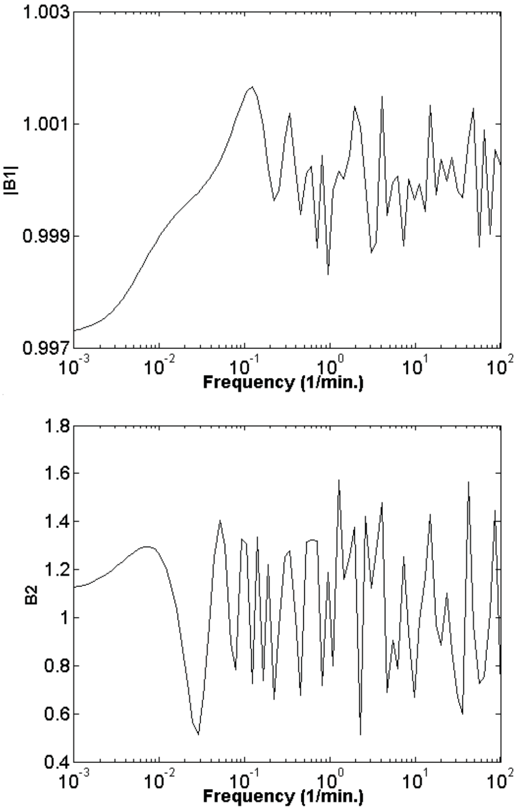

Fig. 4. Dynamic RDG for disturbance variable DV16 and controlled variables CV24 and CV26

Controller settings for each control loop were calculated using different internal model control tuning (IMC) methodologies. Rivera et al [14] have proposed tuning methods for PID controllers based on the IMC methodology. Table 4 gives the IMC tuning rules for the following first order plus delay model:

$$G(s) = \frac{Ke^{-\alpha s}}{1+\tau s} \qquad (8)$$

TABLE IV.
IMC TUNING FORMULAE

| Controller Type | $K_c$ | $\tau_I$ | Recommended λ |
|---|---|---|---|
| PI | $\tau/(\lambda K)$ | $\tau$ | λ/α>1.7 |
| Improved PI | $(2\tau+\alpha)/(2\lambda K)$ | $\tau+\alpha/2$ | λ/α>1.7 |

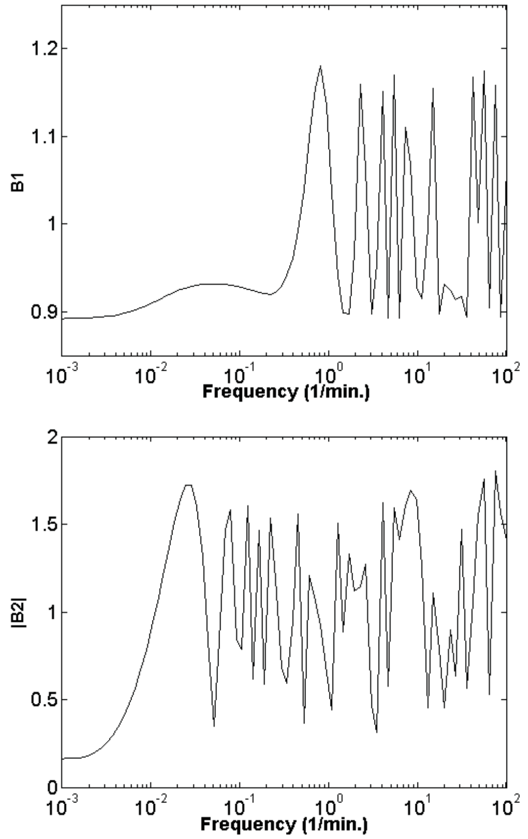

Fig. 5. Dynamic RDG for disturbance variable DV14 and controlled variables CV22 and CV26

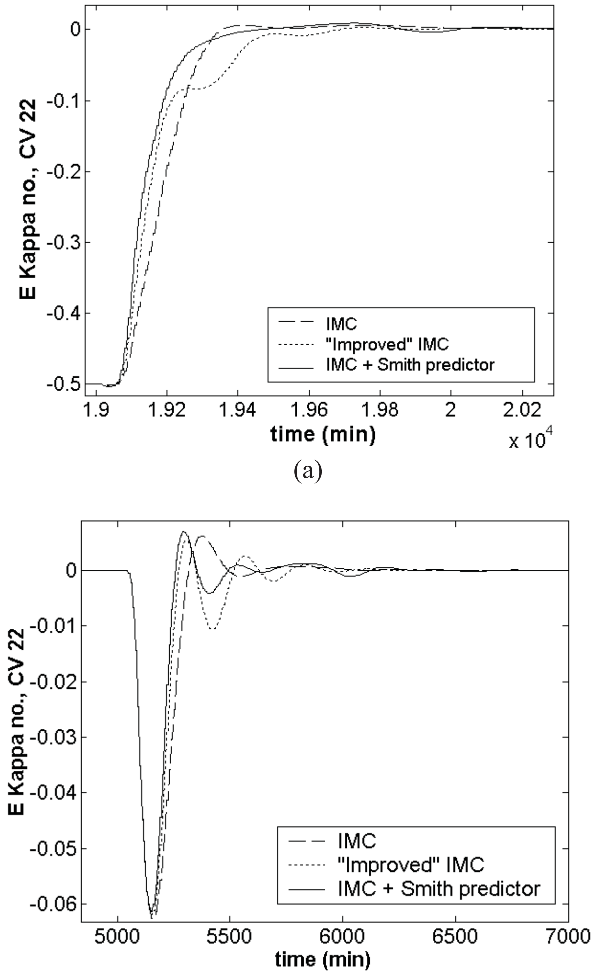
A conservative value of λ=2.5α was used in order to avoid excessive control action due to model-plant mismatch. For variables with no time delay, the value of λ was adjusted by inspection of the controlled responses. Additionally, controller settings were calculated using Smith-Predictors in the quality variables. Using Smith-Predictors, instead of tuning each controller without considering the time delay of the process, a value of λ=2α was introduced in the classical IMC formulae. The best setting of controller parameters was chosen by the behaviour of the system for set-point tracking and disturbance rejection performance. Integral of absolute error (IAE), settling time, time constant and percentage of overshoot were the parameters used for evaluating these performances. PI controllers combined with Smith-predictors, and tuned with classical IMC, providing the set-points of the Kappa factor controllers related to the quality variables of the process and PI-only controllers tuned using IMC controlling the secondary variables give the best control performance. Smith predictors allow the controller designer to provide to the process controllers larger controller gains and smaller reset times, making the controlled response faster.



(a)

(b)

Fig. 6. Set-point tracking and disturbance rejection performances for CV22

Fig. 6 (a) and Fig. 7 (a) show the set-point tracking performances of the primary variables CV22 and CV24. Examples of disturbance rejection performances for the three primary variables are shown in Fig. 6 (b), Fig. 7 (b) and Fig. 8. Fig. 6 (b) represents the disturbance rejection performance of the primary variable CV22 under a positive step change of magnitude 0.25 in the disturbance variable DV14. By the same way, Fig. 7 (b) and Fig. 8 represent, respectively, the disturbance rejection performance of the primary variables CV24 and CV26 under a positive step change of magnitudes 0.25 in respectively the disturbance variables DV16 and DV19. As it can be observed, the use of Smith predictors significantly improves the control performance.

## V. Conclusions

Plant wide control of simulated benchmark bleach plant with emphasis on Kappa number control and brightness control is presented in this study. Dynamic RDG analysis confirms the input-output setting provided by the authors of the benchmark based on RGA analysis. Additionally, it is demonstrated that PI controllers combined with Smith-predictors, and tuned with classical IMC, providing the set-points of the Kappa factor controllers related to the quality variables of the process offers an appropriate methodology to control the main objectives of the plant in terms of set-point tracking and disturbance rejection performances.

# Eco-efficiency of control configurations using Exergy

M. T. Munir is working as a Post doc in the Chemical and Materials Engineering Department, The University of Auckland New Zealand (email: mmun047@aucklanduni.ac.nz).

W. Yu is a lecturer at the Chemical and materials department, The University of Auckland New Zealand (email:wyu048@aucklanduni.ac.nz).

B. R. Young is a professor at the Chemical and materials engineering department, The University of Auckland New Zealand (Phone: +64 9 923 5606; Fax: +64 9 373 7463; email: b.young@auckland.ac.nz).

***Abstract*— For general multi-input multi-output (MIMO) processes, thermodynamic properties like exergy have been previously used for the development of eco-efficiency analysis tools e.g. Relative Exergy Array (REA) [1, 2], and Exergy Eco-efficiency Factor (EEF) [3]. The REA is easy to use, compares several control scheme candidates for single units and ranks them according to their exergy interactions between control loops. The EEF provides means to determine the effect of a control scheme on the eco-efficiency of the whole process. In this paper, our intention is to justify the use of EEF and REA, compare EEF recommendations to REA, and consider EEF for the whole process eco-efficiency and discuss the similarities and differences between REA and EEF. Furthermore these results of testing REA and EEF on a realistic case study will be analysed to provide some practical recommendations on their usage.**

**Keywords- Relative exergy array (REA); Control configurations; Exergy eco-efficiency factor (EEF); Eco-efficiency**

## I. Introduction

Most industrial chemical processes are multi-input multi-output (MIMO) in nature. These systems can be either controlled by a multivariable or centralized MIMO controller or by a set of single-input single-output (SISO) controllers. Since centralized multivariable controllers are complex and lack integrity, decentralized control systems have more attractive advantages: i) simple algorithms; ii) ease of understanding by plant operating personnel; and iii) standard control design developed for common unit operations [4]. Therefore, they are more often selected for control of MIMO systems.

For a decentralized type of control system, the control system structure decides the best control scheme. Control scheme selection pertains to the pairing of manipulated (MV) and controlled variables (CV). For a process or plant, control scheme selection is a straightforward task, provided that no interactions are present between the various control loops in multi-loop control schemes of that process or plant. However, this is rarely the case in process control design practice. A well performing control scheme selection is essential because the incorrect pairing of MV and CV will result in poor performance.

There are several techniques and methods for designing or selecting decentralized MIMO control schemes, such as the relative gain array (RGA), the Niederlinski index (NI), singular value decomposition (SVD), the condition number (CN) and Morari's resiliency index (MRI) [5-7].

In some cases, these steady state information based techniques (RGA, NI, SVD and CN) can lead to incorrect conclusions concerning the control scheme selection. Dynamic effects are also included in some techniques/methods to minimize the deficiency of these steady state techniques. For example, this happens in dynamic relative gain array (DRGA), internal model control (IMC) and effective relative gain array (ERGA). Using the steady state (RGA, NI, SVD and CN) and dynamic (DRGA, IMC and ERGA) techniques, well performing control schemes are further selected. The viability of a well performing/selected control scheme is further validated by the dynamic simulation of responses to the various process disturbances.

Steady state and dynamic techniques for selecting MIMO control schemes focus on controllability and control loop stability. Control system structure or control scheme selection is a large part of process control. In this age of ubiquitous industrialization and in the wake of decreasing energy resources, increasing energy costs and energy crises, special attention must be paid to the control system structure or control scheme selection, as a poorly structured control scheme can lose a great deal of energy from a process or plant. In the wake of energy crises, control scheme selection must also consider energy usage, cost and ecological impacts. This can be achieved by integrating control scheme selection and energy cost/energy usage/environmental impacts.

Thermodynamic properties such as exergy have the potential to amalgamate several elements into a single domain, these include; control system structure/control scheme selection and energy cost/energy usage/environmental impacts. The concept of exergy indicates what is wasted in terms of energy or the eco-efficiency of the process/plant. Exergy is the component of energy which is available for useful work. Kotas [8, pp 7] defines exergy as "The maximum amount of work/useful energy drawn from a process/material stream as it comes from its original state (process condition) to the ultimate dead state (reference state) during which it interacts only with the environment". At the ultimate dead state, the

Corresponding author: b.young@auckland.ac.nz process/material stream is in thermodynamic (thermal, mechanical and chemical) equilibrium with the environment [9].

The total energy of a material stream has two main parts (available energy and unavailable energy). Exergy of a material stream accounts for the quality of energy or available energy. According to the 1st law of thermodynamics energy in and out of a process is equal. According to the 2nd law of thermodynamics exergy in is greater than exergy out due to entropy generation or exergy destruction during the process. The fraction of non-available energy normally increases from input to output due to exergy destruction during a process. The increase in non-available energy is also called available energy loss as shown in Figure 2.

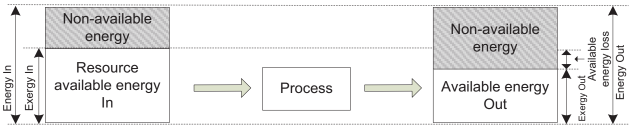

Figure 1. Energy and Exergy

Exergy accounts for the quality of energy/fraction of energy that can be fully converted into useful work and/or other types of energies. Every irreversible process causes exergy destruction leading to an increased exergy/energy requirement or entropy production. Since exergy can detect and evaluate the causes of the thermodynamic imperfections of the considered process/material stream, it can therefore be used as a measure to evaluate the eco-efficiency of the process.

Eco-efficiency is also a measure of progress in green chemical engineering growth. The concept of eco-efficiency can be traced back to the 1960s as the concept of environmental efficiency, or as a business when linked to sustainable development. Eco-efficiency has a role in expressing how efficient economic activity is with regard to nature's goods/services. The concept of eco-efficiency focuses on methods of resource use, obtaining economic and environmental progress through efficient use of resources and lower pollution/emissions.

The World Business Council for Sustainable Development (WBCSD) states that eco-efficiency is achieved through the practice of producing "valuable goods and services that satisfy human needs and bring quality of life with reduced environmental impacts and resource intensity in line with the Earth's estimated carrying capacity." In other words eco-efficiency means producing more with less. An eco-efficient process is ecologically friendly and economically viable. Ecologically friendly practices signify a process with reduced consumption of energy/destroyed exergy. This diminution in energy utilization reduces the operational expenses of that process. Efficient use of energy/exergy plays an important role for sustainability and minimizing environmental impacts.

Exergy has many valuable uses in process design and control to facilitate these complex tasks. There are many exergy based tools and methods, such as; efficiency concepts, exergy flow diagrams, relative exergy array (REA) and exergy eco-efficiency factor (EEF). The REA is used to measure control scheme interactions and exegetic efficiency for the various possible MIMO control schemes [1, 2, 10]. However, the REA only measures the eco-efficiency within the scope of single, decentralized control loops. To overcome this deficiency in REA, the EEF is defined and employed for the eco-efficiency analysis of the whole process [3]. More details of REA and EEF are presented in section II.

In this work, the intention is to justify the use of REA and EEF coupled with classical controllability tools (RGA, NI, SVD and CN), compare EEF recommendations to REA, and consider EEF for the whole process eco-efficiency and discuss the similarities and differences between REA and EEF. The results of REA and EEF are also analyzed to provide some practical recommendations on their usage.

This article is further organized as follows. After this general and brief introduction related to this research, more details of REA and EEF are discussed and explained. Following this, the results of REA and EEF are explained with a realistic case study. Finally, the results are discussed and conclusions drawn.

## II. RELATIVE EXERGY ARRAY (REA) AND EXERGY ECO-EFFICIENCY FACTOR (EEF)

Relative gain is defined as "The ratio of open loop process gain in an isolated loop to apparent process gain in the same loop when all other control loops are closed and are in perfect control", [11]. RGA is a matrix composed of elements defined as the ratio of open-loop to closed-loop gains. One of its elements, relative gain, $\lambda_{ij}$, which relates the $j^{th}$ input $u_j$ and the $i^{th}$ output $y_i$, can be expressed by the following Equation (1).

$$\lambda_{ij} = \frac{\left(\frac{\Delta y_i}{\Delta u_j}\right)_{all-loops-open}}{\left(\frac{\Delta y_i}{\Delta u_j}\right)_{all-loops-closed(in-perfect-control)-except-u_j-loop}} \qquad (1)$$

### A. Relative exergy array (REA)

Exergy helps to develop many tools for the facilitation of process design and control, such as exergetic efficiency, REA and EEF.

For the understanding of Relative Exergy Array (REA), the concept of exergetic efficiency is introduced. Exergetic efficiency is defined as the ratio of the exergy out to the exergy in to a process as shown in Equation (2). A general process for exergetic efficiency calculation is shown in Figure 2.

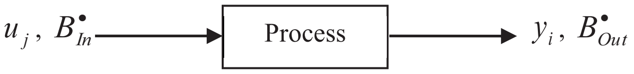

Figure 2. A general control loop portion

$$\eta = \frac{B^{\bullet}_{Out}}{B^{\bullet}_{In}} \tag{2}$$

where $\eta$ = Exergetic efficiency, $B^{\bullet}_{Out}$ = Total exergy going out of a process and $B^{\bullet}_{In}$ = Total exergy coming in to a process.

In a control loop a manipulated variable (MV) is paired with a controlled variable (CV) and both are linked with each other by some process as shown in Figure 2. In a control loop, the exergy of the manipulated variable ($u_j$) stream is the total exergy coming in to the process ($B^{\bullet}_{In}$) and the exergy of the control variable ($y_i$) stream is the total exergy going out of a process ($B^{\bullet}_{Out}$) as shown in Figure 2. The ratio of the exergy of the control variable stream to the exergy of the manipulated variable stream gives the exergetic efficiency.

The Initial exergetic efficiency is based on the exergy of the manipulated variable stream and the exergy of the control variable stream before a step input in the exergy of the manipulated variable stream. The exergy gain ratio is calculated after a step change in the exergy of the manipulated variable stream. The exergy gain ratio defined by Equation (3) gives the exergetic efficiency of the process.

$$\tau_{ij} = \frac{\Delta B(y_i)}{\Delta B(u_j)} = \frac{B^{\bullet}_{Out,Final} - B^{\bullet}_{Out,Initial}}{B^{\bullet}_{In,Final} - B^{\bullet}_{In,Initial}} \tag{3}$$

where $\tau_{ij}$ = Exergy gain ratio

Equation 3 is also called the generic exergy gain ratio which allows an alternate measurement of exergetic efficiency, defined by Equation 2. The open loop exergy gain of a control loop can be calculated via Equation 3 when all other loops are open. The open loop exergy gain is analogous to the open loop gain in the Relative Gain Array (RGA) as shown in Equation 4.

$$k_{ij} = \frac{\Delta y_i}{\Delta u_j} = \frac{y_{i,Final} - y_{i,Initial}}{u_{j,Final} - u_{j,Initial}} \tag{4}$$

where $k_{ij}$ = simple gain ratio

In the open loop gain ratio calculation, all loops are open and no interactions from other loops affect the considered loop ($u_j$ - $y_i$). When all other loops except ($u_j$ - $y_i$) are closed then loop interactions from other loops affect the considered loop ($u_j$ - $y_i$). These loop interactions change the effect of manipulated variable stream step input to the controlled variable stream of control loop ($u_j$ - $y_i$) in terms of control variable $y_i$ and its exergy. So a great variation in open loop gain or open loop exergy gain to closed loop gain or closed loop exergy gain, accounts for large interactions within the control loops. This translates to an alternate measure of loop interactions by using exergy values. With loop interaction measurement it also accounts for exergetic efficiency of a control loop ($u_j$ - $y_i$) effected by interaction from other loops.

So from the above discussion relative exergy gain is defined by Equation 5, (analogous to relative gain in RGA as shown in Equation 1).

$$\gamma_{ij} = \frac{\left(\dfrac{\Delta B_{total}(y_i)}{\Delta B_{total}(u_j)}\right)_{\text{all loops open}}}{\left(\dfrac{\Delta B_{total}(y_i)}{\Delta B_{total}(u_j)}\right)_{\text{all loops closed (in perfect control) except } u_j \text{ loop}}} \tag{5}$$

where $\gamma_{ij}$ = Relative exergy gain ratio

For all pairing combinations in multi-loop SISO control, relative gains ($\lambda_{ij}$) are calculated. These relative gains are arranged into an array called RGA ($\Lambda$) as shown by Equation 6. Similarly for all pairing combinations in multi-loop SISO control, relative exergy gains ($\gamma_{ij}$) are calculated. These relative exergy gains are arranged into an array called REA ($\Gamma$) as shown by Equation 7. The interpretations of RGA and REA values are given by [6, 12].

$$\Lambda = \begin{bmatrix} \lambda_{11} & \lambda_{12} & \cdots & \lambda_{1n} \\ \lambda_{21} & \lambda_{22} & \cdots & \lambda_{2n} \\ \vdots & \vdots & \vdots & \vdots \\ \lambda_{n1} & \lambda_{n2} & \cdots & \lambda_{nn} \end{bmatrix} \tag{6}$$

$$\Gamma = \begin{bmatrix} \gamma_{11} & \gamma_{12} & \cdots & \gamma_{1n} \\ \gamma_{21} & \gamma_{22} & \cdots & \gamma_{2n} \\ \vdots & \vdots & \vdots & \vdots \\ \gamma_{n1} & \gamma_{n2} & \cdots & \gamma_{nn} \end{bmatrix} \tag{7}$$

where $\Lambda$ = Relative gain array (RGA) and $\Gamma$ = Relative exergy gain array (REA)

The definition of the REA implies that the system or process under consideration is linear so that the gains calculated are valid for the full range of operation of the control structure. In the case of non-linear systems or processes the results for the REA have to be recalculated for each range of the process where the linear assumption holds.

The REA can be used mainly as a screening tool for candidate control structures, but for a complete detailed analysis of the control structure performance, a detailed dynamic simulation is recommended.

### B. *Exergy eco-efficiency factor (EEF)*

Exergy eco-efficiency factor (EEF) is based on an understanding of the total exergy of each material stream in and out of the thermodynamic process as shown in Figure 2.

The ratio, Equation (2) is the exergetic efficiency of this process (Figure 2) which is a measure of eco-efficiency. This general process is a portion of the control loop between the manipulated and the control variables. However it does not provide any information about how the control loop configuration affects this exergetic efficiency. EEF connects the control loop configuration to the eco-efficiency. The exergy eco-efficiency factor for a control pair ($u_j$, $y_i$), is defined as,

$$\tau_{ij} = (\Delta B_{out} - \Delta B_{in}) \frac{\Delta u_j}{\Delta y_i} \qquad (8)$$

where $\Delta u_j$ denotes a step change of the *MV* $u_j$, $\Delta y_i$ denotes a response in the *CV*, $y_i$, caused by a step change of $u_j$, and $\Delta B_{out}$ and $\Delta B_{in}$ represent the exergy differences caused by the *MV* step change for exergy out and exergy in, respectively. For example, if $\tau_{21}$is less than $\tau_{22}$, it means that for the same amount of *CV* change $\Delta y_2$, using $u_1$, will cause less exergy destruction than using $u_2$. The final interpretation is that the control pairing ($u_1$, $y_2$) is more eco-efficient than the pairing ($u_2$, $y_2$).

The EEF shows how much exergy will be destroyed by using different *MV* to control the same amount of *CV* change. It can provide a quantitative measurement of the exergy consumption. By comparing the sum of EEF of one control configuration with another, the approximate amount of exergy to be saved can be obtained. This will be very useful in some situations, for example, when control configuration A makes an exergy saving of 10%, compared to control configuration B, the implementation of control configuration B is more expensive than it is for control configuration A, Thus, on this basis, control configuration A may be selected.

For a 2 x 2 example, if $\tau_{21}$ is less than $\tau_{22}$, it means that for the same amount of *CV* change, $\Delta y_2$ using *MV* $u_1$, will cause less exergy change/loss than will using *MV* $u_2$. The final interpretation is that control pair ($u_1$, $y_2$) is more eco-efficient than pair ($u_2$, $y_2$).

EEF helps engineers to build an eco-efficient process which is ecological friendly and economically viable. Since exergy accounts for the quality of energy, thus it can be used as a measure to evaluate the eco-efficiency for a process design. A process is called eco-efficient if it uses a relatively small amount of energy or the destruction of exergy is low.

Control loop configurations can be determined by techniques such as RGA, NI and SVD, it is usual that several candidate control loop configurations can be implemented. In regard to eco-efficiency, the EEF can be used to select the best control loop configuration from among the candidates in the sense of eco-efficiency.

EEF calculation for different cases with all possible control schemes is difficult. It increases the computational load on process design engineers. The development of an algorithm/software package for EEF calculation has been done, which combines together a commercial simulator, VMGSim and Excel to calculate the EEF. A potential help is obtainable in EEF calculation by using a commercial simulator VMGSim [13].

### C. *Validation of EEF Results*

Dynamic simulation is the best way to validate the proposed eco-efficiency factor. By recording the exergy consumptions of several control configurations, the most eco-efficient control configuration can be identified and dynamic results compared to the results from the eco-efficiency factor.

Dynamic exergy versus time can be approximated by several exergy calculations at different conditions during the dynamic response of a process. The exergy values of the process dynamic response at different time intervals are calculated. As chemical simulators still do not have the ability to directly calculate and display the total exergy of a material stream, these simulators cannot automatically calculate exergy versus time at every point. Simulators such as the HYSYS and the VMGSim can only calculate steady state exergy values at given process conditions. For dynamic exergy versus time, different process condition points are selected during the process dynamic response due to step input disturbances. The selection of calculation points depends on the dynamic response of the process. In order to get the maximum information in regard to dynamic response, if the variation in the process conditions with time is large, then the time interval between the selected points is decreased. With less variation in the process conditions, the time interval between the selected points is increased. Then the exergy values are calculated on these selected points during the dynamic process response. Exergy values at different points are calculated with the procedure developed in [14]. Then those exergy points are used to approximate the dynamic exergy response versus time.

## III. CASE STUDY

### A. *Process description*

A monochlorobenzene (MCB) separation process is selected for this case study, and is used to show how the REA and EEF provides information regarding the best control loop configuration among the candidates in the sense of eco-efficiency. MCB plant consists of three main units: a flash vessel (F1), an absorption column (T1) and a distillation column (T2), as shown in Figure **3**. VMGSim (process simulator) with the NRTL activity thermodynamic model was used for the simulation of the MCB separation process. The detailed information regarding feed conditions and column specification can be found in [15].

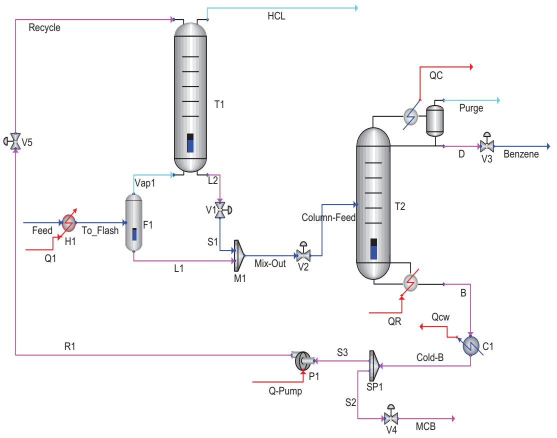

Figure 3. MCB separation process schematic

For comparison, three basic control configurations can be defined for the dual composition control of the distillation column (T2) and composition of HCl ($x_{HCl}$) leaving in the vapour stream of the absorber, namely $LVQ_{cw}$, $LBQ_{cw}$ and $DVQ_{cw}$. Each configuration is comprised of three main composition control loops (name of each configuration). For example, in the $LVQ_{cw}$ control configuration, *L (Reflux rate)* is used to control the composition of the top product ($x_D$), boil-up rate ($V$) is used to control the composition of the bottom product ($x_B$), and cooler duty ($Q_{cw}$) is used to control the composition of vapour stream leaving the absorber ($x_{HCl}$). It behaves as a pseudo 3 x 3 system because; i) three inventory control loops of distillation column and other control loops of MCB plant are assumed to be under perfect control; and ii) Control loops other than the composition control are not interacting with the composition loops, therefore are not included in the analysis.

## B. *Results and Discussion*

The simulation model shown in Figure 3 was used to do the required step tests. Step tests are performed to obtain the necessary information to calculate the RGA, DRGA, REA, NI and CN as shown in Table 1.

The $LVQ_{cw}$ and $DVQ_{cw}$ control configurations are further selected based on classical controllability tools (RGA, NI, SVD and CN) results, to ascertain the most eco-efficient control configuration ($LVQ_{cw}$ or $DVQ_{cw}$) by using the REA and EEF.

The REA results, as shown in Table 1, depict that all three control configurations ($LVQ_{cw}$, $LBQ_{cw}$ and $DVQ_{cw}$) have exergy interactions and the thermodynamic (exergetic) efficiencies of the control loops are affected by these exergy interactions. For the $LVQ_{cw}$ configuration, the REA results show that the exergy changes for open loop are smaller and opposite in direction to the exergy changes caused by loop interactions. For the $LBQ_{cw}$ control configuration, the REA results show that exergy changes due to loop interactions are almost equal and larger than the exergy changes due to the open loop operation. For the $DVQ_{cw}$ control configuration, the REA results show that exergy changes for open loop operation are much smaller and are in the same direction as the exergy changes caused in closed loop operation, except for one element.

Table 1. RGA, DRGA, REA, NI and CN results for the whole MCB plant

| Configurations | RGA | DRGA | REA | NI | CN |
|---|---|---|---|---|---|
| $LVQ_{cw}$ | $\begin{bmatrix} 6.30 & -4.76 & -0.54 \\ -5.80 & 6.50 & 0.35 \\ 0.52 & -0.70 & 1.20 \end{bmatrix}$ | $\begin{bmatrix} 3.80 & -2.80 & 0.02 \\ -1.40 & 2.60 & -0.23 \\ -1.40 & 1.20 & 1.20 \end{bmatrix}$ | $\begin{bmatrix} 0.006 & -0.25 & 1.25 \\ 1.21 & -0.23 & 0.02 \\ -0.21 & 1.48 & -0.27 \end{bmatrix}$ | 1.15 | 31 |
| $LBQ_{cw}$ | $\begin{bmatrix} 0.88 & 0.10 & 0.02 \\ 0.12 & 0.92 & -0.05 \\ 0.00 & -0.03 & 1.02 \end{bmatrix}$ | $\begin{bmatrix} 0.84 & -1.60 & 1.76 \\ 0.18 & 0.38 & 0.43 \\ -0.03 & 2.20 & -1.19 \end{bmatrix}$ | $\begin{bmatrix} 0.88 & 0.13 & -0.007 \\ 0.12 & 0.61 & 0.26 \\ -0.002 & 0.26 & 0.74 \end{bmatrix}$ | -1.0 | 16 |
| $DVQ_{cw}$ | $\begin{bmatrix} 0.52 & 0.49 & -0.01 \\ 0.39 & 0.51 & 0.10 \\ 0.10 & 0.00 & 0.91 \end{bmatrix}$ | $\begin{bmatrix} 0.91 & 0.03 & 0.06 \\ 0.03 & 1.02 & -0.05 \\ 0.06 & -0.05 & 0.99 \end{bmatrix}$ | $\begin{bmatrix} 0.11 & 0.85 & 0.03 \\ 0.83 & 0.14 & 0.03 \\ 0.05 & 0.006 & 0.94 \end{bmatrix}$ | 0.97 | 23 |

According to the guidelines for interpreting the REA results, an element in REA close to the value of 1.0 indicates that thermodynamic (exergetic) efficiency and exergy changes of the control loop are not affected by other loops. The REA results, as shown in Table 1, show that leading diagonal elements of only the $LBQ_{cw}$ control configuration are close to the value of 1.0 and that this would be a good candidate for selection because its thermodynamic (exergetic) efficiency and exergy changes are not affected by loop interactions.

The interpretation of the RGA, DRGA, NI, CN and REA results depict that a trade-off exists in this process between controllability, thermodynamic (exergetic) efficiency and exergy changes. The $LBQ_{cw}$ control configuration is the best choice for selection, from the thermodynamic (exergetic) efficiency and exergy changes points of view, but it is the worst from the controllability point of view. When the results of the classical controllability techniques (RGA, DRGA, NI and CN) and REA contradict each other (as in this case), then dynamic simulation for validation is required

As it is affected by control loop interactions, the REA provides a means for the analysis of the thermodynamic (exergetic) efficiency and exergy changes of a control loop. The REA does not provide any information concerning the eco-efficiency analysis of the whole process or plant.

Table 2. EEFs for MCB plant

| Control pairs | ($L$, $x_D$) | ($D$, $x_D$) | ($V$, $x_B$) | ($B$, $x_B$) | ($Q_{cw}$, $x_{HCl}$) |
|---|---|---|---|---|---|
| EEF (kW. kgmole/h) or (kW) | 94.3 | 3.41 | 78.72 | 1.08 E3 | 1.28 E4 |

The EEF was proposed for the eco-efficiency analysis of the whole process or plant. The EEF was developed to minimize the limitations of the REA e.g. the REA measures eco-efficiency solely within the scope of control loops. The EEF determines the eco-efficiency of the whole plant because its calculation is based on the total exergy destroyed in a process, total exergy coming in and going out of a process. A higher EEF value indicates that selection of that control configuration will result in higher exergy destruction, and vice versa. As the EEF provides the means to determine the true eco-efficiency of the whole plant, EEF analysis is preferred over REA analysis.

There are some similarities and differences between the EEF and REA. For example: the EEF is affected by the recycling of materials and energy streams like REA [10, 16]; and unlike the REA, the EEF considers a single possible control scheme at a time for analysis [3].

EEF results for whole MCB plant, as shown in Table 2, indicate that the control pair ($Q_{cw}$, $x_{HCl}$) will use the most exergy and be the least eco-efficient control pair, and the control pair ($D$, $x_D$) is the most eco-efficient control pair. Since both control configurations ($LVQ_{cw}$ and $DVQ_{cw}$) include the same control pairs ($V - x_B$, $Q_{cw} - x_{HCl}$), we only need to compare the EEF for control pairs ($L$, $x_D$) and ($D$, $x_D$). For controlling $x_D$ if we use $D$, it will make an exergy saving ≈ 2.0 % compared to use of $L$. Dynamic simulation procedure explained in section II.C is used to validate the steady state EEF results.

## IV. Conclusions

The REA integrates concepts of process control and thermodynamic efficiency (exergetic efficiency). The REA provides a means to analyze the exergetic efficiency of a control structure as it is affected by control structure loop interactions. The EEF is employed for eco-efficiency analysis of the whole process, to overcome the deficiencies in REA. The EEF facilitates in the deciding of controllable and eco-efficient control schemes for the whole process. As the EEF provides the means to determine the true eco-efficiency of the whole plant, EEF analysis is preferred over REA analysis.

The $LVQ_{cw}$ and $DVQ_{cw}$ control configurations were selected based on classical controllability techniques. Both the $LVQ_{cw}$ and the $DVQ_{cw}$ control configurations are equally controllable, but the $DVQ_{cw}$ control configuration is preferred over the $LVQ_{cw}$ because it causes less exergy destruction (eco-efficient) than the $LVQ_{cw}$ control configuration.

*Abstract*— **This paper is concerned with the assignment of a desired eigenstructure to linear parameter-varying (LPV) systems as an extended version of the corresponding eigenstructure assignment problem for linear time-invariant systems. Based on a complete parametric solution of parametric generalized Sylvester matrix equation, a controller design method is proposed to guarantee a low sensitivity of the closed-loop eigenvalues. The observer state feedback structure is considered for output feedback control design. An example of control for a satellite attitude system is used to demonstrate the usefulness of the proposed approach.**

***Keywords-*** *Eigenstructure Assignment, Linear Parameter Varying systems, Low Eigenvalue Sensitivity, Sylvester Matrix Equation, Observer State Estimate Feedback*

## I. Introduction

Gain scheduling control has been widely used in practical applications [1, 2] to handle the nonlinearity of real systems. The classic gain scheduling approach consists in designing linear controllers for several operating points and then applying an interpolation strategy to obtain a global controller. Consequently, powerful tools for linear systems can be applied to nonlinear plants. In spite of the numerous applications, there has been no formal framework for gain scheduling until the early 1990s [3]. This framework gives heuristic rules to ensure global stability, but it does not provide a systematic design procedure. The linear parameter varying (LPV) approach to system modeling, estimation and control followed on from gain-scheduling as a strategy for attempting to model non-linear parametric variations using a time-varying linear systems approach [4, 5]

Eigenstructure assignment has been used in many applications and has been proven to be a useful tool both for analysis and design of linear time invariant (LTI) systems [6-8]. This method allows the designer to satisfy directly damping, settling time, and mode decoupling specifications by choosing the eigenvalues and eigenvectors. That is because the transient response of an LTI system is completely specified by the system eigenstructure. Generally, the eigenvalues determine the decay (or growth) rate of the response and the left and right eigenvectors fix the shape of the response [8]. Also, minimum eigenvalue sensitivity to model parameter variation and other performance requirements such as minimum gain control can be accommodated using explicit choices of the free controller parameters [8]. For years, many researchers have attempted to generalize the conventional notions of eigenvalues and eigenvectors for linear time-invariant systems to linear time-varying (LTV) systems [9-12]. Although existing eigenstructure assignment techniques and algorithms for LTV systems confirm the value of using this approach, eigenstructure assignment of LTV systems remains a difficult problem that is still in a state of development.

However, there are very few examples in the literature where eigenstructure assignment is applied within an LPV framework [13, 14]. In [13, 15], polynomial eigenstructure assignment of LTI systems was extended to solve the corresponding eigenstructure assignment problem for LPV systems using output feedback. In [14], a parametric approach for eigenstructure assignment, appropriate for LTI systems, was extended to LPV plants using state feedback. However, with the conditions given in [13], the choice of controller structure, the matching conditions and the solution of the controller are not unique and  require much more additional criteria to constrain the order of controller gains. As discussed in [16], the method used in [14] to calculate the controller parameters is complex.

In this paper, a low eigenvalue sensitivity eigenstructure assignment method for LPV systems is proposed. A general complete parametric solution of the corresponding parametric generalized Sylvester matrix equation [14] is introduced. A parametric eigenstructure assignment is presented based on the proposed solution approach. Using the eigenstructure assignment design freedom, low eigenvalue sensitivity is achieved by projecting the desired eigenstructure into an allowable subspace. An observer-based state estimate feedback controller structure is chosen within an output feedback framework. An algorithm is proposed to calculate a state feedback controller with state observer. The remainder of this paper is organized as follows. Section II briefly introduces a parametric solution of the parametric generalized Sylvester matrix equation, and the eigenstructure assignment to LPV system is presented. In Section III, the definition of the overall eigenvalue sensitivity of matrix to LTI systems is reviewed and extended to LPV systems. The main results and an algorithm are also presented in Section III. Section IV gives an example of a satellite system to illustrate the application of the theory. Finally, conclusions are drawn up in Section V.

## II. Parametric Eigenstructure Assignment for LPV systems

### A. LPV systems

Reference [5] considers that LPV Systems are linear time-varying plants whose state-space matrices are fixed functions of some vector of varying parameters $\theta(t)$. LPV systems can be described by state-space equations of the form:

$$\left.\begin{aligned}\dot{\boldsymbol{x}}(\boldsymbol{t}) = \boldsymbol{A}\big(\boldsymbol{\theta}(\boldsymbol{t})\big)\boldsymbol{x}(\boldsymbol{t}) + \boldsymbol{B}\big(\boldsymbol{\theta}(\boldsymbol{t})\big)\boldsymbol{u}(\boldsymbol{t})\\ \boldsymbol{y}(\boldsymbol{t}) = \boldsymbol{C}\big(\boldsymbol{\theta}(\boldsymbol{t})\big)\boldsymbol{x}(\boldsymbol{t}) + \boldsymbol{D}\big(\boldsymbol{\theta}(\boldsymbol{t})\big)\boldsymbol{u}(\boldsymbol{t})\end{aligned}\right\} \tag{1}$$

where $x(t) \in R^n, u(t) \in R^r and\ y(t) \in R^m$ are the state vectors, the input vectors and measured output vector, respectively. $A(.), B(.), C(.), D(.)$, with corresponding dimensions, are known continuous function of a time-varying parameters vector $\theta(t)$ which satisfies:

$$\theta(t) = \left[\theta_1(t), \cdots \theta_{n_\theta}(t)\right]^T \in \Theta, \forall\, t \geq 0$$

where $\Theta$ is a compact set. The subscript $t$ is omitted through the remainder of the paper without causing confusion.

From a practical point of view, LPV systems have at least two interesting interpretations. They can be viewed as LTI plants subject to time-varying parametric uncertainty $\theta(t)$. On the other hand, they can be models of linear time-varying plants or result from the linearization of nonlinear plants along the trajectories of the parameter θ. From the second view, the parameter $\theta(t)$ can be measured in real time during system operation. Consequently, the control strategy can exploit the available measurements of θ to increase performance. The LPV controller design approach proposed in this paper is based on the second view point.

### B. Parametric Eigenstructure Assignment using state feedback

Consider an LPV system given in form of (1). A linear parameterised state feedback law:

$$u = K(\theta)x, K(\theta) \in R^{r\times n}$$

is applied, such that the closed-loop system is in the following form:

$$\dot{x} = (A(\theta) + B(\theta)K(\theta))x$$

Following [9, 14], the closed-loop self-conjugate eigenvalue set can be described as $\Lambda = \{\lambda_i(\theta): \lambda_i(\theta) \in C, i = 1,2,..\tilde{n}, 1 \leq \tilde{n} \leq n\}$, for which the algebraic and geometric multiplicities of the eigenvalue $\lambda_i$ are denoted by $q_i$ and $r_i$, respectively. Then in the Jordan form of the matrix $A_{cl}(\theta) = A(\theta) + B(\theta)K(\theta)$, there are $r_i$ Jordan blocks, associated with the i-th eigenvalue $\lambda_i$, of orders $p_{ij}$, $j = 1,2,\ldots, r_i.$ , $p_{ij}$, $q_i\ and\ r_i$ satisfy the relations:

$$\sum_{j=1}^{r_i} p_{ij} = q_i, \sum_{i=1}^{\tilde{n}} q_i = n$$

Denoting the left and right eigenvectors and generalized eigenvectors of matrix $A_{cl}(\theta)$ associated with $\lambda_i$ by $L_i(\theta)$ and $R_i(\theta)$, respectively, it follows that:

$$(\lambda_i(\theta)I - A_{cl}(\theta))R_{ij,k}(\theta) = -R_{ij,k-1}(\theta),$$

$$R_{ij,0}(\theta) = 0$$

$$(\lambda_i(\theta)I - A_{cl}(\theta))^T L_{ij,k}(\theta) = -L_{ij,k-1}(\theta),$$

$$L_{ij,0}(\theta) = 0$$

for $k = 1,2, \ldots p_{ij}, j = 1,2, \ldots r_i, and\ i = 1,2, \ldots, \tilde{n}$
and

$$L^T(\theta)R(\theta) = I$$

Hence, the problem to assign a desired closed-loop eigenstructure to a system using a state feedback controller is to find a solution of the parametric equation:

$$A(\theta)R(\theta) + A(\theta)W(\theta) = R(\theta)F(\theta)$$

where $A(\theta), B(\theta)$ are the state space matrices, $R(\theta)$ is the desired right eigenvector matrix, $F(\theta)$ is the desired eigenvalues *diagnosis matrix* and $W(\theta)$ is an auxiliary matrix.

Theorem 1 is introduced to show how the eigenvectors and generalized eigenvectors can be parameterised.

**Theorem 1 [14]**

Let $[A(\theta)\ B(\theta)]$ be controllable, and matrix $B(\theta)$ be of full-column rank, then all the solutions of matrix equation:

$$A(\theta)R(\theta) + B(\theta)W(\theta) = R(\theta)F(\theta)$$

are given by:

$$\begin{bmatrix} R_{ij}^k \\ w_{ij}^k \end{bmatrix} =$$

$$\begin{bmatrix} N\big(\theta, \lambda_i(\theta)\big) & \cdots & \frac{1}{(k-1)!}\frac{d^{k-1}}{d\lambda^{k-1}} N\big(\theta, \lambda_i(\theta)\big) \\ D\big(\theta, \lambda_i(\theta)\big) & \cdots & \frac{1}{(k-1)!}\frac{d^{k-1}}{d\lambda^{k-1}} D\big(\theta, \lambda_i(\theta)\big) \end{bmatrix} \begin{bmatrix} f_{ij}^k(\theta) \\ \vdots \\ f_{ij}^1(\theta) \end{bmatrix} \tag{2}$$

$$\mathrm{k} = 1, 2, \ldots., \mathrm{p}_{ij}, \mathrm{j} = 1,2, \ldots.\mathrm{q}_i, \mathrm{i} = 1,2, \ldots.\mathrm{n}'$$

where $f_{ij}^k \in C^r$ are arbitrarily chosen parameter vectors; N(θ, λ) and D(θ, λ) are right co-prime matrix polynomials satisfying:

$$[\lambda(\theta)I - A(\theta)]^{-1}B(\theta) = N\big(\theta, \lambda(\theta)\big)D^{-1}\big(\theta, \lambda(\theta)\big) \tag{3}$$

From Theorem 1, it can be seen that the desired eigenvectors and generalized eigenvectors can be parameterised by (2) [14].

**Remark 1:**

- Theorem 1 concerns an extension of the eigenstructure assignment of LTI systems to an LPV modeling framework by introducing a solution of the parametric Sylvester matrix equation.
- Theorem 1 gives a clear analytical, complete, and explicit parametric solution expressed by the eigenvalues of the matrix $A_{cl}(\theta)$ and a group of free parameters, namely $f_{ij}$ . By specially choosing the free parameters given in (2), solutions with desired properties can be obtained.

## III. Main Result

It is known in [8, 17] that if a system has low sensitivity to perturbations and parameter variations in the system matrices then there may be a low chance of the closed-loop system becoming unstable compared with the case when controllers are used that are not based on sensitivity minimization. Hence, the eigenvalue sensitivity of a closed-loop system to modeling errors should be given suitable consideration. For the sake of simplicity, only the overall eigenvalue (i.e. Wilkinson) sensitivity is considered here [8, 17].

### *A. Overall Eigenvalue Sensitivity*

The overall eigenvalue sensitivity of the matrix $X$ is defined [8, 17] as:

$$\eta(R) = \|R\|_2 \|R^{-1}\|_2$$

where $R$ is the right eigenvector matrix of the matrix $X$.

Similarly, in this study the overall eigenvalue sensitivity of the parameter varying matrix $X(\theta)$ is defined as:

$$\eta(R(\theta)) = \sup_{\theta\in\Theta} \|R(\theta)\|_2 \|R(\theta)^{-1}\|_2$$

where $R(\theta)$ is the right eigenvector matrix of the matrix $X(\theta)$.

Suppose that the right eigenvector matrix $R$ is unitary, i.e., $R^T R = I$ then $\eta(R) = 1$ . This indicates that if $R$ is a unitary matrix the corresponding eigenvalues are perfectly conditioned and hence minimally sensitive to perturbations or parameter variations.

These observations provide the basis for the algorithms to be described in this paper. The objective of the paper is to show how to assign a set of closed-loop eigenvectors which match the columns of a unitary matrix as closely as possible. If this process is successful, a perfectly conditioned set of closed-loop eigenvalues results [8, 17].

### *B. Performance function*

The desired eigenvectors must be projected into the allowable subspace which is optimal according to some performance function while the desired eigenvectors are not in the allowable subspace. As argued previously, to achieve overall low eigenvalue sensitivity, an LPV system performance function can be defined as:

$$J_p = \left(R_{d,i}(\theta) - R_i(\theta)\right)^T \widetilde{W}_i \left(R_{d,i}(\theta) - R_i(\theta)\right) \qquad (4)$$

where θ is the varying parameter and other symbols have the same meaning as in LTI system case.

If the right eigenvectors are parameterized as:

$$R_i(\theta) = P_{R,i}(\theta) W_i(\theta)$$

The solution that minimises the LPV performance function $J_p$ is obtained by setting:

$$W_{o,i}(\theta) = \left(P_{R,i}^T(\theta)\widetilde{W}_i P_{R,i}(\theta)\right)^{-1} P_{R,i}^T(\theta)\widetilde{W}_i R_{d,i}(\theta) \qquad (5)$$

The least-squares best-fit LPV right eigenvectors can be computed by:

$$R_{o,i}(\theta) = P_{R,i}(\theta) W_{o,i}(\theta)$$

Now set $R_{d,}(\theta) = I$ , the low eigenvalue sensitivity performance function of LPV system is:

$$J_{pl} = \left(R_{d,i}(\theta) - I_i(\theta)\right)^T \widetilde{W}_i \left(R_{d,i}(\theta) - I_i(\theta)\right)$$

### *C. Results and Algorithms*

Consider an LPV system described by (1), and the performance function is described as (4). The solution that minimises the performance function $J_{pl}$ is obtained by setting:

$$\begin{bmatrix} f_{oij}^k(\theta) \\ \vdots \\ f_{oij}^1(\theta) \end{bmatrix} = \left(P_{R,ijk}^T(\theta)\widetilde{W}_i P_{R,ijk}(\theta)\right)^{-1} P_{R,ijk}^T(\theta)\widetilde{W}_i I_{,i}(\theta) \; (6)$$

where:

$$P_{R,ijk}(\theta) = \left[N\left(\theta,\lambda_i(\theta)\right) \quad \cdots \quad \frac{1}{(k-1)!}\frac{d^{k-1}}{d\lambda^{k-1}} N\left(\theta,\lambda_i(\theta)\right)\right], \; (7)$$

$$\mathrm{k} = 1, 2, \ldots., \mathrm{p}_{ij}, \mathrm{j} = 1,2, \ldots.\mathrm{q}_i, \mathrm{i} = 1,2, \ldots.\mathrm{n'}$$

The least-squares best-fit LPV right eigenvector can be computed by

$$R_{oij}^k(\theta) = P_{R,ijk} \begin{bmatrix} f_{oij}^k(\theta) \\ \vdots \\ f_{oij}^1(\theta) \end{bmatrix} =$$

$$\left[N\left(\theta,\lambda_i(\theta)\right) \quad \cdots \quad \frac{1}{(k-1)!}\frac{d^{k-1}}{d\lambda^{k-1}} N\left(\theta,\lambda_i(\theta)\right)\right] \begin{bmatrix} f_{oij}^k(\theta) \\ \vdots \\ f_{oij}^1(\theta) \end{bmatrix},$$

The corresponding auxiliary matrix can be computed as:

$$w_{oij}^k(\theta) = \left[D\left(\theta,\lambda_i(\theta)\right) \quad \cdots \quad \frac{1}{(k-1)!}\frac{d^{k-1}}{d\lambda^{k-1}} D\left(\theta,\lambda_i(\theta)\right)\right] \begin{bmatrix} f_{oij}^k(\theta) \\ \vdots \\ f_{oij}^1(\theta) \end{bmatrix}$$

The following introduces a non-iterative method which involves the direct projection of a unitary matrix into the allowable eigenvector subspace.

**Algorithm 1**

**Step** 1: Chose a set of desired closed-loop eigenvalues $\Lambda = \{\lambda_i(\theta): \lambda_i(\theta) \in \mathrm{C}, \mathrm{i} = 1,2,..\tilde{\mathrm{n}},\ 1 \le \tilde{\mathrm{n}} \le n\}$

**Step** 2: Get $N\ (\theta, \lambda\ (\theta))$ and $D\ (\theta, \lambda\ (\theta))$ satisfying (3) by applying right co-prime factorization

**Step** 3: Project each column of the unitary matrix $U = [U_1 U_2 \cdots U_3]$ into each of the allowable eigenvector subspaces corresponding to each closed-loop eigenvalue using (6) and (7). For each column $U_i$ of $U$, this produces a total of $n$ achievable right eigenvectors $R_{ij}(\theta), j = 1, ..n$;

**Step** 4: Calculate the $n^2$ misalignment angles given by:

$$\alpha_{ij}(\theta) = \sup_{\theta \in \Theta} \cos^{-1}\left(\frac{|U_j^T R_{ij}(\theta)|}{\|U_j\|_2 \|R_{ij}(\theta)\|_2}\right)$$

**Step** 5: Choose the assignment from the $n!$ possibilities which have the smallest sum of misalignment angles $\alpha_{ij}$.

**Step** 6: Calculate the controller $K(\theta) = W(\theta)R(\theta)^{-1}$

**Remark 2**

- The algorithm is an LPV-extended version of the existing right eigenstructure assignment scheme via the Sylvester matrix equation for LTI systems.
- The above algorithm will assign the closed-loop eigenvectors as close to a unitary matrix as possible to achieve optimum sensitivity.
- In the algorithm, if the rank of the control input matrix $B(\theta)$ is equal to the rank of the system matrix $A(\theta)$the desired right eigenvectors (a unitary matrix) as well as the desired eigenvalues can be achieved exactly.
- For a special case, if the desired eigenvalue is constant $\Lambda = \{\lambda_i: \lambda_i \in \mathrm{C}, \mathrm{i} = 1,2,..\tilde{\mathrm{n}},\ 1 \le \tilde{\mathrm{n}} \le n\}$, and if the achieved eigenvectors are parameter-independent, then the closed-loop system could be time invariant.
- As suggested in [8] $n!$ could be very large when $n$ is large. Hence, $n < 7$ is suggested to use in the proposed approach.
- For the Step 4, grid method [18, 19] is proposed to tackle the high dimensionality and nonlinear nature of the optimization problem.

## IV. An Example

Now, an example is given of a satellite attitude control problem to show how to calculate the controller for a given LPV system to achieve low eigenvalue sensitivity. The example is given in [14]. Consider an LPV system:

$$\left.\begin{aligned} \dot{x} &= A(\theta)x + B(\theta)u \\ y &= Cx + Du \end{aligned}\right\} \tag{8}$$

where

$$A(\theta) = \begin{bmatrix} 0 & a12 & 0 & 0 & a15 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & a34 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ a51 & 0 & 0 & 0 & 0 & a56 \\ 0 & 0 & 0 & 0 & 1 & 0 \end{bmatrix}$$

$$B(\theta) = \begin{bmatrix} b11 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & b32 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & b53 \\ 0 & 0 & 0 \end{bmatrix}, C = \begin{bmatrix} 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix}$$

$$D = 0$$

The coefficients of $A(\theta)\ and\ B(\theta)$ are defined as:

$$a12 = 4(\mathrm{Iz} - \mathrm{Iy})\frac{w_0^2}{\mathrm{Ix}}, \mathrm{a15} = 4(\mathrm{Ix} + \mathrm{Iz} - \mathrm{Iy})\frac{\mathrm{w_0}}{\mathrm{Ix}},$$

$$\mathrm{a51} = (\mathrm{Iy} - \mathrm{Iz} - \mathrm{Ix})\frac{\mathrm{w_0}}{\mathrm{Iz}}, \mathrm{a56} = (\mathrm{Ix} - \mathrm{Iy})\frac{w_0^2}{\mathrm{Iz}},$$

$$\mathrm{a34} = 3(\mathrm{Iz} - \mathrm{Ix})\frac{w_0^2}{\mathrm{Iy}}, \mathrm{b11} = \frac{1}{\mathrm{Ix}}, \mathrm{b32} = \frac{1}{\mathrm{Iy}}, \mathrm{b53} = \frac{1}{\mathrm{Iz}},$$

$$\mathrm{w_0} = 1.1 * 10^{-3}, \mathrm{Ix} = 661.4723\ , \mathrm{Iy} \in [2620 \quad 3700],$$

$$\mathrm{Iz} \in [2780 \quad 3850]$$

$\theta$ is defined as $\theta = \{\theta_1, \theta_2\} = \{\mathrm{Iy}, \mathrm{Iz}\}$, where Iy and Iz are the moment of inertia parameters.

### A. Controller design

The desired eigenvalues are set to be the same as in [18]:

$$\Lambda = \{-1.00 \pm 2.063i \quad -1.023 \pm 2.354i, \quad -1.592 \pm 1.676i\}$$

Using elementary transformations and the rational matrix factorization method [20, 21], it follows that:

$$N(\theta, s) = \begin{bmatrix} s & 0 & 0 \\ 1 & 0 & 0 \\ 0 & s & 0 \\ 0 & 1 & 0 \\ 0 & 0 & s \\ 0 & 0 & 1 \end{bmatrix},$$

$$D(\theta, s) = \begin{bmatrix} \frac{s^2 - a12}{b11} & 0 & \frac{s * a15}{b11} \\ 0 & \frac{s^2 - a34}{b32} & 0 \\ \frac{s * a51}{b53} & 0 & \frac{s^2 - a56}{b53} \end{bmatrix}$$

The desired eigenvector matrix is set to be the identity matrix $I_6$ to force the closed-loop system to have low eigenvalue sensitivity to parameter uncertainty.

Using the above algorithm, the desired eigenvector Identity Matrix ($I_6$) is projected to the allowable subspace. The calculated controller is:

$$K = \begin{bmatrix} \frac{3.185}{b11} & k_{12} & 0 & 0 & \frac{a15}{b11} & 0 \\ 0 & 0 & \frac{2.0466}{b32} & k_{24} & 0 & 0 \\ \frac{a51}{b53} & 0 & 0 & 0 & \frac{2}{b53} & k_{36} \end{bmatrix} \quad (9)$$

$$k_{12} = \frac{5.3454-\text{a12}}{b11}, k_{24} = \frac{6.588+\text{a34}}{b32}, k_{36} = \frac{5.2539+\text{a56}}{b53}$$

When the designed state feedback controller (9) is applied to the original model (8); the closed-loop matrix is obtained as in (10).

$$A - BK = \begin{bmatrix} -3.185 & a_{cl} & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & -2.0466 & -6.588 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & -2 & -5.2539 \\ 0 & 0 & 0 & 0 & 1 & 0 \end{bmatrix} \quad (10)$$

$$a_{cl} = 2 * a12 - 5.3454$$

### B. Observer design

Based on the Separation Principle, an observer state estimate feedback is used to achieve a form of output feedback control. The observer design can be achieved by recognizing the duality between the state feedback control and state estimation problems. A full order observer for the LPV system is considered with the following structure:

$$\left.\begin{aligned} \dot{\hat{x}} &= A(\theta)\hat{x} + B(\theta)u + L(\theta)(y - \hat{y}) \\ \hat{y} &= C\hat{x} + Du \end{aligned}\right\} \quad (11)$$

where $\hat{x} \in R^n$ is the estimated state and $L(\theta)$ is the designed observer gain.

To make the estimated states converge to real system states fast enough, the real part of the observer eigenvalues should be large enough. So, the desired eigenvalues for the observer system are chosen as:

$$\Lambda = \{-3 \pm 3\text{i}, \quad -6 \pm 3\text{i}, \quad -9 \pm 6\text{i}\}$$

Using the proposed procedure, the obtained observer gain is:

$$L = \begin{bmatrix} 72.04 & 18.03 & 0 & 0 & \frac{a15}{b11} & 0 \\ 0 & 0 & \frac{2.046}{b32} & \frac{6.588 + \text{a34}}{b32} & 0 & 0 \\ \frac{a51}{b53} & 0 & 0 & 0 & \frac{2}{b53} & \frac{5.254 + \text{a56}}{b53} \end{bmatrix}$$

### C. Simulation Result

In the simulation model, the initial conditions are set to be $x(0) = [0, 0.0175, 0, 0.0175, 0, 0.0175]^T$. The simulation results are shown in Fig. 1. From the time responses it can be seen that their steady-state errors converge to zero asymptotically. And from the result of the closed-loop system matrix, it can be seen that the modes are decoupled from each other. This is because the system eigenstructure is also considered which would make the system more insensitive to parameter perturbations.

## V. Conclusion

In this paper, a low eigenvalue sensitivity eigenstructure assignment approach is presented for LPV systems via observer/state feedback, based on the complete parametric solution of a parametric generalized Sylvester matrix equation. Furthermore, for the sake of practical applications, an example is used to demonstrate the usefulness and advantage of the proposed LPV control scheme. The results show that the closed-loop system transient response performance requirements are satisfied and low eigenvalue sensitivity to perturbation and parameter variation is achieved. The dynamic output feedback controller should be considered in the case where the Separation Principle breaks down.

*Abstract*—**This paper concerns phase plane description and modulation of the performance for a nonlinear Unmanned Aerial Vehicle (UAV) system based on Variable Structure Control (VSC) by reaching sliding mode. The novelty lies in the application of a phase analysis approach to achieve a robust controller for a complex nonlinear system. The aircraft dynamics are introduced and approximately linearized and decoupled on-line using feedback linearization theory. Then the sliding mode control (SMC) scheme is accomplished for the decoupled sub-channels. The phase modulation method is applied for theoretically ensuring further robustness. The simulation results demonstrate the efficiency and effectiveness of the proposed strategy.**

***Keywords-nonlinear aircraft; feedback linearization; sliding mode; phase modulation; robust controller***

## I. INTRODUCTION

Flight control systems have strict real application requirements to achieve high reliability against model uncertainties. The model-based approach to sustainable control for dynamic systems (based on analytical redundancy instead of hardware redundancy) has long been emphasized for achieving robustness and minimizing the effects of modelling uncertainty to the system [1-4]. Some approaches are based on robust control or passive fault tolerant control (FTC) as an alternative to achieve system reconfiguration [5-7]. Here we consider the robust approach for passive flight FTC system.

Advanced high-performance aircraft, not only have the characteristics of high nonlinearity and are Multiple Input and Multiple Output (MIMO) from a control standpoint, but also require high manoeuvrability with static instability [8]. For the purpose of efficiency and simplification, the feedback linearization technique is well-proven and has been developed to be one of the feasible control strategies in the study of nonlinear system, especially for aircraft [9], [10]. Feedback linearization can remove nonlinear features from the system and provide a linearized and decoupled closed-loop form. In addition to these features, dynamic linearization has advantages such as insensitivity to parameter changes and disturbances, and simplicity in physical realization [11-13].

For the linearized and decoupled aircraft system, a further robust controller is required to achieve tracking accuracy and passive FTC performance. As a main mode of VSC, the SMC technique turns out to be characterized by high simplicity and robustness [14], [15]. The main idea at the basis of the SMC strategy is the design of a particular control surface to coerce the controlled system trajectories into the sliding manifold to achieve expected performance via rapid switching between positive and negative control gains, resulting in variable structure of the control law. An advantage of sliding behavior is its insensitivity similar as the on-line feedback linearization strategy. The undesired phenomenon of so-called "chattering" of real-time SMC system, which is due to the finite switching frequency, could be avoided by using an approximated saturation function instead of the sign function during SMC system design [16-18]. In this study, the simultaneously worked feedback linearization controller and sliding mode controller optimize the system response against most of disturbances and even chattering.

As another aspect to this work, the literature of the development of SMC within phase modulation is well summarized in the work of [19] and [20]. By just using a real-time system response signal, a simple and effective phase modulation strategy can be used to purposely rectify the controller structure and parameters. This method also facilitates an approach to theoretical analysis for ensuring robustness of the SMC system, before adding external disturbances for certification. The approach, also presents a unique and efficient criterion for studying system characterization, especially when using linearised systems approaches for which the most suitable mathematical description is difficult to conclude because of unpredictable error during linearization and decoupling.

The contribution of this paper lies in the application of the combined SMC strategy based on feedback linearization with phase modulation theory to a nonlinear aircraft system. The aircraft example includes full force and moment longitudinal and lateral dynamics, which are deliberately linearised and decoupled into three second order sub-systems. The phase diagrams are then feasibly obtained and successfully used as criteria for achieving system robustness. The designed SMC systems illustrate the efficiency for real-time application.

Section II introduces the theoretical foundation of the control strategies. The mathematical model and linearization processing for a nonlinear UAV, the Machan, are introduced in Section III. The modulation analysis and simulation results are

given in Section IV to illustrate the proposed approach. The concluding discussion is given in Section V.

## II. Control System Scheme

### A. Nonlinear Feedback Linearization

The concept of feedback linearization makes use of the principle of transforming a smooth non-linear dynamical system into linear input-output form [21].

For the MIMO affine nonlinear system:

$$\left.\begin{aligned} x &= f(x) + G(x)u \\ y &= H(x) \end{aligned}\right\} \tag{1}$$

where $x = (x_1, \ldots, x_n)^T$ is an n-D (dimensional) states vector of the system, $u \epsilon R^m$ and $y \epsilon R^m$ are the input and output vectors of the system, $f \epsilon R^n$ is a sufficiently smooth vector field. $G(x) = [g_1\,(x)\; g_2\,(x) \ldots g_m\,(x)]^T$, $g_i\;(i = 1,2, \ldots, m)$ is an m-D sufficiently smooth vector field , $H(x) = [h_1\,(x)\; h_2\,(x) \ldots h_m\,(x)]^T$, $h_i\;(i = 1,2, \ldots, m)$ is a sufficiently smooth scalar function.

For the affine nonlinear system (1), define $\gamma_i$ to be the smallest integer such that at least one of the inputs appears in $y_i^{(\gamma_i)}$ using Lie derivatives as:

$$y_i^{(\gamma_i)} = L_f^{\gamma_i} h_i + \sum_{j=1}^{m} (L_{g_j} L_f^{\gamma_i - 1} h_i u_j) \tag{2}$$

with at least one of the $L_{g_j} L_f^{\gamma_i - 1} h_i \neq 0 \forall x$, and $u_j$ is the $jth$ row of $u$. The input-output relation can then be defined as:

$$\begin{bmatrix} y_1^{(\gamma_1)} & y_2^{(\gamma_2)} & \ldots & y_m^{(\gamma_m)} \end{bmatrix}^T = A(x) + B(x)u \tag{3}$$

$$A(x) = \begin{bmatrix} L_f^{\gamma_1} h_1(x) & L_f^{\gamma_2} h_2(x) & \ldots & L_f^{\gamma_m} h_m(x) \end{bmatrix}^T \tag{4}$$

$$B(x) = \begin{bmatrix} L_{g_1} L_f^{\gamma_1 - 1} h_1 & \cdots & L_{g_m} L_f^{\gamma_1 - 1} h_1 \\ \vdots & \ddots & \vdots \\ L_{g_1} L_f^{\gamma_m - 1} h_m & \cdots & L_{g_m} L_f^{\gamma_m - 1} h_m \end{bmatrix} \tag{5}$$

If the matrix $A(x) \epsilon R^{m \times m}$ is invertible, then the system can be linearized by decoupling the non-linear terms in (3) by choosing $u$ as follows:

$$u = B^{-1}(x)[-A(x) + v] \tag{6}$$

which leads to the closed-loop decoupled, linear system:

$$\begin{bmatrix} y_1^{(\gamma_1)} & y_2^{(\gamma_2)} & \ldots & y_m^{(\gamma_m)} \end{bmatrix}^T = [v_1 \quad v_2 \quad \cdots \quad v_m]^T \tag{7}$$

Once linearization has been achieved, any further control objectives may be easily met [22], [23].

Furthermore, if the system has the total relative degree $\gamma = \gamma_1 + \gamma_2 + \cdots + \gamma_m < n$, the standard MIMO form for system states can be reformulated as:

$$\left.\begin{aligned} z_1^1 = h_1(x), z_2^1 = L_f h_1(x), \ldots, z_{\gamma_1}^1 = L_f^{\gamma_1 - 1} h_1(x) \\ z_1^2 = h_2(x), z_2^2 = L_f h_2(x), \ldots, z_{\gamma_2}^2 = L_f^{\gamma_2 - 1} h_2(x) \\ \vdots \\ z_1^m = h_m(x), z_2^m = L_f h_m(x), \ldots, z_{\gamma_m}^m = L_f^{\gamma_m - 1} h_m(x) \end{aligned}\right\} \tag{8}$$

where $z$ are the chosen transformed states for linearization and decoupling. The system in (8) can be converted into a pseudo-linearized system as:

$$\left.\begin{aligned} \dot{z}_1^1 &= z_2^1 \\ &\vdots \\ \dot{z}_{\gamma_1}^1 &= a_1(z, v) + \textstyle\sum_{j=1}^{m} b_j^1(z, v) u_j \\ &\vdots \\ \dot{z}_1^m &= z_2^m \\ &\vdots \\ \dot{z}_{\gamma_m}^m &= a_m(z, v) + \textstyle\sum_{j=1}^{m} b_j^m(z, v) u_j \\ v &= P(z, v) + Q(z, v)u \\ y_1 &= z_1^1 \\ &\vdots \\ y_m &= z_1^m \end{aligned}\right\} \tag{9}$$

where

$$\left.\begin{aligned} a_i(z, v) &= L_f^{\gamma_i} h_i \cdot \Phi^{-1}(z, v) \\ b_j^i(z, v) &= L_{g_i} L_f^{\gamma_i - 1} h_i \cdot \Phi^{-1}(z, v) \\ p_i(z, v) &= L_f \eta_i \cdot \Phi^{-1}(z, v) \\ q_{ij}(z, v) &= L_{g_i} \eta_i \cdot \Phi^{-1}(z, v) \end{aligned}\right\} \tag{10}$$

Note that $\in R^{n-\gamma}$ , $Q \in R^{(n-\gamma) \times m}$ and the aforesaid state transform $\Phi: x \rightarrow (z, v)$ is a diffeomorphism that maps $x$ onto standard coordinates. The transformed input vector $v$ has the expression from (9) as:

$$v = \Phi(z, v, u) \tag{11}$$

Once the linearization has been achieved, any further control objectives may be easily met.

### B. Variable Structure Control and Robustness Analysis

As mentioned above, the nonlinear terms of the system can be eliminated by selecting an appropriate set of input transformations. However, the input-output linearization only fits in with systems with accurate models. In order to ensure control system robustness in the presence of system uncertainties, such as parameter uncertainties or unmodelled dynamics, the sliding mode control based on variable structure theory is chosen and applied to the linearized system.

Taking into account the presence of uncertainties in the nonlinear system (1), and (7) becomes:

$$\begin{bmatrix} y_1^{(\gamma_1)} & y_2^{(\gamma_2)} & \ldots & y_m^{(\gamma_m)} \end{bmatrix}^T = (A + \Delta A) + (B + \Delta B)u \tag{12}$$

where the uncertainties represented by $||\Delta B||$ and $||\Delta A||$ are bounded. The switching surface is chosen as [24]:

$$s_i = \left(\frac{d}{dt} + \lambda_i\right)^{\gamma_i} \left(y_i - y_{iref}\right) \tag{13}$$

where $\lambda_i$ is a positive constant and $y_{iref}$ the reference command signal. Differentiating (13) with respect to time $t$ leads to:

$$\dot{s}_i = y_i{}^{\gamma_i} + \sum_{j=0}^{\gamma_i - 1} k_{ij} \left(y_i^j - y_{iref}^j\right) - y_{iref}^{\gamma_i} \tag{14}$$

In order to design a robust controller, the exponential approaching law is selected for SMC. The control input can then be expressed in the following form [25]:

$$u = B^{-1}(x)\{Y_{ref} - A - KY - \varepsilon \operatorname{sgn}(s)\} \tag{15}$$

$$KY = \begin{bmatrix} \sum_{j=0}^{\gamma_1 -1}\left[k_{1j}\left(y_1^j - y_{1ref}^j\right)\right] \\ \sum_{j=0}^{\gamma_2 -1}\left[k_{2j}\left(y_2^j - y_{2ref}^j\right)\right] \\ \vdots \\ \sum_{j=0}^{\gamma_m -1}\left[k_{mj}\left(y_m^j - y_{mref}^j\right)\right] \end{bmatrix} \tag{16}$$

Substituting $u$ and (12) into (14) yields to:

$$\dot{s} = \Delta A - \varepsilon sgn(s) -$$
$$\Delta B(x)B^{-1}(x)\left[KY + \varepsilon sgn(s) + A - Y_{ref}\right] \tag{17}$$

where $Y_{ref} = \left[y_{1ref}^{\gamma_1} \quad y_{2ref}^{\gamma_2} \quad \cdots \quad y_{mref}^{\gamma_m}\right]^T$.

In order to guarantee asymptotic stability of the control system, $s^T\dot{s} < 0$ must be ensured yields to:

$$s^T\dot{s} \leq \|s\|[\|\varDelta A\| - \varepsilon + \|\varDelta BB^{-1}KY\| + \varepsilon\|\varDelta BB^{-1}\| + \|\varDelta BB^{-1}A\| + \|\varDelta BB^{-1}Y_d\|] \tag{18}$$

If $\|\varDelta B\| < \|B\|$, and satisfy $\varepsilon > (\|\varDelta A\| + \|\varDelta BB^{-1}KY\| + \|\varDelta BB^{-1}A\| + \left\|\varDelta BB^{-1}Y_{ref}\right\|)/(1 - \|\varDelta BB^{-1}\|)$, then $s^T\dot{s} < 0$ can be guaranteed. This means that the reaching condition of the sliding mode is tenable and the desired sliding motion is reachable by means of a suitable control law $u$ [26], [27].

### *C. Phase Modulation Analysis*

A proper selection of parameters that satisfy the above-cited conditions can ensure stability and robustness of the control system, although this is a sufficient but not necessary condition for reachability of the sliding mode. Moreover, the system uncertainties come from the unmodelled information and linearization error make the transformed system, even a simple one, more complicated to obtain desirable results.

Phase plane portraits are traditionally used to graphically show the SMC working performance [28], [29]. Recent research considers it as a modulation strategy to instructively adjust system structure and parameters for ensuring the system robustness [19], [20]. The basic principle of phase modulation is introduced in Fig. 1. The system real-time response error $e$ and its derivative form $\dot{e}$ are used to establishing the coordinates. The switching line $s = 0$ defined by VSC theory divides the phase plane into four regions dominated by negative and positive feedback, respectively. Once the control system reach the designed sliding surface, the phase trajectory will frequently cross the switching line to repeatedly enter the different regions for compensating system uncertainties through switching between negative and positive feedback with high-frequency [30].

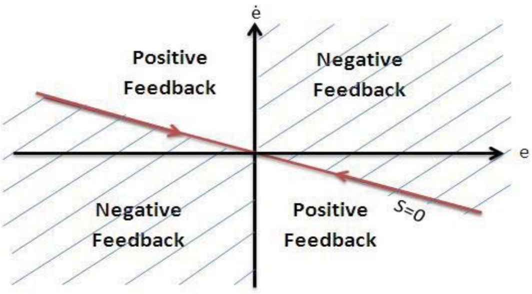

Figure 1. Phase plane with switching line

## III. NONLINEAR MACHAN AIRCRAFT

The aircraft chosen is a UAV (or remotely piloted vehicle), the Machan, used as a development vehicle by Marconi Avionics, RAE Farnbrough and NASA Dryden for research on high incidence flight and non-linear control laws [31]. The methodology has wider application for FTC for systems with known nonlinear dynamic structure.

The Machan Euler equations relate the forces $X$, $Y$, $Z$ and moments $L$, $M$, $N$ in the aircraft body axes to the angular and linear velocities in the inertial axes are shown as:

$$\left.\begin{aligned} m(\dot{u} + qw - rv) &= X \\ m(\dot{v} + ur - pw) &= Y \\ m(\dot{w} + vp - qu) &= Z \\ I_x\dot{p} + (I_z - I_y)rq &= L \\ I_y\dot{q} + (I_x - I_z)pr &= M \\ I_z\dot{r} + (I_y - I_z)pq &= N \end{aligned}\right\} \tag{19}$$

where, $m$ is the mass of the aircraft; $I_x$, $I_y$, $I_z$ are the moments of inertia about the axes through the centre of gravity parallel to the aircraft body axes; $u$, $v$ and $w$ are the forward, side and vertical velocity of the aircraft respectively; $p$, $q$ and $r$ are the roll, pitch and yaw rates, respectively.

The aerodynamic force and moment equations are:

$$\left.\begin{gathered} X = X_E - Dcos\alpha + (L_w + L_T)sin\alpha - mgsin\theta \\ Y = Y_a + mgcos\theta sin\phi \\ Z = -(L_W + L_T)cos\alpha - Dsin\alpha + mgcos\theta cos\phi \\ L = L_a + L_E \\ M = M_a + L_w(cg - 0.25)\bar{c} - L_q(l_t + 0.25 - cg) \\ N = N_a \end{gathered}\right\} \tag{20}$$

where $\alpha$ (degrees) is the angle of attack; $\theta$ and $\phi$ (degree) are the pitch and roll angles, respectively; $Y_a$ (N) is the side force; $cg$ (m) is the position of the aircraft centre of gravity; $X_E$ (N) is the thrust force due to the engine; $l_t$ (N·m$^{-1}$) is the tail moment; $D$ (N) is the force acting on the airframe; $L_w$, $L_T$ and $L_q$ (N) represent the wing, total tail and tail lift due to the pitch rate respectively; $M_a$, $N_a$ and $L_a$ (N·m$^{-1}$) are the pitching, yawing and rolling moment components respectively; $\bar{c}$ (m) is the mean aerodynamic chord and $L_E$ (N·m$^{-1}$) is the rolling moment due to the engine.

The first order non-linear engine dynamic is given as:

$$\dot{X}_E = (P_{max}T_H\delta_p - X_EU_2)/K_e \tag{21}$$

where, $P_{max}$, $T_H$, $\delta_p$, $K_e$ and $U_2$ represent the maximum engine power, the throttle demand, the propeller efficiency, the engine rise rate and the air flow rate, respectively. The parameter details are given in Aslin 1985. The open-loop Machan UAV is unstable, thus a closed-loop "base-line" control system must be configured for stability before the further robust or FTC system can be developed.

To simplify the system, this paper only considers the angle states and their rates. Thus the system state vector $x$, and the output state vector $y$ for the nonlinear aircraft model are chosen as:

$$x = [\phi \quad \theta \quad \psi \quad p \quad q \quad r]^T$$
$$y = [\phi \quad \theta \quad \psi]^T \tag{22}$$

where $\psi$ is yaw angle.

## *A. State-space Description*

The states $p$, $q$ and $r$ in (19) can be expressed as:

$$\left.\begin{aligned} \dot{p} &= \frac{(I_y - I_z)}{I_x} rq + \frac{L}{I_x} \\ \dot{q} &= \frac{(I_z - I_x)}{I_y} pr + \frac{M}{I_y} \\ \dot{r} &= \frac{(I_x - I_y)}{I_z} pq + \frac{N}{I_z} \end{aligned}\right\} \tag{23}$$

Additionally, the roll, pitch and yaw angles $\phi$, $\theta$and $\psi$ can be expressed in the terms of $p$, $q$ and $r$ as:

$$\left.\begin{aligned} \dot{\phi} &= p + qsin\phi tan\theta + r\, cos\phi tan\theta \\ \dot{\theta} &= qcos\phi - r\, sin\phi \\ \dot{\psi} &= qsin\phi sec\theta + rcos\phi sec\theta \end{aligned}\right\} \tag{24}$$

The real input vectors for the aircraft system are as:

$$u_{real} = [\delta_{\mathrm{a}} \quad \delta_{\mathrm{e}} \quad \delta_{\mathrm{t}}]^{\mathrm{T}} \tag{25}$$

where $\delta_{\mathrm{a}}$, $\delta_{\mathrm{e}}$, $\delta_{\mathrm{t}}$ are the aileron, elevator and rudder input, respectively. By only considering the nonlinear part of system, the input vectors $u$ of feedback linearization and decoupling control issue in (1) is chosen as described in (23):

$$u = [u_1 \quad u_2 \quad u_3]^T = \begin{bmatrix} \frac{L}{I_x} & \frac{M}{I_y} & \frac{N}{I_z} \end{bmatrix}^T \tag{26}$$

Then $u_{real}$ can be easily calculated in the terms of $u$ since they are linearly related from the form of the forces and moments equations [31], which can be shown as:

$$u_{real} = [l_{\delta_{\mathrm{a}}} \quad l_{\delta_{\mathrm{e}}} \quad l_{\delta_{\mathrm{r}}}]^T u \tag{27}$$

where $l_{\delta_{\mathrm{a}}}$, $l_{\delta_{\mathrm{e}}}$, $l_{\delta_{\mathrm{r}}}$are all the linear parameters.

Thus the affine system in (1) for this nonlinear UAV is simplified as:

$$f(x) = \begin{bmatrix} p + qsin\phi tan\theta + r\, cos\phi tan\theta \\ qcos\phi - r\, sin\phi \\ qsin\phi sec\theta + rcos\phi sec\theta \\ \frac{(I_y - I_z)}{I_x} rq \\ \frac{(I_z - I_x)}{I_y} pr \\ \frac{(I_x - I_y)}{I_z} pq \end{bmatrix}$$
$$G(x) = \begin{bmatrix} 0_{3\times3} \\ I_{3\times3} \end{bmatrix}$$
$$H(x) = [I_{3\times3} \quad 0_{3\times3}] \tag{28}$$

## *B. System Feedback Linearization and Decoupling*

For achieving linearization and decoupling, the pseudo-linearized system states in (9) for transforming the nonlinear system in (28) are chosen as [32]:

$$\left.\begin{aligned} z_1^1 &= \phi \\ z_2^1 = \dot{z}_1^1 &= p + qsin\phi tan\theta + r\, cos\phi tan\theta \\ z_1^2 &= \theta \\ z_2^2 = \dot{z}_1^2 &= qcos\phi - r\, sin\phi \\ z_1^3 &= \psi \\ z_2^3 = \dot{z}_1^3 &= qsin\phi sec\theta + rcos\phi sec\theta \end{aligned}\right\} \tag{29}$$

To check whether this coordinate transformation is invertible, the Jacobi Matrix for $z = z(x)$ is organized as:

$$\nabla z = \frac{\partial z(x)}{dx} =$$
$$\begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ (qcos\phi - rsin\phi)tan\theta & (qsin\phi + rcos\phi)sec^2\theta & 0 & 1 & sin\phi tan\theta & cos\phi tan\theta \\ 0 & 1 & 0 & 0 & 0 & 0 \\ -qsin\phi - rcos\phi & 0 & 0 & 0 & cos\phi & -sin\phi \\ 0 & 0 & 1 & 0 & 0 & 0 \\ (qcos\phi - rsin\phi)sec\theta & (qsin\phi + rcos\phi)sec\theta tan\theta & 0 & 0 & sin\phi sec\theta & cos\phi sec\theta \end{bmatrix} \tag{30}$$

where $z = [z_1^1 \quad z_2^1 \quad z_1^2 \quad z_2^2 \quad z_1^3 \quad z_2^3]^T$.

The rank of $\nabla z$ is $det(\nabla z) = -sec\theta \neq 0$and $z = z(x)$ is a sufficiently smooth vector field with inversion, thus $z = z(x)$ is a global diffeomorphism of the system in (28) [9].

The input transformation $\nu$ in (6) takes the form:

$$\nu = P + Qu \tag{31}$$

where $\nu = [\nu_1 \quad \nu_2 \quad \nu_3]^T$ , $P = [P_1 \quad P_2 \quad P_3]^T$ , $Q = [Q_1 \quad Q_2 \quad Q_3]^T$ follow the description in (9), (10) as:

$$P(\bar{z}) = \frac{\partial z(x)}{dx} f(x)_{|x=f^{-1}(z)} \tag{32}$$

$$Q(\bar{z}) = \frac{\partial z(x)}{dx} G(x)_{|x=f^{-1}(z)} \tag{33}$$

Now, by choosing $\bar{z} = [z_1^1 \quad z_1^2 \quad z_1^3]^T$ to be the three output channels for the transformed system, each of these channels can be expressed as:

$$\begin{aligned} P_1 = (qcos\phi - rsin\phi)[(p &+ qsin\phi tan\theta \\ &+ r\, cos\phi tan\theta)tan\theta \\ &+ (qsin\phi + rcos\phi)sec^2\theta] + (I_y - I_z)rq/I_x \\ &+ (I_z - I_x)prsin\phi tan\theta/I_y \\ &+ (I_x - I_y)pqcos\phi tan\theta/I_z \end{aligned}$$

$$\begin{aligned} P_2 = (-qsin\phi - rcos\phi)&(p + qsin\phi tan\theta + r\, cos\phi tan\theta) \\ &+ (I_z - I_x)prcos\phi/I_y \\ &- (I_x - I_y)pq\, sin\phi/I_z \end{aligned}$$

$$\begin{aligned} P_3 = (qcos\phi - rsin\phi)[sec\theta&(p + 2qsin\phi tan\theta \\ &+ 2r\, cos\phi tan\theta)] \\ &+ (I_z - I_x)prsin\phi sec\theta/I_y \\ &+ (I_x - I_y)pqcos\phi sec\theta/I_z \end{aligned}$$

$$Q_1 = [1 \quad sin\phi tan\theta \quad cos\phi tan\theta]^T$$
$$Q_2 = [0 \quad cos\phi \quad -sin\phi]^T$$
$$Q_3 = [0 \quad sin\phi sec\theta \quad cos\phi sec\theta]^T \tag{34}$$

After input-output feedback linearization for the system, the nonlinear aircraft dynamics have been theoretically decoupled into three 2nd order linear sub-systems with the transformed states and outputs described in (3) as:

$$\left.\begin{aligned} \dot{z} &= A_0 z + B_0 v \\ y &= C_0 z \end{aligned}\right\} \tag{35}$$

where

$$A_0 = \begin{bmatrix} A_0^1 & & \\ & A_0^2 & \\ & & A_0^3 \end{bmatrix}, A_0^i = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix} (i = 1,2,3)$$

$$B_0 = \begin{bmatrix} B_0^1 & & \\ & B_0^2 & \\ & & B_0^3 \end{bmatrix}, B_0^i = \begin{bmatrix} 0 \\ 1 \end{bmatrix} (i = 1,2,3)$$

$$C_0 = \begin{bmatrix} C_0^1 & & \\ & C_0^2 & \\ & & C_0^3 \end{bmatrix}, C_0^i = [1 \quad 0] (i = 1,2,3) \tag{36}$$

Each of the three sub-systems is a single-input single-output (SISO) 2nd order linear system in controllable (or phase variable) canonical form and is hence suitable for phase portrait analysis. For the 2nd order system in phase variable canonical form, the quality of the sliding mode invariance properties are satisfied, which means that once the states reach the sliding surface, the system dynamic performance is critically decided by the parameters of the designed SMC system [29].

### C. *Sliding Mode Controller Design*

For the Machan system, the thrust input $\delta_t$ related to all the states is set as a very small constant value $T_c$to limit it's effect on the nonlinear aircraft dynamics, which could be modeled as system uncertainty. The SMC theory is used to achieve sub-controllers for each decoupled channel. The complete control system scheme is shown as Fig. 2.

Figure 2. Control system scheme

For the 2nd order subsystems, the switching surface can be derived from (13) as:

$$s_i = k_i e_i + \dot{e}_i (i = 1,2,3) \tag{37}$$

where $k_i$ is the adjustable parameter for SMC; $e_i = y_{ref} - y_i$ is system output error; $y_{ref}$ and $y_i$ are system reference input and real output, respectively.

The time derivative of (37) is then given as:

$$\dot{s}_i = k_i \dot{e}_i + \ddot{e}_i = k_i \left( y_{ref} - z_i^0 \right) + \left( \dot{y}_{ref} - z_i^1 \right) (i = 1,2,3) \tag{38}$$

By choosing a proper $k_i$ for each subsystem, the sliding surface would take on desired characteristics. The SMC approaching law used in this system has the proportional form:

$$\dot{s}_i = -\varepsilon_i \mathrm{sgn} s_i (i = 1,2,3) \tag{39}$$

where $\varepsilon_i$ is positive constant. From (37)-(39), the subsystem control inputs $v_i (i = 1,2,3)$ derived from SMC are as:

$$v_i = k_i \dot{e}_i + \varepsilon_i \mathrm{sgn} s_i \tag{40}$$

The above system with discontinuous control is termed a VSC since the effect of the switching surface is to alter the system feedback structure. The state trajectories on either sides of the surface $s_i = 0$ will remain in the vicinity of the sliding manifold since $s_i \dot{s}_i < 0$ on this surface. Once $v_i$ is obtained, the system chosen input vector $u$ and real input $u_{real}$ could be easily calculated from (31) and (27).

## IV. SIMULATION AND ANALYSIS

The SMC parameters are chosen as $K = [k_1, k_2, k_3]^T = [10,10,4]^T$, $\varepsilon = [\varepsilon_1, \varepsilon_2, \varepsilon_3]^T = [3,3,10.6]^T$.

The system responses and their phase trajectories shown in Fig. 3 appear to be stable but the phase trajectories for the states $\phi$ and $\psi$ are tangential to the switching line instead of crossing it, which indicates that the controllers are of dubious value without robustness. The reason for this phenomenon is that the linearized system may have conjugate poles too close to the imaginary axis, which makes the system readily unstable through the high controller gain action.

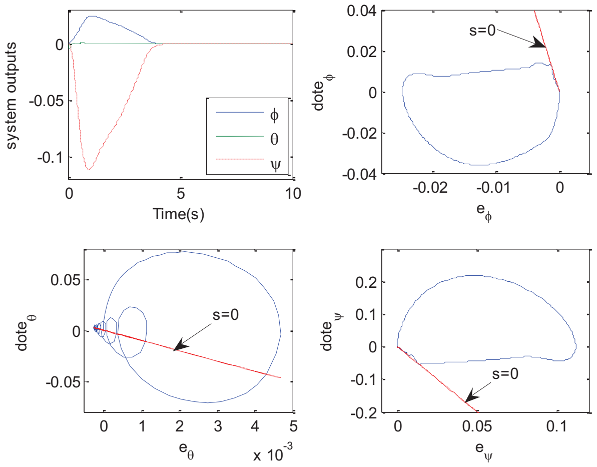

Figure 3. System responses and coordinating phase portraits

The solution is to add integrators for the corresponding states to replace system poles [30]. The new SMC parameters $K$ are chosen as: $[k_1, k_2, k_3]^T = [8,15,5]^T$, $\varepsilon$ is the same one as above. The developed system responses and their phase trajectories are shown in Fig. 4. The trajectories in Fig. 4 satisfy the principle of phase criterion for SMC described in Section II. For this case, the actuator faults $F$ are chosen as step signals $F = \left[ f_{\delta_a} \; f_{\delta_e} \; f_{\delta_r} \right]^T = [0.3,0.1,0.3]^T$ acting at time $t = 2s$. The system responses shown in Fig. 5 demonstrate the control scheme robustness and the efficiency of the modulation strategy.

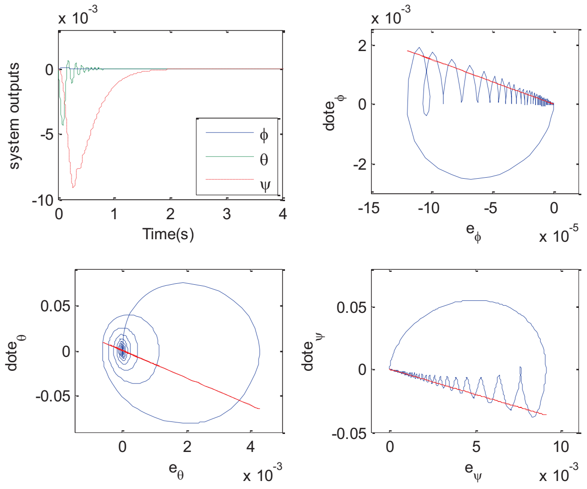

Figure 4. System responses and coordinating phase portraits

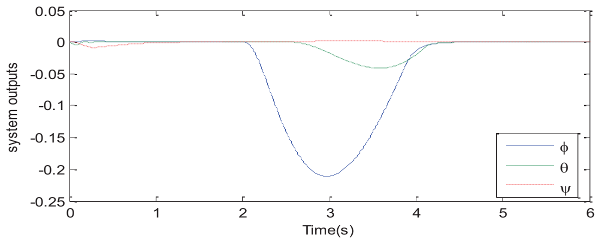

Figure 5. System responses with faults

## V. CONCLUSION

The design of a passive FTC scheme for the highly nonlinear dynamics of a UAV, the Machan is achieved via VSC theory based on feedback linearization. The inner stable control loop is designed for on-line linearizing and decoupling the nonlinear system. The principle of phase plane analysis is outlined for observing the system robustness. The further SMC sub-systems are developed using the phase modulation principle to guarantee robust performance and robust stability. The designed system responses illustrate that this strategy is feasible valid and a very promising passive approach to robust FTC for flight systems.

# Frequency-Domain Tuning of Fixed-Structure Control Systems

Pascal Gahinet and Pierre Apkarian

*Abstract*— **This paper presents two new MATLAB-based tools for tuning fixed-structure linear control systems in the frequency domain: `hinfstruct` and `looptune`. These tools can directly tune control architectures with multiple feedback loops and multiple fixed-order, fixed-structure control elements. The controller parameters are tuned using non-smooth $H_\infty$ optimization but little a-priori knowledge of the $H_\infty$ theory is required. This makes such tools ideally suited for real-world applications where the control system structure and complexity are constrained. An application to helicopter control is discussed and the results of an extensive benchmark of `hinfstruct` vs. `hifoo` are reported.**

## I. Introduction

$H_\infty$ theory [1], [2], [3], [4] provides powerful techniques for synthesizing controllers in the frequency-domain. Typical design requirements such as speed of response, control bandwidth, disturbance rejection, and robust stability are naturally expressed as constraints on the gain ($H_\infty$ norm) of well-chosen closed-loop transfer functions. In turn, efficient algorithms and software tools are available to synthesize MIMO controllers that satisfy such gain constraints [1], [5], [6].

Yet existing $H_\infty$ synthesis tools have practical limitations that have slowed their adoption in industry. $H_\infty$ controllers are monolithic whereas most embedded control architectures are decentralized collections of simple control elements such as gains and PID controllers. $H_\infty$ controllers tend to be opaque and complex (high number of states) whereas embedded controllers tend to be intuitive and have low complexity. And recasting the design requirements as a single aggregate $H_\infty$ constraint can be challenging for engineers. As a result, hand tuning and optimization-based tuning tend to remain the norm for decentralized control systems.

This paper presents new MATLAB tools for *Structured $H_\infty$ Synthesis* [6] that overcome the limitations listed above. These tools leverage state-of-the-art nonsmooth optimizers [7], [8] to directly and efficiently tune arbitrary control architectures. By "arbitrary," we mean any single- or multiple-loop block diagram arrangement containing any number and type of linear control elements, from simple gains and PIDs to more complex notch filters and state-space controllers. Some of these tools also automate the $H_\infty$ formulation, allowing users to tune the controller elements directly from high-level specifications. Finally, despite the lack of convexity, these tools perform well in practice, both in terms of speed of execution and quality of the solutions.

The paper is organized as follows. Section 2 discusses the standard formulation of structured $H_\infty$ synthesis and the representation of tunable control elements. Section 3 presents `hinfstruct`, a general-purpose tool for structured $H_\infty$ synthesis. Section 4 presents `looptune`, a more specialized tool that automates mainstream tuning tasks. Finally, Section 5 gives an application example and Section 6 reports the results of a comparison with `hifoo`.

## II. Framework for Tuning Fixed-Structure Control Systems

As mentioned earlier, our starting point is any linear control architecture with one or more fixed-structure blocks to tune, for example the feedback structure shown in Figure 4 where the shaded blocks are tunable. Since there are infinitely many possible architectures, we use a formal representation called *Standard Form* that is both general and convenient to work with. The Standard Form is depicted in Figure 1 and consists of two main components:

- An LTI model $P(s)$ that combines all fixed (non tunable) blocks in the control system
- A structured controller $C(s) = \text{Diag}(C_1(s), \ldots, C_N(s))$ that combines all tunable control elements. Each control element $C_j(s)$ is assumed to be linear time invariant and to have some prescribed structure.

C(s)

Fig. 1. Standard Form for Structured $H_\infty$ Synthesis

External inputs to the system such as reference signals and disturbances are gathered in $w$ and performance-related outputs such as error signals are gathered in $z$. The closed-loop transfer function from $w$ to $z$ is given by the linear-fractional transformation (LFT) [9]:

$$T_{zw}(s) = F_l(P, C) := P_{zw} + P_{zu}C(I - P_{yu}C)^{-1}P_{yw}. \quad (1)$$

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

It is well known from Robust Control theory that any block diagram can be rearranged into this Standard Form by isolating the tunable blocks and collapsing the rest of the diagram into $P(s)$. The resulting model has the same structure as the uncertain models used in $\mu$ analysis (with the uncertainty blocks $\Delta_j(s)$ replaced by the control elements $C_j(s)$) [10], [11], [12]. Figure 1 is also reminiscent of standard $H_\infty$ synthesis [1] but differs in one key aspect, namely, the special structure of the controller $C(s)$. Since systematic procedures and automated tools are available to transform any architecture to the Standard Form of Figure 1, we henceforth assume that the control architecture is specified in this form.

The next challenge is to describe the tunable control elements. Again we are faced with a wide range of possible structures, from simple gains and PIDs to more complex lead-lag and observer-based controllers. Since our approach is based on optimization, it is natural to use parameterizations of such components. For example, a PID can be parameterized by four scalars $K_p, K_i, K_d, T_f$ as

$$C_j(s) = K_p + \frac{K_i}{s} + \frac{K_d s}{T_f s + 1}. \qquad (2)$$

Similarly, a state-space controller with fixed order $n$ can be parameterized by four matrices $A, B, C, D$ of suitable sizes. To parameterize more general elements like the lowpass and notch filters

$$\frac{a}{s+a}, \quad \frac{s^2 + 2\zeta_1\omega_0 s + \omega_0^2}{s^2 + 2\zeta_2\omega_0 s + \omega_0^2}, \qquad (3)$$

we introduce a basic building block called "real parameter" (`realp`). If $a$ is a real parameter, then any well-posed rational function $R(a)$ can be written as the LFT:

$$R(a) = F_l(M, a \otimes I) \qquad (4)$$

where $M$ is a fixed matrix and $a \otimes I := \mathrm{Diag}(a, \ldots, a)$ [13]. Since any interconnection of LFT models is an LFT model, it is easily seen that if the control element $C_j(s)$ is a rational function of $a$, the Standard Form of Figure 1 can be rearranged so that $C_j(s)$ is replaced by a block-diagonal matrix with copies of $a$ on the diagonal. This remains true when $C_j(s)$ depends on multiple parameters $a_1, \ldots, a_M$. In other words, we can absorb the specific structure of $C_j(s)$ into $P(s)$ and keep only the low-level tunable parameters $a_1, \ldots, a_M$ in the $C(s)$ block of Figure 1. Note that unlike $\mu$-analysis, "repeated" blocks do not affect the optimization outcome and only incur some small overhead.

For example, consider the lowpass filter $F(s) = \frac{a}{s+a}$ where $a$ is tunable. This tunable element is specified by:

```
a = realp('a',1);  % a initialized to 1
F = tf(a,[1 a]);   % creates a/(s+a)
```

This automatically builds the following LFT representation of $F(s)$:

$$F(s) = F_l\left(\left(\begin{array}{ccc} 0 & 0 & 1 \\ 1/s & -1/s & 0 \\ 1/s & -1/s & 0 \end{array}\right), \left(\begin{array}{cc} a & 0 \\ 0 & a \end{array}\right)\right). \qquad (5)$$

Note that while it is possible to parameterize $F(s)$ using a single copy of `a`, the convenience of the syntax shown above more than makes up for the small overhead incurred by the extra copies of $a$.

## III. Structured $H_\infty$ Synthesis

Now that we have a framework for describing arbitrary control architectures and linear control elements, we turn to the question of using $H_\infty$ synthesis to tune the controller parameters in the Standard Form of Figure 1. $H_\infty$ synthesis is a frequency-domain method for enforcing typical control design requirements. At the heart of the method is the $H_\infty$ norm, which measured the peak input/output gain of a given transfer function:

$$\|H(s)\|_\infty := \max_\omega \overline{\sigma}(H(j\omega)). \qquad (6)$$

In the SISO case, this norm is just the peak gain over frequency. In the MIMO case, it measures the peak 2-norm of the frequency response $H(j\omega)$ over frequency.

It is well-known from robust control theory [14] that classical design requirements (bandwidth, roll-off, disturbance attenuation, stability margins) can be recast as normalized $H_\infty$ constraints of the form

$$\|W_j(s)T_j(s)\|_\infty < 1, \quad j = 1, \ldots, M \qquad (7)$$

where the $T_j$'s are suitable closed-loop transfer functions and the $W_j$'s are weighting functions that reflect the nature and parameters of each requirement. So a typical controller tuning task consists of adjusting the controller parameters to satisfy the constraints (7). Introducing

$$H(s) := \mathrm{Diag}(W_1(s)T_1(s), \ldots, W_M(s)T_M(s)). \qquad (8)$$

(7) is equivalent to $\|H(s)\|_\infty < 1$. Since each transfer function $T_j$ can be expressed as an LFT model depending on the structured controller $C(s) := \mathrm{Diag}(C_1(s), \ldots, C_N(s))$, the Standard Form of $H(s)$ looks like

$$H(s) = F_l\left(P(s), \mathrm{Diag}(C(s), \ldots, C(s))\right) \qquad (9)$$

where $P(s)$ is a fixed LTI model. So *independently* constraining two or more closed-loop transfer functions $T_j(s)$ as in (7) leads to repeating the controller $C(s)$ multiple times in the Standard Form. The resulting block-diagonal controller structure is beyond the scope of standard $H_\infty$ algorithms but poses no problem in our framework since this merely amounts to repeating the tunable blocks along the diagonal (see Section II for a discussion of repeated blocks). This is an important advantage over traditional $H_\infty$ synthesis where all requirements must be expressed in terms of a *single* MIMO closed-loop transfer function $T(s)$.

Summing up, decentralized controller tuning can be recast as a structured $H_\infty$ synthesis problem where the controller has a block-diagonal structure, each block being parameterized and possibly repeated. In turn, we can use the nonsmooth algorithms described in [7], [15], [16] to optimize the controller parameters and enforce the constraint $\|H(s)\|_\infty < 1$. The MATLAB sofware described here is based on [7], [17] and consists of three main components:

- Simple objects to specify tunable parameters (realp) and elementary control elements such as gains, low-order transfer functions, and PIDs
- Overloaded arithmetic and interconnection algebra to automatically build the Standard Form of $H(s)$ by combining/connecting together ordinary LTI models, tunable elements, and weighting functions
- The hinfstruct function for minimizing the $H_\infty$ norm of $H(s)$ with respect to the tunable controller parameters. This function can be seen as the counterpart of hinfsyn for structured $H_\infty$ synthesis

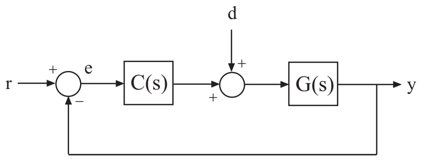

Fig. 2. Elementary feedback loop.

To get a feel for these tools, consider the simple scenario where the requirements for the feedback loop of Figure 2 can be expressed as

$$\|w_S S\|_\infty < 1, \quad \|w_T T\|_\infty < 1 \tag{10}$$

where $S = 1/(1 + L)$, $T = L/(1 + L)$, $L = GC$, and $w_S, w_T$ are suitable frequency-weighting functions. Also assume that $C(s)$ is constrained to be a PID controller. Using the sofware, you can construct a parametric model of $H(s) = \text{Diag}(w_S S, w_T T)$ as follows:

```
G = tf([1 2],[1 5 10]);       % plant model
C = ltiblock.pid('C','pid'); % tunable PID
S = feedback(1,G*C);
T = feedback(G*C,1);
H0 = blkdiag(wS * S, wT * T);
```

The result H0 is a MATLAB representation of the (untuned) Standard Form for $H(s)$ and depends on the tunable PID block C. Next invoke hinfstruct to tune the PID controller gains so as to enforce $\|H(s)\|_\infty < 1$:

```
H = hinfstruct(H0);
```

The output H contains the tuned Standard Form of $H(s)$ and you can access the tuned value of the PID controller C with

```
C = getBlockValue(H,'C')
```

Note that hinfstruct actually minimizes the $H_\infty$ norm of $H(s)$ but can be configured to terminate as soon as the target value of 1 is achieved. Also, hinfstruct can be configured to automatically run multiple optimizations from randomly generated starting points. This helps mitigate the local nature of the optimizer and increases the likelihood of finding parameter values that meet the design requirements. See [18], [6], [19] for more details and examples.

## IV. Automated Tuning of Feedback Loops

While hinfstruct addresses the first two practical limitations of traditional $H_\infty$ synthesis tools, familiarity with the $H_\infty$ methodology is still required to turn typical design specifications into a well-posed $H_\infty$ optimization problem. This difficulty is exacerbated in multi-loop control systems because of scaling and coupling issues. For example, a poor choice of units in one feedback channel may skew the sensitivity function and lead to an ill-posed $H_\infty$ problem [14, p. 5-8]. Also, classical one-loop-at-a-time stability margins may be misleading when cross-coupling exists between feedback loops [20]. Such challenges led us to seek ways to automate the $H_\infty$ formulation of high-level requirements. This turns out to be possible and to often lead to satisfactory results. We now discuss this "push-button" approach and the looptune function that embodies it.

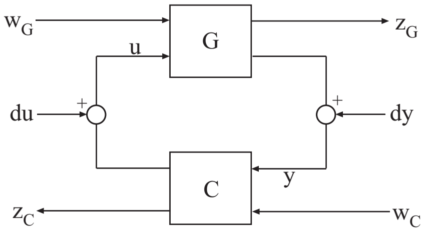

Fig. 3. Generic MIMO feedback loop.

Our starting point is the generic MIMO feedback loop of Figure 3 where $G$ represents the "plant" and $C$ represents the overall controller. Any control structure can be rearranged in this fashion by using the measurement signals $y$ and control signals $u$ to separate the controller from the plant. Both $G$ and $C$ may contain tunable elements, which allows for co-tuning of plant and controller parameters. To formulate an $H_\infty$ synthesis problem for this feedback system, observe that most controller tuning tasks involve some combination of the following requirements:

1) **Performance**: The feedback loops should have high gain at low frequency to reject disturbances and follow setpoint changes
2) **Roll off**: The feedback loops should have low gain at high frequency to guard against unmodeled dynamics and measurement noise
3) **Stability**: The feedback loops should be stable with enough margin to sustain typical amounts of gain and phase variations at the plant inputs and outputs.

Typically, the first two requirements amount to shaping the open-loop response to have integral action at low frequency and roll off in excess of -20 dB/decade at high frequency. The transition from high to low open-loop gain occurs in the *gain crossover band* (an interval in the MIMO case since in general it is neither possible nor desirable to make all loops cross at the same frequency). The gain crossover band determines the response time and bandwidth of the control system. Using the standard "mixed-sensitivity" formulation, we can express these loop-shaping requirements as

$$\left\| \begin{pmatrix} W_{LF} S_i \\ W_{HF}(I - S_i) \end{pmatrix} \right\|_\infty < 1 \tag{11}$$

where $S_i$ is the sensitivity function at the plant inputs $u$ and the weighting functions $W_{LF}, W_{HF}$ reflect the desired loop shape. Note that $S_i$ should be replaced by the sensitivity

$S_o$ at the plant outputs if there are more controls $u$ than measurements $y$.

For the stability requirement, we use the notion of multivariable disk margins discussed in [20]. This measure guarantees robustness against simultaneous gain and phase variations at all plant inputs and outputs, which is much stronger than one-loop-at-a-time stability margins. With the notation

$$L(s) = \begin{pmatrix} 0 & G(s) \\ C(s) & 0 \end{pmatrix}, \quad X(s) = (I+L)(I-L)^{-1}, \tag{12}$$

the robust stability condition is

$$\mu(X(s)) < 1/\alpha \tag{13}$$

where $\mu(.)$ denotes the structured singular value for a diagonal block structure [4] and the parameter $\alpha$ is a function of the desired gain and phase margins [20]. For tractability reasons, we replace this condition by:

$$\min_{D} \max_{\omega\in[\omega_1,\omega_2]} \|D^{-1}X(jw)D\| < 1/\alpha \tag{14}$$

where $D$ is a constant and diagonal scaling matrix and $[\omega_1, \omega_2]$ is some interval containing the gain crossover band. The rationale for this simplification is that (a) stability margins are worst near the gain crossovers, and (b) the gain crossover band is typically narrow enough that we can get away with a constant rather than frequency-dependent D-scaling in the $\mu(.)$ upper bound.

Note that the scaling $D = \begin{pmatrix} D_o & 0 \\ 0 & D_i \end{pmatrix}$ is equivalent to the plant I/O scaling $G \to D_o^{-1}GD_i$. In other words, $D$ automatically corrects scaling issues in the vector signals $u$ and $y$, e.g., $u$ having both small and large entries due to a poor choice of units. Because the $H_\infty$ norm is not invariant under I/O scaling, this turns out to be essential to formulate a meaningful $H_\infty$ synthesis problem [14, Remark 1]. Finally, (14) is tractable in our framework if we treat the diagonal entries of $D$ as tunable parameters ($D^{-1}X(jw)D$ is an LFT in the controller and scaling matrix $D$).

Summing up, for a given crossover frequency/band, tuning the controller amounts to finding a scaling $D$ and controller parameter values that satisfy

$$\left\| \begin{pmatrix} W_{LF}D_i^{-1}S_iD_i \\ W_{HF}(I - D_i^{-1}S_iD_i) \end{pmatrix} \right\|_\infty < 1 \tag{15}$$

$$\max_{\omega\in[\omega_1,\omega_2]} \|\alpha D^{-1}X(jw)D\| < 1. \tag{16}$$

Note that we use the scaled input sensitivity $D_i^{-1}S_iD_i$ instead of $S_i$ to take advantage of the $u$ scaling provided by $D$.

The `looptune` function [6] formulates and solves this $H_\infty$ optimization problem. The basic interface is

```
[G,C] = looptune(G0,C0,wc,Req1,Req2,...)
```

where `G0,C0` are (untuned) parametric models of $G$ and $C$, `wc` is the target crossover frequency/band, and the optional arguments `Req1,Req2,...` specify additional requirements such as maximum gain or setpoint tracking. Note that `wc` can be omitted and replaced by more sophisticated loop shaping requirements, thus providing a fair amount of flexibility.

## V. Helicopter Example

This section presents an application to a challenging helicopter control problem. We use an 8-state model of the Westland Lynx helicopter at the hovering trim condition. The controller generates commands $d_s, d_c, d_T$ in degrees for the longitudinal cyclic, lateral cyclic, and tail rotor collective using measurements of $\theta, \phi, p, q, r$ (pitch and roll angles and roll/pitch/yaw rates). For details and data, see [21] and the demo in [6]. The controller structure is shown in Figure 4 and consists of two feedback loops:

- The inner loop (static output feedback SOF) provides stability augmentation and decoupling
- The outer loop (PI controllers PI1-PI3) provides the desired setpoint tracking performance.

The main control objective is to track setpoint changes in $\theta, \phi, r$ with zero steady-state error, settling times of about 2 seconds, minimal overshoot, and minimal cross-coupling.

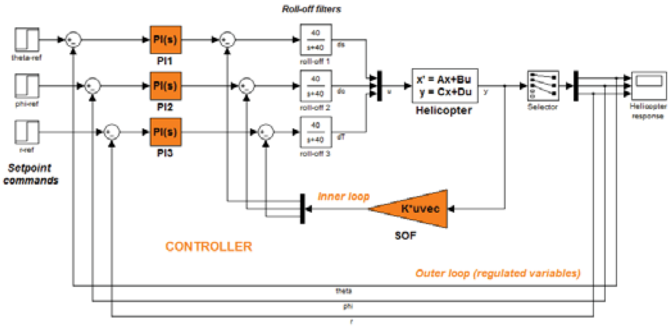

Fig. 4. Control architecture for Westland Lynx helicopter.

Since the helicopter is modeled in Simulink we use the `slTunable` interface to quickly set up the `looptune` optimization. With this interface you just specify the Simulink blocks to tune, the measurement and control signals (controller I/Os), and the I/O signals of interest for closed-loop analysis:

```
ST0 = slTunable('helico',...
                {'PI1','PI2','PI3','SOF'});
ST0.addControl('u')
ST0.addMeasurement('y')
ST0.addIO({'theta_ref','phi_ref','r_ref'},'in')
ST0.addIO({'theta','phi','r'},'out')
```

This information is used to automatically parameterize the tuned blocks and linearize the Simulink model to extract the plant model $G$ and a parametric model of the controller $C$. Note that the static-output-feedback gain is initialized to zero and the PI controllers to $1 + 1/s$, values for which the closed-loop response is unstable.

We want the outer loop to settle in about 2 seconds so the open-loop bandwith should be at least 2 rad/s (based on first-order characteristics). The inner loop must typically be faster so we seek a gain crossover band between 10 and 30 rad/s:

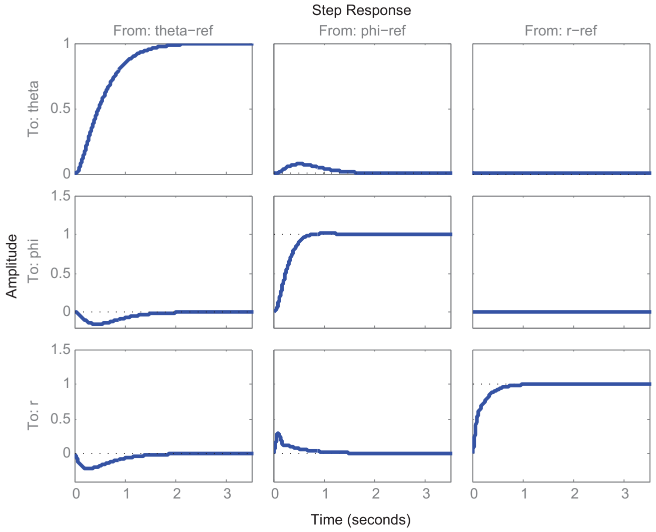

Fig. 5. Closed-loop responses to $\theta, \phi, r$ commands.

```
wc = [10,30];
```

Because there are fewer actuators (3) than measurements (5), integral action in the open-loop response is not enough to guarantee that $\theta, \phi, r$ will track the setpoint commands $\theta_{\text{ref}}, \phi_{\text{ref}}, r_{\text{ref}}$. We therefore add an explicit tracking requirement with a 2-second response time:

```
TR = TuningGoal.Tracking(...
      {'theta_ref','phi_ref','r_ref'},...
      {'theta','phi','r'},2);
```

Finally, we specify the desired minimum gain and phase margins:

```
Opt = looptuneOptions('GainMargin',5,...
                      'PhaseMargin',40);
```

We can now tune the controller parameters with `looptune`:

```
ST = ST0.looptune(wc,TR,Opt);
```

The final $H_\infty$ norm is 1.28, again close to 1, and the closed-loop step responses are shown in Figure 5. These responses settle in less than two seconds with no overshoot and small cross-coupling. The tuned values are:

$$\begin{aligned}
PI_1(s) &= 0.45 + 12.2/s \\
PI_2(s) &= -0.17 - 9.15/s \\
PI_3(s) &= -0.66 - 8.22/s \\
SOF &= \begin{pmatrix} 7.24 & -0.84 & -0.0031 & 1.02 & -0.045 \\ -1.30 & -2.45 & 0.01 & -0.14 & -0.21 \\ -1.43 & 0.81 & -1.47 & -0.23 & 0.17 \end{pmatrix}
\end{aligned}$$

Tuning these 21 parameters starting from an unstable initial guess took 11 seconds on a 64-bit PC with a 3 GHz dual-core processor and 6 GB of RAM.

## VI. BENCHMARK

This section reports the result of a comprehensive benchmark of `hinfstruct` vs. `hifoo`. Both `hifoo` and `hinfstruct` implement state-of-the-art nonsmooth programming techniques. `hifoo` is a two-stage technique where a smooth linesearch BFGS approach is followed by nonsmooth gradient sampling. This means gradients are randomized around the current iterate to refine or establish optimality in the second phase. `hinfstruct` exploits extension sets of the Clarke sub-differential at each iteration and derives a tangent subproblem in the form of a nonsmooth convex QP approximation of the original problem. A search direction is then computed and a linesearch is carried out. `hinfstruct` is fully deterministic and does not use randomization except for (optionally) choosing the starting point. Both techniques have local optimality certificates.

Our assessment is based on 234 test cases from the *COMP*l$_e$*ib* benchmark library [22] and compares the following versions:

- `hinfstruct` from [6]
- `hifoo 3.5` with `hanso 2.1` [15].

Details on the test cases can be found at [19]. Both codes are run in default mode with 3 starting points in each case. For `hifoo` we run the gradient sampling phase to enhance accuracy and provide an optimality certificate.

A graphical comparison of the achieved objective values and execution times for both techniques appears in Figure 6. Recall that the objective value is the closed-loop $H_\infty$ norm. The top plot shows a bar chart of the $H_\infty$-norm log-ratios:

$$\log_2(H_\infty\text{-norm } \texttt{hinfstruct}/H_\infty\text{-norm } \texttt{hifoo})\,.$$

Bars to the left of the vertical line $x = 0$ indicate that `hinfstruct` terminated with a lower $H_\infty$-norm than `hifoo`, and bars to the right indicate the opposite. A bar of unit length materializes improvement by a factor 2, a bar of length 2 improvement by a factor of 4, etc. Similarly, the bottom plot shows a bar chart of the CPU time log-ratios:

$$\log_{10}(\text{cpu time } \texttt{hinfstruct}/\text{cpu time } \texttt{hifoo})\,.$$

Here a bar of unit length means 10 times faster, a bar of length 2 means 100 times faster, etc.

Further comparison of CPU times for problems where `hinfstruct` and `hifoo` terminate with essentially the same objective value is shown in Figure 7. These results show that `hinfstruct` is significantly faster and often more accurate than `hifoo`.

## CONCLUSION

We have presented a new methodology and tool set for tuning fixed-structure SISO or MIMO control systems. While our approach is rooted in $H_\infty$ theory, it is clear that these tools and techniques are not restricted to Robust Control applications and can be seen as a systematic framework for tuning decentralized control architectures and exploring the trade-offs between performance and complexity.

***Abstract*—This paper focuses on the robust $H_\infty$ control problem for a class of nonlinear switched systems containing neutral uncertainties with average dwell time (ADT). Uncertainties are assumed to be nonlinearly dependent on state and state derivative and allowed to appear in channels of state, control input and disturbance input. The robust $H_\infty$ control problem of the switched system with stabilizable and unstabilizable subsystems is solvable if the stabilizable and unstabilizable subsystems satisfy certain conditions and admissible switching strategy among them. ADT and piecewise Lyapunov function approaches are applied to achieve the control design. A numerical example is provided to illustrate the effectiveness of the proposed results.**

## I. INTRODUCTION

The last decades have witnessed a rapidly growing interest from the control field in the study of switched systems [1-7]. More specifically, switched systems belonging to a class of hybrid dynamical systems contain a finite number of subsystems and a switching signal that must be designed in order to orchestrate the switching among the subsystems. Recently, there is increasing growth of interest in applying ADT switching to handle the switched systems [8-10]. As a class of typical controlled switching signals, ADT switching means that the number of switches in a finite interval is bounded and the average time between the consecutive switching is not less than a specified value. It is widely recognized that ADT switching is of practical and theoretical significance to deal with the related stability analyses and control syntheses problems.

As is well known, uncertainties are unavoidable in engineering control and are frequently the source of instability and performance deterioration. Thus during the past decades, the problems of stability analysis and controller synthesis with uncertainties have received much attention [11-13]. [14] studied the robust stabilization problem for a class of uncertain nonlinear cascaded systems, in which the uncertain parameters are from a known compact set. In [15], the problem of robust $l_2$-$l_\infty$ filtering for switched linear discrete-time systems with polytopic uncertainties and time-varying delays is investigated. Furthermore, neutral uncertainties describing many practical parameter perturbations are often nonlinearly state and nonlinearly state derivative dependent. [16] discussed the robust $L_2$-gain performance synthesis problem for a class of nonlinear systems with neutral uncertainties. However, few results have focused on switched systems with neutral uncertainties so far.

On the other hand, $H_\infty$ control theory for switched systems has attracted considerable attention by researchers and has been a hot topic in the control area [17-21]. Especially, results about nonlinear $H_\infty$ control of switched systems have progressively appeared to solve robust stabilization and disturbance attenuation issues [22-25]. The nonlinear $H_\infty$ control problem for switched systems can be stated as follows: Find a compensator, either state feedback or more general output feedback and a switching rule (if necessary) such that (1) the internal state of the closed-loop system is stable and (2) the $L_2$ gain of the mapping from the exogenous input disturbance to the controlled output is minimized or guaranteed to be less than or equal to a prescribed value. In [26], the $H_\infty$ control problem of switched systems has been addressed with ADT in both linear and nonlinear contexts. [27] investigated the $H_\infty$ control problem for a class of switched nonlinear cascade systems using the multiple Lyapunov function method.

In this paper, we discuss the problem of robust $H_\infty$ control for a class of nonlinear switched systems with neutral uncertainties. For the case where states are measurable, sufficient conditions for the switched system to be asymptotically stable with $H_\infty$-norm bound and design of both switching law and state feedback controller are proposed for all admissible uncertainties. ADT switching is used so that the results cover the case where stabilizable and unstabilizable subsystems both exist in the switched system. An numerical example is given to illustrate the applicability of the developed method. As compared to the existing results, this paper deals with neutral uncertainties. Additionally, uncertainties are also allowed to appear in channels of state, control input and disturbance input.

*Notation:* we use standard notations throughout this paper. $R^n$ denotes the n-dimensional real Euclidean space, and given a matrix $P, P > 0$ denotes that $P$ is positive definite, $P^T$ stands for the transpose of $P$, $I$ is the identity matrix, $\| \cdot \|$

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

represents either the Euclidean vector norm or the induced matrix 2-norm, and $\overline{\sigma}(\cdot)$ denotes the largest singular value of a matrix.

## II. Problem Statement And Preliminaries

In this paper, we consider a class of nonlinear switched systems described by equations of the form:

$$\begin{aligned} \dot{x} + \Delta j_{\sigma(t)}(\dot{x}, t) =& f_{\sigma(t)}(x) + \Delta f_{\sigma(t)}(x, t) + (c_{\sigma(t)}(x) \\ &+ \Delta c_{\sigma(t)}(x, t))\omega_{\sigma(t)}, \\ y =& h_{\sigma(t)}(x), \end{aligned} \tag{1}$$

where $\sigma(t) : [0, +\infty) \to I_m = \{1, \cdots, m\}$ is the switching signal, which is assumed to be a piecewise constant function depending on time, $x \in R^n$ is the state, $\omega_i \in R^{c_i}$ is the disturbance input belongs to $L_2[0, \infty)$ , $u_i \in R^{m_i}$ and $y \in R^{p_i}$ stand for the control input and the measurement output of the $i$th subsystem respectively. $f_i(x), c_i(x)$ and $h_i(x)$ are known smooth nonlinear function matrices of appropriate dimensions satisfying $f_i(0) = 0$ and $h_i(0) = 0$, $\Delta j_i(\dot{x}, t), \Delta f_i(x, t)$ and $\Delta c_i(x, t)$ represent unknown smooth nonlinear function matrices, $i \in I_m$.

The switching sequence $\sigma(t)$ associated with the switched system (1) is given by

$$\begin{aligned} \sum = \{x_0; (i_0, t_0), (i_1, t_1), \cdots, (i_k, t_k), \cdots, \\ |i_k \in I_m, k \in N\}, \end{aligned} \tag{2}$$

in which $t_0$ is the initial time, $x_0$ is the initial state. When $t \in [t_k, t_{k+1}), \sigma(t) = i_k$, the $i_k$th subsystem is active, and the trajectory $x(t)$ of the switched system (1) is the trajectory $x_{i_k}$ of the $i_k$th subsystem. As commonly assumed in the literature, we exclude Zeno behavior for all types of switching signal in this paper. In addition, we assume that the state of the switched system (1) does not jump at the switching instants, i.e., the trajectory $x(t)$ is everywhere continuous.

In this paper, we assume all uncertainties in the switched system (1) having the following properties.

**Assumption 1.** The uncertain functions $\Delta j_i(\dot{x}, t), \Delta f_i\ (x, t)$ and $\Delta c_i(x, t)$ are gain bounded smooth functions described as follows:

$$\begin{aligned} \Delta j_i(\dot{x}, t) &= e_{j_i}\delta_{j_i}(\dot{x}, t), \|\delta_{j_i}\| \le \|W_{j_i}\dot{x}\|, \\ \Delta f_i(x, t) &= e_{f_i}\delta_{f_i}(x, t), \|\delta_{f_i}\| \le \|W_{f_i}(x)\|, \\ \Delta c_i(x, t) &= e_{c_i}\delta_{c_i}(x, t), \|\delta_{c_i}\| \le \|W_{c_i}(x)\|, \end{aligned} \tag{3}$$

where $e_{j_i}, e_{f_i}, e_{c_i}$ are known constant matrices and $\delta_{j_i}, \delta_{f_i}, \delta_{c_i}$ are unknown function vectors with $\delta_{j_i}(0, t) = 0$ and $\delta_{f_i}(0, t)$ $= 0$. $W_{j_i}, W_{f_i}$ are known smooth function matrices, $W_{c_i}$ are given weighting matrices, $i \in I_m$.

Now, the robust $H_\infty$ control problem to be addressed in this paper can be represented as: given a constant $\gamma > 0$, design a switching law $i = \sigma(t)$ for the switched system (1) such that

(i) The autonomous system (1) is globally asymptotically stable when $\omega_i \equiv 0$.

(ii) System (1) has weighted $L_2$-gain from $\omega_i$ to $y$ for all admissible uncertainties, ie., there holds

$$\int_0^\infty e^{-\lambda\tau} y^T(\tau) y(\tau) d\tau \le \gamma^2 \int_0^\infty \omega_i^T(\tau)\omega_i(\tau) d\tau + \beta(x_0)$$

for some real-valued function $\beta(\cdot)$ with $\beta(0) = 0$.

**Assumption 2.** For robust $H_\infty$ control problem, suppose that not all the subsystems of the switched system (1) are stabilizable.

**Definition 1.** For any $T_2 > T_1 \ge 0$, let $N_\sigma(T_1, T_2)$ denote the number of switching of $\sigma(t)$ over $(T_1, T_2)$. If $N_\sigma(T_1, T_2) \le N_0 + \frac{T_2 - T_1}{\tau_a}$ holds for $\tau_a > 0, N_0 \ge 0$, then $\tau_a$ is called average dwell time.

**Definition 2.** For the switched system (1), suppose that $V_i(t)$ is the corresponding Lyapunov function for the $i$th subsystem, then $V(t)$ is called a piecewise Lyapunov function candidate if it can be written as $V(t) = V_{\sigma(t)}(x)$, where $V_{\sigma(t)}(x)$ is switched among $V_i(t)$ in accordance with the piecewise constant switching signal $\sigma(t)$.

## III. Main Results

For the switched system (1) with stabilizable and unstabilizable subsystems, the robust $H_\infty$ control problem is solvable if the stabilizable and unstabilizable subsystems satisfy certain conditions and admissible switching law among them, respectively. In what folllows, we give the design method for the robust $H_\infty$ control problem of the switched system (1).

Consider the switched system (1). Under Assumption 2, for the robust $H_\infty$ control problem, not all the subsystems are stabilizable, without loss of generality, we assume that the $i$th subsystem ($1 \le i \le s$) is stabilizable (where the positive integer s satisfies $1 \le s < m$), whereas the other subsystems of (1) are unstabilizable.

Then, for any piecewise constant switching signal $\sigma(t)$ and any $0 \le t_0 < t$, we let $\Pi^-(t_0, t)$ (resp.,$\Pi^+(t_0, t)$) denote the total activation time of stabilizable (resp., unstabilizable) subsystems during $(t_0, t)$. Then, we present the following switching law:

(F): Let $t_0 < t_1 < t_2 < \cdots < t_i$ ($\lim_{i\to\infty} t_i = \infty$) be a specified sequence of time instants satisfying $\max_i(t_{i+1} - t_i) = T < \infty$. Determined the switching signal $\sigma(t)$ so that the inquality

$$\frac{\Pi^-(t_i, t_{i+1})}{\Pi^+(t_i, t_{i+1})} \ge \frac{\beta + \lambda^*}{\alpha - \lambda^*} \tag{4}$$

holds on time every interval $[t_i, t_{i+1})(i = 0, 1, \cdots)$ with $\alpha > 0, \beta > 0$ and $\lambda^* \in (0, \alpha)$. Meanwhile, we choose $\lambda^* \le \alpha$ as the average dwell time scheme: for any $t > t_0$,

$$N_\sigma(t_0, t) \le N_0 + \frac{t - t_0}{\tau}, \tau > \tau^* = \frac{\ln u}{\lambda^*}. \tag{5}$$

Under the switching law (F) for any $t_0$, $t$ satisfying $t_{i-1} <$

$t_0 < t_i < t_{i+1} < \cdots < t_k < t$, we can infer

$$\begin{aligned}
&\beta\Pi^+(t_0,t) - \alpha\Pi^-(t_0,t)\\
\le&\beta(t_i - t_0) + \sum_{l=i}^{k-1}[\beta\Pi^+(t_l,t_{l+1}) - \alpha\Pi^-(t_l,t_{l+1})]\\
&+\beta(t-t_k)\\
\le&\beta(t_i-t_0) - \lambda^*(t_k-t_i) + \beta(t-t_k)\\
\le&(\beta+\lambda^*)(t_i-t_0) - \lambda^*(t-t_0) + (\beta+\lambda^*)(t-t_k). \qquad (6)
\end{aligned}$$

Since on any interval $[t_i, t_{i+1})$, the total activation time period of unstable subsystems satisfies $\Pi^+(t_i,t_{i+1}) \le \frac{\alpha-\lambda^*}{\alpha+\beta}(t_{i+1}-t_i)$ according to the requirement in (F), we get from (6) that

$$\beta\Pi^+(t_0,t) - \alpha\Pi^-(t_0,t) \le c - \lambda^*(t-t_0), \qquad (7)$$

Where $c = \frac{2(\beta+\lambda^*)(\alpha-\lambda^*)}{(\alpha+\beta)}T$.

The following theorem provides theoretical basis for the robust $H_\infty$ control problem of the switched system (1).

**Theorem 1.** Given any constant $\gamma > 0$, suppose that there exist radially unbounded positive definite differentiable functions $V_i(x)$, $i = 1, \cdots, m$, constants $\mu \ge 1$, such that the following inequalities

$$\begin{aligned}
&\frac{\partial V_i}{\partial x}f_i + \gamma_i^2 C_i^T C_i + \gamma_i^2(\frac{1}{2\gamma_i^2}\frac{\partial V_i}{\partial x}B_i + C_i^T D_i)R_i^{-1}(\frac{1}{2\gamma_i^2}\frac{\partial V_i}{\partial x}\\
&\cdot B_i + C_i^T D_i)^T + \alpha V_i < 0, i \le s, \qquad (8)
\end{aligned}$$

$$\begin{aligned}
&\frac{\partial V_i}{\partial x}f_i + \gamma_i^2 C_i^T C_i + \gamma_i^2(\frac{1}{2\gamma_i^2}\frac{\partial V_i}{\partial x}B_i + C_i^T D_i)R_i^{-1}(\frac{1}{2\gamma_i^2}\frac{\partial V_i}{\partial x}\\
&\cdot B_i + C_i^T D_i)^T - \beta V_i < 0, i > s, \qquad (9)
\end{aligned}$$

$$V_i \le \mu V_j, \qquad (10)$$

and

$$\alpha_1^*(\|x\|) \le V_i(x) \le \alpha_2^*(\|x\|), \quad i,j = 1,\cdots,m \qquad (11)$$

hold, where $\alpha_1^*(x)$ and $\alpha_2^*(x)$ are two class $K_\infty$ functions and

$$\begin{aligned}
&\gamma_i^2 = \frac{\gamma^2}{1+\bar\sigma(W_{c_i})/\lambda_{c_i}^2}, B_i = [c_i, \lambda_{j_i}e_{j_i}, \lambda_{f_i}e_{f_i}, \lambda_{c_i}e_{c_i}],\\
&C_i^T = [({}^1/_{\gamma_i})h_i^T, ({}^1/_{\lambda_{j_i}})f_i^T W_{j_i}^T, ({}^1/_{\lambda_{f_i}})W_{f_i}^T, 0],\\
&D_i^T = [0, ({}^1/_{\lambda_{j_i}})B_i^T W_{j_i}^T, 0, 0], R_i = I - D_i^T D_i \qquad (12)
\end{aligned}$$

with $\lambda_{j_i}, \lambda_{f_i}$, and $\lambda_{c_i}, i \in I_m$ are positive constants.

Then, the robust $H_\infty$ control problem of the switched system (1) is solvable under the switching condition (F) and the average dwell-time (5).

**Proof:** From Definition 2, we choose the following piecewise Lyapunov function candidate:

$$V(t) = V_{\sigma(t)}(x) \qquad (13)$$

for the switched system (1), where $V_{\sigma(t)}(x)$ is switched among the solution $V_i(x)$'s of (8)-(11) in accordance with the piecewise constant switching signal $\sigma$.

Regard neutral uncertainty $\Delta j_i(\dot x, t)$ as an exogenous disturbance and make a new extended disturbance input including it. In this case, define

$$d_i^T = [\omega_i^T, -({}^1/_{\lambda_{j_i}})\delta_{j_i}^T, ({}^1/_{\lambda_{f_i}})\delta_{f_i}^T, ({}^1/_{\lambda_{c_i}})\omega_i^T\delta_{c_i}^T]. \qquad (14)$$

Then, we can conclude that

$$\begin{aligned}
d_i^T d_i \le& \|\omega_i\|^2 + ({}^1/_{\lambda_{j_i}^2})\delta_{j_i}^T\delta_{j_i} + (\bar\sigma(W_{c_i})/\lambda_{c_i}^2)\|\omega_i\|^2\\
&+({}^1/_{\lambda_{f_i}^2})\delta_{f_i}^T\delta_{f_i}\\
\le&(1+\bar\sigma(W_{c_i})/\lambda_{c_i}^2)\|\omega_i\|^2 + ({}^1/_{\lambda_{j_i}^2})\delta_{j_i}^T\delta_{j_i}\\
&+({}^1/_{\lambda_{f_i}^2})\delta_{f_i}^T\delta_{f_i}, \qquad (15)
\end{aligned}$$

which means

$$-\gamma^2\|\omega_i\|^2 \le \gamma_i^2 d_i^T d_i + ({}^{\gamma_i^2}/_{\lambda_{j_i}^2})\delta_{j_i}^T\delta_{j_i} + ({}^{\gamma_i^2}/_{\lambda_{f_i}^2})\delta_{f_i}^T\delta_{f_i}.$$

Owing to Assumption 1, it holds that

$$\begin{aligned}
&\dot V + \|y\|^2 - \gamma^2\|\omega_i\|^2\\
=&\frac{\partial V_i}{\partial x}(f_i + \Delta f_i + c_i\omega_i + \Delta c_i\omega_i - \Delta j_i) + \|y\|^2 - \gamma^2\|\omega_i\|^2\\
=&\frac{\partial V_i}{\partial x}(f_i + e_{f_i}\delta_{f_i} + c_i\omega_i + e_{c_i}\delta_{c_i}\omega_i - e_{j_i}\delta_{j_i}) + \|y\|^2\\
&-\gamma^2\|\omega_i\|^2\\
=&\frac{\partial V_i}{\partial x}(f_i + B_i d_i) + h_i^T h_i - \gamma_i^2 d_i^T d_i + \frac{\gamma_i^2}{\lambda_{j_i}^2}\delta_{j_i}^T\delta_{j_i}\\
&+\frac{\gamma_i^2}{\lambda_{f_i}^2}\delta_{f_i}^T\delta_{f_i}. \qquad (16)
\end{aligned}$$

Furthermore

$$\begin{aligned}
\frac{\gamma_i^2}{\lambda_{j_i}^2}\delta_{j_i}^T\delta_{j_i} \le& \frac{\gamma_i^2}{\lambda_{j_i}^2}(f_i + \Delta f_i + c_i\omega_i + \Delta c_i\omega_i - \Delta j_i)^T W_{j_i}^T\\
&\cdot W_{j_i}(f_i + \Delta f_i + c_i\omega_i + \Delta c_i\omega_i - \Delta j_i)\\
=&\frac{\gamma_i^2}{\lambda_{j_i}^2}(f_i + B_i d_i)^T W_{j_i}^T W_{j_i}(f_i + B_i d_i)\\
=&\frac{\gamma_i^2}{\lambda_{j_i}^2}f_i^T W_{j_i}^T W_{j_i} f_i + \frac{2\gamma_i^2}{\lambda_{j_i}^2}f_i^T W_{j_i}^T W_{j_i} B_i d_i\\
&+\frac{\gamma_i^2}{\lambda_{j_i}^2}d_i^T B_i^T W_{j_i}^T W_{j_i} B_i d_i. \qquad (17)
\end{aligned}$$

Combining the previous two inequalities (16)-(17) and considering (8)-(9), then by completing the squares, there holds

$$\begin{aligned}
&\dot V(x(t)) + \|y\|^2 - \gamma^2\|\omega_i\|^2\\
=&\frac{\partial V_i}{\partial x}(f_i + B_i d_i) + h_i^T h_i - \gamma_i^2 d_i^T d_i + \frac{\gamma_i^2}{\lambda_{j_i}^2}f_i^T W_{j_i}^T W_{j_i} f_i\\
&+\frac{2\gamma_i^2}{\lambda_{j_i}^2}f_i^T W_{j_i}^T W_{j_i} B_i d_i + \frac{\gamma_i^2}{\lambda_{j_i}^2}d_i^T B_i^T W_{j_i}^T W_{j_i} B_i d_i\\
&+\frac{\gamma_i^2}{\lambda_{f_i}^2}\delta_{f_i}^T\delta_{f_i}\\
\le&\frac{\partial V_i}{\partial x}(f_i + B_i d_i) + \gamma_i^2 C_i^T C_i - \gamma_i^2 d_i^T R_i d_i + 2\gamma_i^2 C_i^T D_i d_i
\end{aligned}$$

$$
\begin{aligned}
=&\frac{\partial V_i}{\partial x} f_i - \gamma_i^2 \left\| R_i^{\frac{1}{2}} d_i - R_i^{-\frac{1}{2}} (\frac{1}{2\gamma_i^2} \frac{\partial V_i}{\partial x} B_i + C_i^T D_i)^T \right\|^2 \\
&+ \gamma_i^2 (\frac{1}{2\gamma_i^2} \frac{\partial V_i}{\partial x} B_i + C_i^T D_i) R_i^{-1} (\frac{1}{2\gamma_i^2} \frac{\partial V_i}{\partial x} B_i + C_i^T D_i)^T \\
&+ \gamma_i^2 C_i^T C_i \\
\le&\frac{\partial V_i}{\partial x} f_i + \gamma_i^2 C_i^T C_i + \gamma_i^2 (\frac{1}{2\gamma_i^2} \frac{\partial V_i}{\partial x} B_i + C_i^T D_i) R_i^{-1} \\
&\cdot (\frac{1}{2\gamma_i^2} \frac{\partial V_i}{\partial x} B_i + C_i^T D_i) \\
\le&\left\{ \begin{array}{l} -\alpha V_i, i \le s, \\ \ \beta V_i, \ \ i > s. \end{array} \right.
\end{aligned} \tag{18}
$$

Note that when $\omega(t) \equiv 0$, we know from (18) that for any $t \in [t_k, t_{k+1})\,(t_0 \le k \le N_\sigma(t_0, t))$, the piecewise Lyapunov function candidate (13) satisfies

$$
V(t) = V_{\sigma(t)}(t) \le \left\{ \begin{array}{ll} e^{-\alpha(t-t_0)} V_{\sigma(t_k)}(t_k), & if \ \ i \le s, \\ e^{\beta(t-t_0)} V_{\sigma(t_k)}(t_k), & if \ \ i > s. \end{array} \right. \tag{19}
$$

From (10), $V_{\sigma(t_k)}(t_k) \le \mu V_{\sigma(t_k^-)}(t_k^-)$ is true at the switching point $t_k$. Therefore, we obtain by induction that

$$
\begin{aligned}
V(t) &\le e^{\beta\Pi^+(t_k,t) - \alpha\Pi^-(t_k,t)} V_{\sigma(t_k)}(t_k) \\
&\le \mu e^{\beta\Pi^+(t_k,t) - \alpha\Pi^-(t_k,t)} V_{\sigma(t_k^-)}(t_k^-) \\
&\le \mu e^{\beta\Pi^+(t_k,t) - \alpha\Pi^-(t_k,t)} V_{\sigma(t_{k-1})}(t_{k-1}) \\
&\le \cdots \le \mu^k e^{\beta\Pi^+(t_k,t) - \alpha\Pi^-(t_k,t)} V_{\sigma(t_0)}(t_0) \\
&\le \mu^{N(t_0,t)} e^{\beta\Pi^+(t_k,t) - \alpha\Pi^-(t_k,t)} V_{\sigma(t_0)}(t_0),
\end{aligned} \tag{20}
$$

where $N(t_0, t)$ is the switching numbers in the time interval $(t_0, t)$.

Taking (5) and (7) into account, we get

$$
\begin{aligned}
V(t) &\le \mu^{N(t_0,t)} e^{\beta\Pi^+(t_k,t) - \alpha\Pi^-(t_k,t)} V_{\sigma(t_0)}(t_0) \\
&\le e^{N_0 \ln\mu + c} e^{-(\lambda^* - \frac{\ln\mu}{\tau})(t-t_0)} V_{\sigma(t_0)}(t_0) \\
&\le c_0 e^{-\lambda(t-t_0)} V_{\sigma(t_0)}(t_0),
\end{aligned} \tag{21}
$$

where $c_0 = e^{N_0 \ln\mu + c}$, $\lambda = (\lambda^* - \frac{\ln\mu}{\tau})$.

According to (11), we have

$$
\alpha_1^* \left(\|x\|\right) \le V_i\left(x\right) \le \alpha_2^* \left(\|x\|\right). \tag{22}
$$

Combining (20)-(22) gives

$$
\|x(t)\| \le \alpha_1^{*-1} (c_0 e^{-\lambda(t-t_0)} \alpha_2^* \left(\|x(t_0)\|\right), \tag{23}
$$

which means global asymptotic stability of the switched system (1) with $\omega(t) \equiv 0$. The proof of internal stability is completed.

It can be easily seen from (18) that for any $t \in [t_k, t_{k+1})\,(t_0 \le k \le N_\sigma(t_0, t))$, the piecewise Lyapunov function candidate (13) satisfies

$$
V(t) \le \left\{ \begin{array}{l} e^{-\alpha(t-t_k)} V_{\sigma(t_k)}(t_k) - \int_{t_k}^t e^{-\alpha(t-\tau)} \Gamma(\tau) d\tau, \\ if \ \ \sigma(t_k) = i \le s, \\ e^{\beta(t-t_k)} V_{\sigma(t_k)}(t_k) - \int_{t_k}^t e^{\beta(t-\tau)} \Gamma(\tau) d\tau, \\ if \ \ \sigma(t_k) = i > s. \end{array} \right.
$$

From (10), $V_{\sigma(t_k)}(t_k) \le \mu V_{\sigma(t_k^-)}(t_k^-)$ is true at the switching point $t_k$. Therefore, we obtain by induction that

$$
\begin{aligned}
V(t) \le& e^{\beta\Pi^+(t_k,t) - \alpha\Pi^-(t_k,t)} V_{\sigma(t_k)}(t_k) \\
&- \int_{t_k}^t e^{\beta\Pi^+(\tau,t) - \alpha\Pi^-(\tau,t)} \Gamma(\tau) d\tau \\
\le& \mu e^{\beta\Pi^+(t_k,t) - \alpha\Pi^-(t_k,t)} V_{\sigma(t_k^-)}(t_k^-) \\
&- \int_{t_k}^t e^{\beta\Pi^+(\tau,t) - \alpha\Pi^-(\tau,t)} \Gamma(\tau) d\tau \le \cdots \\
\le& \mu^k e^{\beta\Pi^+(t_0,t) - \alpha\Pi^-(t_0,t)} V_{\sigma(t_0)}(t_0) \\
&- \mu^k \int_{t_0}^{t_1} e^{\beta\Pi^+(\tau,t) - \alpha\Pi^-(\tau,t)} \Gamma(\tau) d\tau \\
&- \mu^{k-1} \int_{t_1}^{t_2} e^{\beta\Pi^+(\tau,t) - \alpha\Pi^-(\tau,t)} \Gamma(\tau) d\tau - \cdots \\
&- \mu^0 \int_{t_k}^{t} e^{\beta\Pi^+(\tau,t) - \alpha\Pi^-(\tau,t)} \Gamma(\tau) d\tau \\
=& \mu^k e^{\beta\Pi^+(t_0,t) - \alpha\Pi^-(t_0,t)} V_{\sigma(t_0)}(t_0) \\
&- \int_{t_0}^t \mu^{N_\sigma(\tau,t)} e^{\beta\Pi^+(\tau,t) - \alpha\Pi^-(\tau,t)} \Gamma(\tau) d\tau \\
=& e^{\beta\Pi^+(t_0,t) - \alpha\Pi^-(t_0,t) + N_\sigma(t_0,t)\ln\mu} V_{\sigma(t_0)}(t_0) \\
&- \int_{t_0}^t e^{\beta\Pi^+(\tau,t) - \alpha\Pi^-(\tau,t) + N_\sigma(\tau,t)\ln\mu} \Gamma(\tau) d\tau.
\end{aligned} \tag{24}
$$

Multiplying both sides of the above inequality by $e^{-N_\sigma(t_0,t)\ln\mu}$ leads to

$$
\begin{aligned}
&e^{-N_\sigma(t_0,t)\ln u} V(t) \\
&+ \int_{t_0}^t e^{\beta\Pi^+(\tau,t) - \alpha\Pi^-(\tau,t) - N_\sigma(t_0,\tau)\ln u} y^T(\tau) y(\tau) d\tau \\
\le& e^{\beta\Pi^+(t_0,t) - \alpha\Pi^-(t_0,t)} V_{\sigma(t_0)}(t_0) \\
&+ \gamma^2 \int_{t_0}^t e^{\beta\Pi^+(\tau,t) - \alpha\Pi^-(\tau,t) - N_\sigma(t_0,\tau)\ln\mu} \omega^T(\tau) \omega(\tau) d\tau.
\end{aligned}
$$

Under the switching law (F) and the average dwell time scheme (5) with $\sigma < \lambda^*$, we can obtain

$$
\begin{aligned}
&\int_{t_0}^t e^{-\alpha(t-\tau) - \sigma\tau} y^T(\tau) y(\tau) d\tau \\
\le& e^{c-\lambda^*} V_{\sigma(t_0)}(t_0) + \gamma^2 \int_{t_0}^t e^{c-\lambda^*(t-\tau)} \omega^T(\tau) \omega(\tau) d\tau.
\end{aligned} \tag{25}
$$

Integrating both sides of the foregoing inequality from $t_0$ to $\infty$ and rearranging the double-integral area, we obtain

$$
\begin{aligned}
&\int_{t_0}^\infty e^{-\sigma\tau} y^T(\tau) y(\tau) d\tau \\
\le& \frac{\alpha e^c}{\lambda^*} V_{\sigma(t_0)}(t_0) + \frac{\alpha e^c}{\lambda^*} \gamma^2 \int_{t_0}^\infty \omega^T(\tau) \omega(\tau) d\tau,
\end{aligned} \tag{26}
$$

which means that the switched system achieves the weighted disturbance attenuation level $\sqrt{\frac{\alpha e^c}{\lambda^*}}\gamma$ under the average dwell time scheme (5) and the switching law (F).

When the switched system (1) is in the following linear form:

$$\begin{aligned}[I+E_{j_i}\sum\nolimits_{j_i}(t)F_{j_i}]\dot{x}=&[A_i+E_{a_i}\sum\nolimits_{a_i}(t)F_{a_i}]\\&+[H_i+E_{h_i}\sum\nolimits_{h_i}(t)F_{h_i}]\omega_i,\\y=&C_ix,\end{aligned}\tag{27}$$

where the uncertain matrices satisfy $\sum_{\upsilon}(t)\sum_{\upsilon}(t)\le I, \upsilon\in\{j_i,a_i,h_i,i\in I_m\}$. Let $\delta_{j_i}=\sum_{j_i}(t)F_{j_i}\dot{x},\delta_{f_i}=\sum_{j_i}(t)F_{j_i}x,\delta_{g_i}=\sum_{h_i}(t)F_{h_i}x$, it is clear that $\upsilon\in\{j_i,a_i,h_i,i\in I_m\}$. satisfy Assumption 1 with $M_{j_i}=F_{j_i},W_{f_i}=F_{a_i},W_{c_i}=F_{h_i}$. Then, we have the following Theorem.

**Theorem 2.** Given any constant $\gamma>0$, suppose that there exist a set of positive definite matrices $P_i, i\in I_m$, constants $\alpha>0,\beta>0$ and $\mu\ge1$, such that the following inequalities

$$\begin{aligned}&P_iA_i+A_i^TP_i+\gamma_i^2C_i^TC_i+\gamma_i^2(\frac{1}{2\gamma_i^2}P_iB_i+C_i^TD_i)R_i^{-1}\\&\cdot(\frac{1}{2\gamma_i^2}P_iB_i+C_i^TD_i)^T+\alpha P_i<0, i\le s,\end{aligned}\tag{28}$$

$$\begin{aligned}&P_iA_i+A_i^TP_i+\gamma_i^2C_i^TC_i+\gamma_i^2(\frac{1}{2\gamma_i^2}P_iB_i+C_i^TD_i)R_i^{-1}\\&\cdot(\frac{1}{2\gamma_i^2}P_iB_i+C_i^TD_i)^T-\beta V_i<0, i>s,\end{aligned}\tag{29}$$

and

$$P_i\le\mu P_j,\quad i,j\in I_m\tag{30}$$

hold, where

$$\begin{aligned}&\gamma_i^2=\tfrac{\gamma^2}{1+\bar{\sigma}(F_{h_i})/\lambda_{p_i}^2},\hat{B}_i=[H_i,\lambda_{j_i}E_{j_i},\lambda_{f_i}E_{a_i},\lambda_{p_i}E_{h_i}],\\&C_i^T=\begin{bmatrix}(^1/_{\gamma_i})C_i\\(^1/_{\lambda_{j_i}})F_{j_i}A_i\\(^1/_{\lambda_{f_i}})F_{a_i}\\0\end{bmatrix},D_i=\begin{bmatrix}0\\(^1/_{\lambda_{j_i}})F_{j_i}B_i\\0\\0\end{bmatrix},\\&R_i=I-D_i^TD_i,\end{aligned}$$

with $\lambda_{j_i},\lambda_{f_i}$, and $\lambda_{c_i}, i\in I_m$ are positive constants.

Then, the switching strategy (5) satisfying (F) solve the robust $H_\infty$ control problem of the switched system (27).

**Proof:** The proof is similar to Theorem 1.

## IV. Example

In this section, we give a numerical example to illustrate the performance of the proposed approach.

**Example 1.** Consider the nonlinear switched system (1) with $\sigma=\{1,2\}$ and

$$\begin{aligned}&f_1(x)=\frac{1}{4}x,c_1=1,h_1=-\frac{1}{2}x,f_2(x)=-2x,c_2=-1,\\&h_2=x,\Delta j_1(\dot{x},t)=a_1\dot{x}\sin t,e_{j_1}=1,\delta_{j_1}=a_1\dot{x}\sin t,\\&W_{j_1}=1,\Delta j_2(\dot{x},t)=a_2\dot{x}\cos t,e_{j_2}=1,\delta_{j_2}=a_2\dot{x}\cos t,\\&W_{j_2}=1,\Delta f_1(x,t)=\frac{1}{2}b_1x\cos t,e_{f_1}=1,\delta_{f_1}=\frac{1}{2}b_1x\sin t,\\&W_{j_2}=\frac{1}{2}x,\Delta f_2(x,t)=b_2x\sin t,e_{f_2}=1,\delta_{f_2}=b_2x\sin t,\\&W_{f_2}=x,\Delta c_1(x,t)=c_1e^{-t},e_{c_1}=1,\delta_{c_1}=c_1e^{-t},W_{c_1}=1,\\&\Delta c_2(x,t)=c_2e^{-t},e_{c_2}=1,\delta_{c_2}=c_2e^{-t},W_{c_2}=1,\end{aligned}\tag{31}$$

and $a_i,b_i,c_i,i=1,2$ are unknown constants in the set $[0,1]$.

It is easy to check that the first subsystem is unstabilizable and the second one is stabilizable. Let $\gamma^2=2$ and $\lambda_{j_i}=\lambda_{f_i}=\lambda_{c_i}=1$, then according to Theorem 1, we obtain

$$\begin{aligned}&\gamma_1=\gamma_2=1,B_1=[-1,1,1,1],B_2=[1,1,1,1],\\&C_1=[x,-2x,x,0],C_2=[-\tfrac{1}{2}x,\tfrac{1}{4}x,\tfrac{1}{2}x,0],\\&D_1^T=\begin{bmatrix}0&-1&0&0\\0&1&0&0\\0&1&0&0\\0&1&0&0\end{bmatrix},D_2^T=\begin{bmatrix}0&1&0&0\\0&1&0&0\\0&1&0&0\\0&1&0&0\end{bmatrix},\end{aligned}$$

We choose $V_1(x)=2x^2,V_2(x)=4x^2$, and $\alpha=0.8,\beta=0.5$. Then following (8)-(9),we can infer

$$\begin{aligned}&\frac{\partial V_1}{\partial x}f_1+\gamma_1^2C_1^TC_1+\gamma_1^2(\frac{1}{2\gamma_1^2}\frac{\partial V_1}{\partial x}B_1+C_1^TD_1)R_1^{-1}\\&\cdot(\frac{1}{2\gamma_1^2}\frac{\partial V_1}{\partial x}B_1+C_1^TD_1)^T-\beta V_2=-\frac{315}{16}x^2\le0,\end{aligned}\tag{32}$$

and

$$\begin{aligned}&\frac{\partial V_2}{\partial x}f_2+\gamma_2^2C_2^TC_2+\gamma_2^2(\frac{1}{2\gamma_2^2}\frac{\partial V_2}{\partial x}B_2+C_2^TD_2)R_2^{-1}\\&\cdot(\frac{1}{2\gamma_2^2}\frac{\partial V_2}{\partial x}B_2+C_2^TD_2)+\alpha V_1=-\frac{182}{15}x^2\le0,\end{aligned}\tag{33}$$

Let $\mu=2,\lambda^*=0.3$, we have $\tau^*=\frac{\ln\mu}{\alpha}=0.8664$ and the activation ratio of stabilizable subsystems to unstabilizable subsystems is $\frac{\Pi^-(t_0,t)}{\Pi^+(t_0,t)}=\frac{\beta+\lambda^*}{\alpha-\lambda^*}=1.6$. Using the switching strategy provided by Theorem 1, we obtained that the robust $H_\infty$ control problem of (1) is solvable, the simulation results are depicted in Figs. 1-2.

## V. Conclusion

In this paper, we have investigated the problem of robust $H_\infty$ control for a class of uncertain nonlinear switched systems based on ADT. Uncertainties are considered to be nonlinearly relied on state and state derivative and allowed to appear in the state, control input and disturbance input. Under the condition that the activation time ratio between stabilizable subsystems and unstabilizable ones is not less than a specified constant, we have derived sufficient conditions for the stabilization and weighted $L_2$-gain property of the switched system. The feasibility of the developed results have been proved by using a numerical example.

*Abstract*— **The widespread application of inverted pendulum principles requires better dynamic performance and steady state performance of the inverted pendulum system. The objective of this paper is to design and investigate the time specification performance of the inverted pendulum controllers. Two control methods are proposed in this paper, an innovative double PID control method and a modern LQR (liner quadratic regulator) control method. Dynamic performance and steady state performance are investigated and compared of the two controllers. This paper proves that the LQR controller can guarantee the inverted pendulum a faster and smoother stabilizing process and with better robustness and less oscillation than the double-PID controller. The novelty of this paper is the design of the two controllers, and the adoption of limits cycles as the performance assessment method for the inverted pendulum, which not only makes the steady state performance assessment available, but also, provides an effective way for the evaluation of any equilibrium control problem with friction involved.**

*Keywords- inverted pendulum; performance assessment; double-PID controller; LQR controller; limits cycles*

## I. INTRODUCTION (HEADING 1)

The inverted pendulum system, as a typical experimental device for the research and application of control theory, is a single input and multiple outputs, nonlinear and unstable system. The inverted pendulum problem is one of the most important problems in control theory and has always been appealing among researchers [1]. Because the control of the inverted pendulum is similar to other position and equilibrium control tasks, such as the control of the electric two-wheeled self-balancing vehicles, the stabilization of aircraft in the turbulent air flow, the arm position control of open loop robots etc. All these tasks bring new challenges to control engineering, and therefore, much attention has been given to explore better solutions for the inverted pendulum system and to acquire better control performance, include dynamic performance and steady state performance.

In this paper, an innovative double-PID control method and a modern LQR (liner quadratic regulator) control method are designed respectively, and the dynamic performance and steady state performance are assessed and compared based on virtual prototype simulation and experimental setup. The virtual prototype is built which consists of control model, mechanical model, and comprehensive friction model with obtained parameters to fully investigate the steady state performance. Experimental setup validates the virtual prototype simulation and especially the predicted limit circle, which is caused by friction as is proposed in this paper and is adopted as steady state performance assessment indices. The paper proposes a comprehensive assessment on the two designed controllers for an inverted pendulum based on both traditional performance indices and the novel limits cycles.

## II. SESTEM DESCRIPTION AND MODELING

### A. Sestem Description

A schematic of the inverted pendulum is shown in Fig. 1. In this paper, the simulation and experiment are both based on a direct driven inverted pendulum system, in which a pendulum is mounted on a stage driven by an ironless permanent magnet linear motor. Linear motor is a new type driving device which can directly transform electric energy to mechanical linear motion. Sensors are attached to the cart and the pivot in order to measure the cart position and pendulum inclined angle respectively.

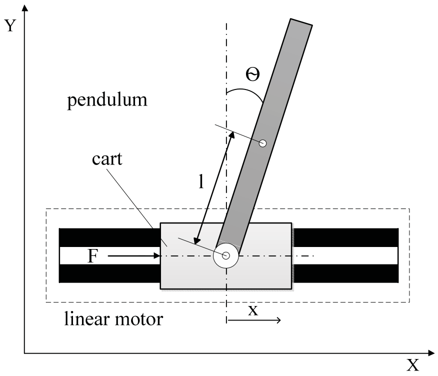

Figure 1. Schematic of the inverted pendulum

Usually the pendulum is in its pendant configuration and there are many methods to swing up the pendulum from its pendant position [2]; when the pendulum approaches the upright unstable equilibrium the control is switched to using a stabilizing controller. This paper focuses on designing the stabilizing controllers. A control force exerted by the linear motor is required on the cart to maintain the pendulum in its upright equilibrium. The control objective in this paper is to maintain the upright unstable equilibrium of the inverted pendulum system with better dynamic qualities, robustness and steady state performance.

### B. *Nonlinear Differential Equations of Seytem Motion*

The motion equations of the cart and pendulum in Fig. 1 can be obtained using Hamilton's principle, shown in (1), (2):

$$(M+m)\ddot{x}(t)+ml\ddot{\theta}(t)\cos\theta(t)-ml\dot{\theta}^2(t)\sin\theta(t)=F_M(t)+F_{fric}(t) \quad (1)$$

$$\frac{4}{3}ml^2\ddot{\theta}(t)+ml\ddot{x}(t)\cos\theta(t)-mgl\sin\theta(t)=f_{fric}(t) \quad (2)$$

where *x* is the position of the cart, $\theta$ is the pendulum angle, measuring from the upright position, *F* is the force applied to the cart, $F_{\text{fric}}$(t)is the friction force between cart and the track, and $f_{\text{fric}}$(t) is the friction force between the pendulum and the pivot, which is very small thus ignored. In this section, since we concern the design of the inverted pendulum controllers, especially the dynamic performance of the controllers, the friction forces are simplified as viscous frictions, as in (3).

$$F_{fric}(t)=-\varepsilon\dot{x} \quad (3)$$

In (3) $\varepsilon$ is coefficient of viscous friction. The definition and value of the inverted pendulum system parameters are given in Table 1.

TABLE I. PARAMETERS IN THE INVERTED PENDULUM SYSTEM

| Parameter | Description | Value |
|---|---|---|
| *M* | Mass of the cart | 1.336kg |
| *m* | Mass of the pendulum | 0.083kg |
| *l* | Distance from the pivot to mass center of the pendulum | 0.1685m |
| *g* | Gravitational constant | 9.8m/s$^2$ |
| *K*$_\text{f}$ | Current to force conversion factor | 1N/A |

### C. *Mathematical Model of Sestem Input Force*

In experimental setup, the effective electromagnetic thrust applies by the linear motor to the cart is given by (4)

$$F_M(t)=\frac{3\pi}{2\tau}\left[\lambda_{PM}i_q+(L_d-L_q)i_qi_d\right] \quad (4)$$

where $\lambda_{PM}$ is flux linkage generated by permanent magnet, $L_\text{d}$ and $L_\text{q}$ is flux linkage of *d*-axis and *q*-axis respectively. The linear motor adopts the zero *d*-axis current control method, thus the applied force can be simplified as (5).

$$F_M(t)=K_fi_q \quad (5)$$

In (5) $i_\text{q}$ is the *q*-axis current after coordinate conversion from the external current supplied to the linear motor, and $K_\text{f}$ is current to force conversion factor, which is given in Table 1 in experimental apparatus.

### D. *Mathematical Model of Inverted Pendulum System*

Combine the equations (1), (2) and the input force equation (5), solve for $\ddot{x}$ and $\ddot{\theta}$ from the differential equations, and introduce the variable: $y=(y_1,y_2,y_3,y_4)^T=(x,\dot{x},\theta,\dot{\theta})$ then after linearization the first-order mathematical model of the inverted pendulum system can be obtained as described in (6).

$$\dot{\mathbf{y}}(t)=\begin{pmatrix}0 & 1 & 0 & 0\\ 0 & \dfrac{-4\varepsilon}{(4M+m)} & \dfrac{\text{-}3mg}{(4M+m)} & 0\\ 0 & 0 & 0 & 1\\ 0 & \dfrac{3\varepsilon}{(4M+m)l} & \dfrac{3(M+m)g}{(4M+m)l} & 0\end{pmatrix}\mathbf{y}(t)+\begin{pmatrix}0\\ \dfrac{4K_f}{4M+m}\\ 0\\ \dfrac{-3K_f}{4M+ml}\end{pmatrix}i_q(t) \quad (6)$$

$$=A\mathbf{y}+\mathbf{b}i_q(t)$$

## III. DESIGN AND TUNING OF DOUBLE-PID CONTROLLER

Taking the Laplace transform of the system first-order equation, we can obtain the transfer function of the system as

$$G_A(s)=\frac{\Theta(s)}{I(s)}$$
$$=\frac{mlK_fs}{[m^2l^2-\frac{4}{3}ml(M+m)]s^3-\frac{4}{3}\varepsilon ml^2s^2+ml(M+m)gs+\varepsilon mgl} \quad (7)$$

$$G_P(s)=\frac{X(s)}{I(s)}$$
$$=\frac{4ml^2K_fs^2-3mglK_f}{[4m(M+m)l^2-3m^2l^2]s^4+4\varepsilon ml^2s^3\text{-}3m(M+m)gls^2-3\varepsilon mgls} \quad (8)$$

Several methods have been proposed to control the inverted pendulum, such as traditional PID control [3], fuzzy control [4], genetic algorithm optimizing control [5], and linear quadratic regulator (LQR) control [6]. Although a lot of control algorithms are researched in the designing of the inverted pendulum system controller, PID controller is still the most widely used controller structure in the realization of a control system. However, the inverted pendulum system is a one input and two output system which contradicts to the one input and one output control characteristic of the single PID controller. The steady state error of the pendulum angle using single PID controller results in the one direction displacement of the cart. In [3], the displacement of the cart cannot be controlled very well because the PID controller can control only one variable, and in [7], the cart position control problem is ignored and only pendulum angle is focused. In this paper, we attempt to use double PID control structure to solve the multi-output problem. Block diagram of the designed double-PID control method is shown as follows in Fig. 2.

The angle reference signal is zero at the upright equilibrium position. The position reference signal is given by a pulse signal, with pulse amplitude 0.5m, pulse period 20s and pulse width 50% of period, to test the position tracking ability of the controller. After tuning the control parameters, we obtain a group of parameters for double-PID controller, with which the controller is capable of controlling the inverted pendulum system and providing a very robust performance.

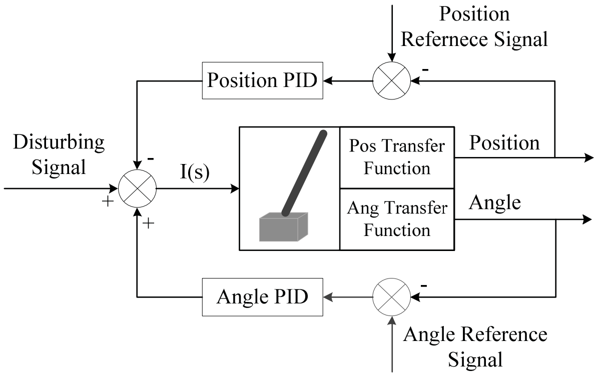

Figure 2. Block diagram of double-PID control method

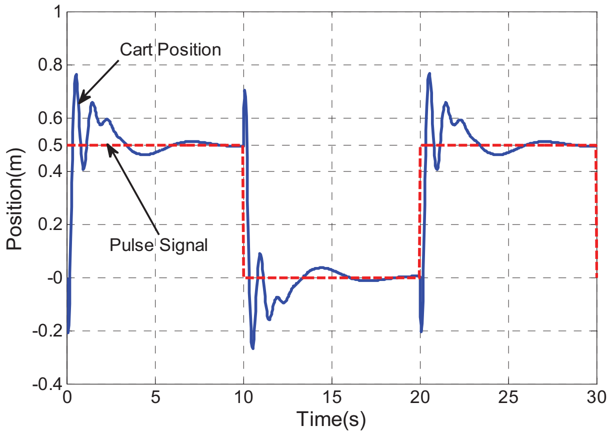

Figure 3. Cart position when tracking pulse signal

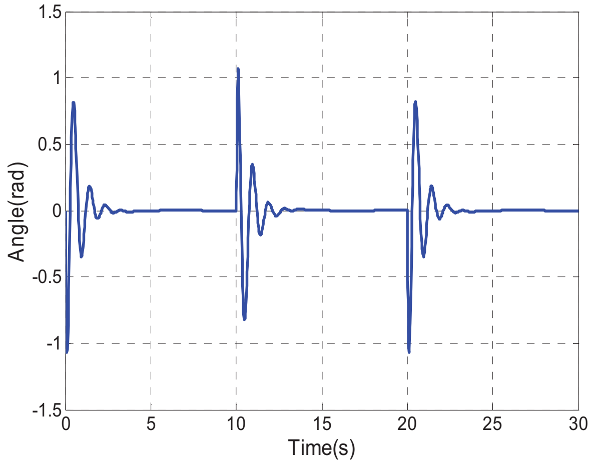

Figure 4. Pendulum angle keep balancing while cart tracking reference signal

The control parameters are:

[$K_{pp}$=20, $K_{pi}$=30, $K_{pd}$=14; $K_{ap}$=50, $K_{ai}$=90, $K_{ad}$=8].

Simulation result shows that the cart can track the position reference signal while the pendulum angle still balancing at the upright equilibrium point with occasional tracking disturbing, as shown in Fig. 3 and Fig. 4. Dynamic performance of the inverted pendulum using double-PID controller will be discussed later.

## IV. Design and Tuning of LQR Controller

### A. *Design of LQR Controller*

Still considering the first-order mathematical model of inverted pendulum system (6), using linear quadratic control theory to design the control $i_q$(t) so that the upright position becomes a stable equilibrium point as described in [8]. Consider the linear quadratic cost function (9)

$$J = \inf_{i_q(t)\in L(0,\infty)} \int_0^\infty [\mathbf{y}(t)^T Q\mathbf{y}(t) + r i_q^2(t)]dt \qquad (9)$$

The weights $Q \geq 0$ , $r \geq 0$ are then chosen to reflect the relative importance error loss of the state **y**, and energy loss of the current $i_q$(t). $Q$ and $r$ are weighting matrixes that penalize certain states and control inputs of the system. $Q$ is positive semi-definite matrix, while $r$ is positive definite matrix. If this system is disturbed and offset the zero state, the control $i_q$(t) can make the system come back to zero state and $J$ is minimal at the same time [9]. The solution to this problem is the feedback law as shown in (10)

$$i_q(t) = -r^{-1}\mathbf{b}^T P(t)\mathbf{y}(t) \qquad (10)$$

where $P$(t) is the solution of Riccati equation, which is

$$A^T P + PA - P\mathbf{b}r^{-1}\mathbf{b}^T P + Q = 0 \qquad (11)$$

Then we can obtain the value of $P$, and the linear optimal feedback matrix can be obtained using (12)

$$K = r^{-1}B^T P = [k_1, k_2, k_3, k_4]^T \qquad (12)$$

The Riccati equation may be solved numerically for given values for $A$, **b**, $r$, and $Q$. Fig. 5 shows the full states feedback representation of inverted pendulum system.

### B. *Controller Solving and System Simulation*

According to the LQR optimal control law, its optimality is totally depended on the selection of $Q$ and $r$. However, there is no resolving method to choose these two matrices. The widespread method used to choose $Q$ and $r$ is by means of simulation and trial [10, 11, and 12]. Since we consider the control of the cart position and pendulum angle, so in this section, the LQR controller is tuned by changing the nonzero elements of the $Q_{11}$ and $Q_{33}$ elements, which, corresponding to and closely influence the two concerned states: cart position and pendulum angle. We choose the weighting matrix $Q$=diag[4000, 0, 5100, 0], and $r$=1 after trial and error.

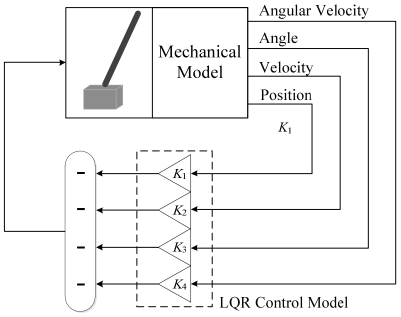

Figure 5. Block diagram of LQR controller possesses full states feedback

The linear optimal feedback matrix $K$ can be calculated using the weighting matrix $Q$, which is

$$K = [-63.2456, -40.0071, 137.2913, 17.6830]$$

Dynamic performance of LQR controller can be assessed by means of step response of the cart and the corresponding disturbing response of the pendulum. Suppose that the cart position reference input is 0.5m (step signal), and the pendulum angle reference input is zero, Simulation Result in Fig. 6 shows that the cart position can be controlled and pendulum can be balanced smoothly using LQR optimal controller, and the system possess good performance.

## V. Dynamic Performance Assessment on the Designed Controllers

Dynamic performance indices are chosen to reflect practical control effect. Performance indices include *rise time*, *transition time*, *steady state error*, and *maximum overshoot*, for the response of cart position and pendulum angle.

For comparison of the system dynamic response, plot the step response (cart position reference input is 0.5m for double-PID and LQR) of the cart and the corresponding disturbing response of the pendulum about the double-PID and LQR controller in one figure, see Fig. 7.

Table 2 and Table 3 show the summary of the dynamic performance indices for the double-PID controller and LQR controller.

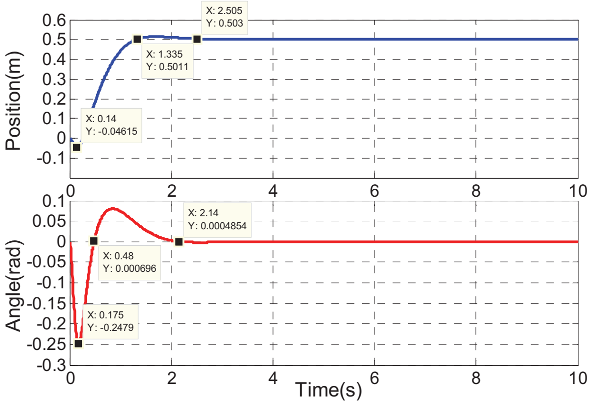

Figure 6. Dynamic response of the system using LQR controller

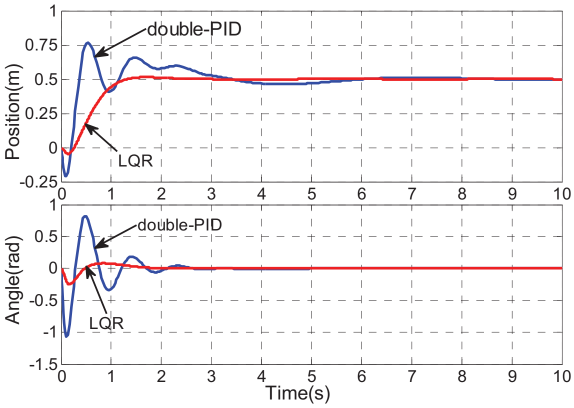

Figure 7. Dynamic response comparison of designed controllers

TABLE II. PERFORMANCE INDICES OF CART POSITION

| Time Response Specification | Double-PID | LQR |
|---|---|---|
| Rise Time | 0.36s | 1.34s |
| Transition Time | 8.65s | 2.51s |
| Steady State Error | ≈0.00 | ≈0.00 |
| Maximum Overshoot | 0.265m | 0.046m |

TABLE III. PERFORMANCE INDICES OF PENDULUM ANGLE

| Time Response Specification | Double-PID | LQR |
|---|---|---|
| Rise Time | 0.28s | 0.48s |
| Transition Time | 3.13s | 2.14s |
| Steady State Error | ≈0.00 | ≈0.00 |
| Maximum Overshoot | 1.07rad | 0.248rad |

Based on the performance indices tabulated in the two tables, LQR controller has the faster transition time both in cart position and pendulum angle, and with the longer rise time of cart position and pendulum angle, the balancing process will be more smooth. Furthermore, the pendulum angle maximum overshoot using double-PID method is bigger than using LQR method, which is because of the shorter rise time of the cart position when using double-PID contributes to larger pendulum angle shocking and maximum overshoot.

In conclusion, for dynamic response, the inverted pendulum controlled by LQR controller 1) balances faster because of the shorter settling time; 2) has a smoother response because of longer rise time; 3) has better robustness due to less maximum overshoot and shocking numbers. So, the LQR controller can guarantee the inverted pendulum system possess better dynamic performance.

## VI. Assessment on Steady State Performance of the Designed Controllers

In the former section, friction is simplified as viscous friction, and this is valid in the designing of the double-PID and LQR controllers, especially for evaluating the dynamic performance of the designed controllers. However, this kind of simplification leads to near zero steady state error, and obviously it is not the case. In this section, the steady state performance, with the influence of friction, can be investigated by means of virtual prototype and experimental setup.

### *A. Comprehensive Friction Model*

The viscous friction, as described before, is described as $F_{fric}(t) = -\varepsilon \dot{x}$. The Coulomb friction $F_C$ is proportional to the normal load, i.e. $F_C = \mu_s F_N$. The static friction $F_{\text{static}}$ counteracts the external applied linear motor forces $F_M$(t). Define $F_S$ as the maximum static friction, which is higher than the Coulomb friction, however we simplify it as $F_S$=$F_C$. Thus the static friction can be described as in (13).

$$F_{static} = \begin{cases} -F_M & \text{if } \dot{x} = 0 \text{ and } |F_{applied}| < F_S \\ \mu_s F_N \,\text{sgn}(F_M) & \text{if } \dot{x} = 0 \text{ and } |F_{applied}| \geq F_S \end{cases} \quad (13)$$

The friction components (viscous friction, Coulomb friction and static friction) can be combined in different ways and such combination is referred as the classical model. However, the classical combination results of a discontinuous friction force at the transition segment from static friction to the Coulomb and viscous friction. The discontinuity contradicts to experimental observation [13]. A common way that can smooth the transition segment is to add an exponential factor [14]. This leads to the comprehensive friction model in (14).

$$F_{fric} = \begin{cases} F_{static} & \text{if } \dot{x} = 0 \\ -(\mu_c + (\mu_s - \mu_c)e^{-(\dot{x}/v_s)^{\gamma}})F_N \operatorname{sgn}(\dot{x}) - \varepsilon \dot{x} & \text{if } \dot{x} \neq 0 \end{cases} \quad (14)$$

where $\varepsilon$ , $\mu_s$ and $\mu_c$ are the coefficient of viscous, Coulomb, and static frictions, respectively. $F_N$ is the magnitude of the normal force equal to gravitation of the cart plus the pendulum, $v_s$ is called the Stribeck velocity, and $r$ is the form factor. The using of the comprehensive friction models confronts the problem of detecting zero velocity. Karnopp proposed the creation of a range of values and within the range the movement velocity is zero [15]. For velocities within this range, the friction is static friction. In the simulation we set ZR=0.005m/s.

To estimate $\mu_c$ and $\varepsilon$ we applied two constant current values $i_q$ to the linear motor and let the cart to reach a steady state, and the corresponding constant final velocity, $\dot{x}$ , can be obtained. Then we can use the steady state equation of motion to solve for $\mu_c$ and $\varepsilon$ . When estimating the value of th static friction coefficient $\mu_s$ , the Armstrong-Helouvry procedure [16] was used, that is to gradually increase the current applied to the linear motor and measure the current (and hence force) necessary to make the cart start to move. The Stribeck parameters, $v_s$ and $r$ can be chose by trial and error, so that the simulations of the model can best match experimental data. The value of the friction parameters are given in Table 4.

TABLE IV. PARAMETERS OF THE COMPREHENSIVE FRICTION MODEL

| Parameter | Description | Value |
|---|---|---|
| $\mu_s$ | Coefficient of static friction | 0.042 |
| $\mu_c$ | Coefficient of Coulomb friction | 0.027 |
| $\varepsilon$ | Coefficient of viscous friction | 0.1N/m/sec |
| $\upsilon_s$ | Stribeck velocity | 0.083m/s |
| $\gamma$ | Form factor | 2 |

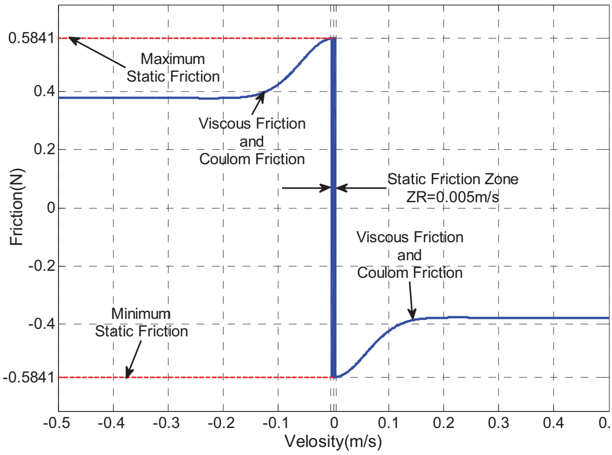

Figure 8. Force-Velocity plot of the friction model

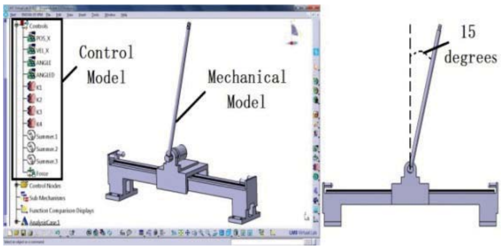

Figure 9. Virtual prototype of the inverted pendulum system

A Force-Velocity plot for the comprehensive friction model with parameters obtained from experiment is shown in Fig. 8. The figure shows that the maximum friction is 0.5841N.

### B. Assessment on the Steady State Performance based on Virtual Prototype Simulation

A virtual prototype of the inverted pendulum system is developed in Virtul.Lab environment, as shown in Fig. 9. The virtual prototype allows us easily inputting the conditions in real environment, such as frictions. The virtual prototype consists of mechanical model and control model. The mechanical model simulates the experimental setup of the inverted pendulum in size and mass. The control model simulates the double-PID and LQR controller respectively. The initial condition is that the pendulum starts with an inclined angle 15 degrees from upright position.

The steady state performance indices, as well as the dynamic performance indices, of the two controllers are shown in Fig. 10 and Fig. 11. The figures show that the steady-state response of the system has oscillation, the so called limit cycle, which is validated both in theory and in experiment, and can be seen as steady state error. Reference [17] proposed that the presence of friction produces limits cycles. Considering one of the practical use of inverted pendulum, the electric two-wheeled self-balancing vehicle, lots of efforts have been spent to reduce the existed vibration by improved control algorithm [18] or available friction compensation model. Thus for practical application of the inverted pendulum, the smaller oscillation amplitude is the better.

Table 5 shows a comparison between the performance indices of double-PID controller and LQR controller. The oscillation amplitude of cart position is 0.095m and pendulum angle is 5.73deg when using double-PID controller, while using LQR controller the amplitude is 0.025m and 1.15deg respectively, which means that the LQR controller can guarantee smaller steady state error. The oscillation frequency of cart position and pendulum angle is 0.417Hz when using double-PID controller, while using LQR controller the frequency is 0.250Hz, which means that the oscillation is slower, this indicates that the cart or the pendulum will oscillate with more smooth.

TABLE V. STEADY STATE PERFORMANCE INDICES

| Performance Index | double-PID | LQR |
|---|---|---|
| Cart Position *Oscillation Amplitude* | 0.095m | 0.025m |
| Pendulum Angle *Oscillation Amplitude* | 5.73deg | 1.15deg |
| Cart Position *Oscillation Frequency* | 0.417Hz | 0.250Hz |
| Pendulum Angle *Oscillation Frequency* | 0.417Hz | 0.250Hz |

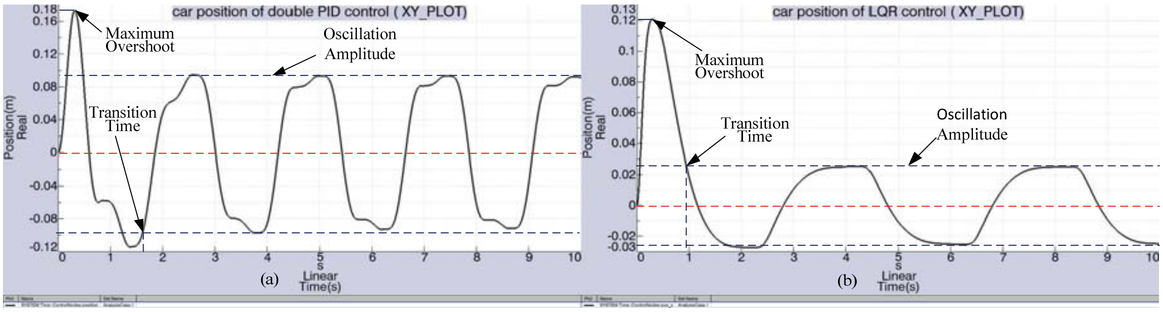

Figure 10. Comparison of cart position between double-PID controller and LQR controller based on virtual prototype

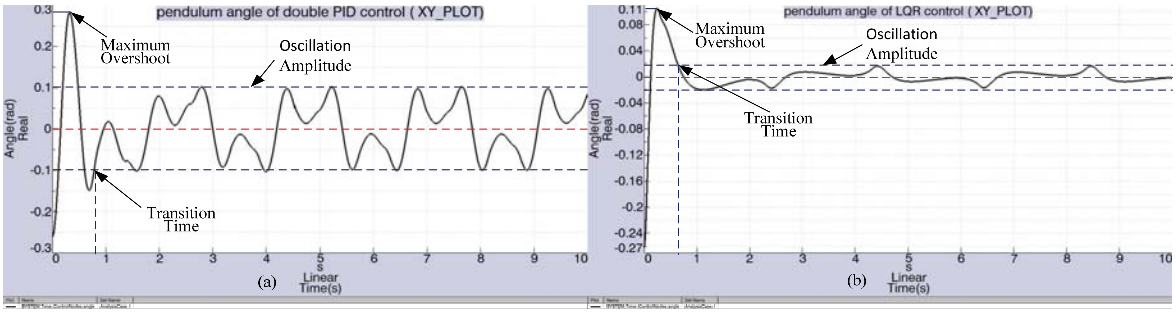

Figure 11. Comparison of pendulum angle between double-PID controller and LQR controller based on virtual prototype

### C. *Assessment on the Steady State Performance based on Experimental Setup*

Experimental setup based on real-time control in dSPACE environment provides the interface between the Simulink environment variables and the real system. Experimental setup, as shown in Fig. 12, intends to investigate the steady state performance of the two controllers. Results are shown in Fig. 13, Fig. 14 and Fig. 15. Table 5 summarizes the steady state performance indices of the two double-PID and LQR controllers. Note that Figure 15 plots the control error signal which equals the control force applied by linear motor. We can see that smaller control force is needed for maintaining the equilibrium position at steady state when using LQR controller. Thus we can conclude that the steady state performance of the LQR controller is better for its smaller oscillation amplitude, oscillation frequency and maintaining force. The data also shows that the simulation results of virtual prototype and that of the experiments is very close.

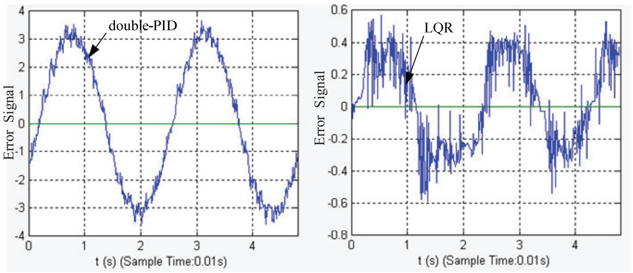

Figure 15. Control error signal in experimental setup

TABLE VI. STEADY STATE PERFORMANCE OF THE DESIGNED CONTROLLERS BASED ON EXPERIMENTAL SETUP

| **Performance Index** | **double-PID** | **LQR** |
|---|---|---|
| Cart Position *Oscillation Amplitude* | 110mm | 10mm |
| Pendulum Angle *Oscillation Amplitude* | 4deg | 0.6deg |
| Cart Position *Oscillation Frequency* | 0.455Hz | 0.431Hz |
| Pendulum Angle *Oscillation Frequency* | 0.455Hz | 0.431Hz |
| Control *Error (Force) Amplitude* | 3N | 0.6N |

## VII. CONCLUSIONS

This paper proposes two control methods for the inverted pendulum, an innovative double-PID control method and modern LQR control method. Control parameters are tuned based on simulation, and results show the two proposed controllers are all capable of controlling the cart position and pendulum angle of the inverted pendulum system with acceptable performance. Dynamic performance and steady state performance are investigated of the two proposed control methods. Dynamic performance proves that the proposed LQR controller can guarantee the inverted pendulum a faster and smoother stabilizing process and with better robustness than the double-PID controller. Steady state performance adopts limits cycles as assessment indices, which not only makes the assessment available, but also, provides an effective way for the evaluation of any equilibrium control problem with friction involved. Results show that the steady state performance of the proposed LQR controller has smaller oscillation amplitude than that of the double-PID controller. Further improvement need to be done for both of the controllers. The double-PID controller should be improved to guarantee better dynamic and steady state performance, and the LQR controller can be improved, such as using friction compensation, to further reduce the oscillation amplitude and frequency.

## ACKNOWLEDGMENT

The authors would like to thank Winner Motor Ltd for kindly supporting the experimental equipment for this research.

***Abstract*—Event-based sampling allows saving energy in the sensor transmitter by avoiding unnecessary messages. One important application is room temperature control with wireless sensors. Optimizing the controller parameters of a PI controller for this application is a difficult task, because usually no process model is available and challenging issues like actuator saturation have to be taken into account. Adaptive controllers offer the possibility to tune themselves automatically. In this paper, an adaptive PI controller based on pattern recognition is proposed, designed for room temperature control, sensor energy efficiency, and level-crossing sampling. The implementation is much easier than that of most other adaptive controllers and robustness to disturbances and noise is high. The focus of this paper lies rather on the basic idea, simulations and practical issues than on theoretical investigations.**

## I. Introduction

Room temperature control loops using wireless sensor networks allow high quality control with lower costs than using wired sensors, especially if the building automation system is not installed in the construction phase of the building. Reduction of the energy consumption of the nodes is one of the most investigated research issues in that field. Much energy can be saved by reducing the message count because sending messages requires much more energy than computing [1]. It has been shown that level-crossing sampling (also called send-on-delta, deadband, or Lebesgue sampling) allows a reduction of messages compared to periodic sampling while assuring the same control quality [2]. Therefore, level-crossing sampling can be used in common commercial building automation system technologies, e. g. LonWorks and EnOcean. The main idea of level-crossing sampling is that a new message from the sensor to the controller is only sent if the controlled (measured) signal has changed from the last sent value at least by a threshold $\Delta_{lc}$:

$$|y_m(t_n) - y_m(t_{n-1})| \geq \Delta_{lc} \tag{1}$$

where $y_m(t)$ is the measured signal, and $t_n$ and $t_{n-1}$ are two subsequent time instances at which a message is sent. Usually the sensor wakes up periodically, measures then the current value of the controlled variable (here: room temperature) and decides according to (1) whether a message has to be sent [2].

Adaptive control allows near-optimal control without manual process identification because the controller sets its parameters itself based on available information from past control actions. Additionally, adaptive controllers change their parameters automatically if the process changes. This allows to install an untuned controller in each room of a building, and after start-up each controller optimizes itself according to the room it has to control. This allows cost reductions compared to manual tuning and higher control performance than using always-working, safe, but conservative settings.

Possible reasons for differences between the rooms are the varying room size, wall material, window area, leaking doors or windows, heating and cooling equipment, duct architecture, sensor/actuator location and sensor inertia. Reasons for process changes are variations of the flow temperature from the central heat generator, larger changes of furniture (energy storages), refurbishments (e. g. new windows, new façade insulation), sensor/actuator replacement, variations of the air flow, and changes in the HVAC (heating, ventilation and air conditioning) system.

The main contribution of this paper is an adaptive control algorithm for usage with level-crossing sampling and special emphasis on typical problems of room temperature control, i. e. actuator saturation, typical disturbances, and processes of unknown order. The goal of the adaptation is good control performance in combination with energy efficiency of the sensor. The focus of this paper is the basic idea, practical problems and simulation results; a more theoretical investigation is currently done by the authors.

This article is structured as follows. Section II gives an overview on possibilities for adaptive control based on nonuniformly sampled signals. Section III defines precisely the objective of the adaptive controller. Improvements over an older tuning rule are presented in section IV. The new adaptive controller is explained in section V. The approach is verified using simulations in section VI. While the algorithm is based on reference step responses, in section VII disturbance compensation is briefly discussed. Finally, section VIII draws the conclusions.

## II. Overview: Possibilities for adaptive control with level-crossing sampling

To the authors' knowledge, there are only few works towards adaptive control with nonuniform sampling. Pawlowski et al. used a gain-scheduling controller based on outside temperature and outside wind speed together with several event-based sampling schemes for controlling the temperature in a greenhouse [3]. Dormido et al. published an autotuner

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

based on a relay test with level-crossing sampling [4]. But, it cannot be used without interrupting the usual control action. Wang and Hovakimyan presented an $\mathcal{L}_1$ Adaptive Controller for an event-based, but not level-crossing sampling scheme [5].

A usual adaptive controller consists of one component identifying the process and another component for tuning the controller based on this process model [6]. In combination with level-crossing sampling the task can be split in the process identification for nonuniformly sampled signals and a separate PI controller tuning rule based on the identified model. A tuning rule for the latter point has been given by the authors [7].

In literature, there exist three basic approaches for process identification using nonuniformly sampled signals:

1) Resampling/interpolation followed by the application of methods for uniformly sampled signals.
2) Approximate Fourier transform and application of methods based on the frequency spectrum.
3) Identification of continuous-time ARMA (autoregressive moving average) models.

All these possibilities are quite complex and computationally expensive [8]–[10]. Besides, the usual adaptation methods for periodically sampled signals have strong disadvantages [6], [11], e. g. if the time delay or process order is not known in advance or if there are larger disturbances. Unfortunately, these issues are unavoidable in room temperature control. Even critical effects like *bursting* [12] or instability are possible. In addition to the methods above, there are many well known simple graphical approaches based on the open-loop step response, but these cannot be applied in closed loop what is necessary for an adaptive controller.

However, there are some approaches for adaptive control which do not need a detailed model and are thus also independent of the sampling scheme: Model free adaptive control and pattern recognition based adaptive control.

In *Model-free adaptive control* a sensitivity function is estimated from measured data and the controller output is computed using a simple learning algorithm [13]–[15] or an artificial neural network [16], [17]. Tuning the parameters of these methods (e. g. special learning parameters of the prevailing method, or security parameters for avoiding division by zero) is difficult, especially without a process model, because the optimal learning parameter settings depend on the controlled process while the final adapted parameters depend on the learning parameters. The meaning and magnitude of these parameters is not comprehensible for non-experts.

*Pattern recognition based adaptive control* imitates the procedure which a skilled control engineer would perform if there would be the task to improve a running but insufficiently tuned control loop without building a model of the process. The common part of these algorithms is that the first step is to extract special *features* from the measured signals. Pattern recognition based adaptive controllers usually update the controller parameters not permanently but only after significant events like set-point changes or larger disturbances. Some authors avoid therefore the name "adaptive" and use "auto-tuning" instead [18]. However, the problem with the term "auto-tuning" is that most commercially available auto-tuning controllers update their parameters not regularly but only when the user starts a procedure, mostly an open-loop experiment.

Note that the term "pattern recognition" is more known for classification and grouping of patterns [19] what is not done in any of the algorithms itemized below. However, as most authors of such control algorithms use the term "pattern recognition" [18], [20]–[24], that is also done in this paper.

The first one who made pattern based adaptive control popular was Bristol in 1977 [20]. This controller ignores the dynamics of the process and is thus relatively slow.

Seif modeled the transients by a set of elementary patterns without giving details about the adaptation rules [21].

Seem proposed a control algorithm where the changes of the PI controller parameters are described as functions of two features of the closed-loop set-point or disturbance step response [22], [23]. Some details of Seem's algorithm need periodic information of the current process output and are therefore not suitable for nonuniform sampling, but the basic idea can be transferred to level-crossing sampling. Seem's algorithm is optimized to minimize IAE (integral of absolute error) instead of considering also sensor energy efficiency. Seem spent much attention on reaching robustness for many practically important special cases of HVAC control. The algorithm has been used successfully in more than 500,000 controllers [23].

Morilla et al. published a multi-step approach for PID controllers [18]. The results are good, but unfortunately some practically important aspects like disturbances and actuator saturation have not been considered. Some of their used features of the step-responses (e. g. decay ratio and oscillation period) are practically not measurable with level-crossing sampling and sensitive to disturbances and measurement noise.

INTUNE is a commercial adaptive controller using pattern recognition for updating the parameters of a PID controller [25]. To the authors' knowledge, the details of the adaptation rules have not been published.

Segovia et al. proposed a simple iterative pattern based PID controller scheme [24] roughly based on the Ziegler/Nichols tuning rule, but they gave only a tuning rule for oscillatory step responses. Furthermore, they did not write anything about actuator saturation or disturbances.

## III. Assumptions and objective

This paper deals with the control loop shown in Fig. 1 where $y_m(t)$ is the signal measured by the sensor (process output $y_p(t)$ with disturbance $d(t)$) and $y_c(t)$ the signal which is sent to the controller. $w(t)$ is the set-point or reference signal, $e_c(t) = w(t) - y_c(t)$ the control error and $u_c(t)$ the control signal (manipulated variable) which is sent to the actuator. The actuator uses a zero-order hold and its output is called $u_p(t)$. For ease of notation, a distinction between continuous-time and discrete-time signals has been avoided here.

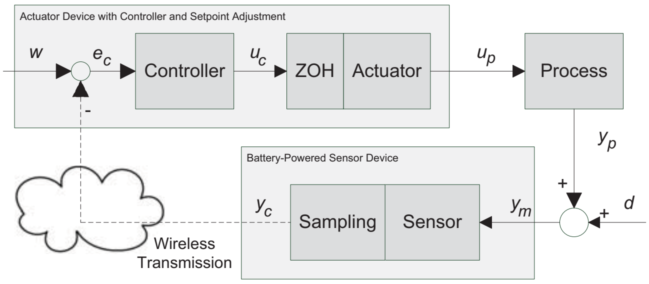

Fig. 1. Control loop with battery-powered sensor device.

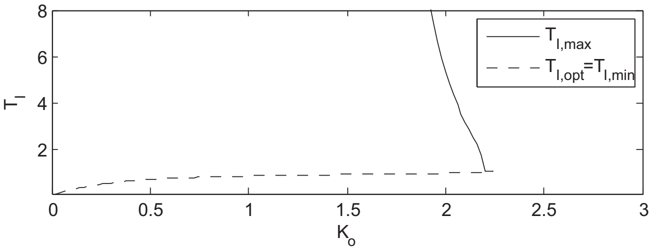

Fig. 2. Minimum (optimal) and maximum value of $T_I$ as a function of $K_o$ for avoiding oscillations for the example of $T_m = 1$ and $\tau = 0.2$, with continuous-time control.

In contrast to this control loop, some other authors integrate sensor and controller in one device and transmit the control signal to the actuator using level-crossing sampling [26]. The advantage of separating the sensor from the controller is that the sensor does not need a receiver or display (for editing the current set-point, weekly schedules or controller parameters) and can therefore save much energy. The actuator usually needs far more energy anyhow as well as it must power a receiver for getting the sensor messages and so the energy consumption of the controller and display is less critical.

For describing the algorithm, the process is assumed to be a FOLPD (first order lag plus time delay) process

$$G(s) = \frac{Y_p(s)}{U_p(s)} = \frac{K_m}{1+sT_m}e^{-s\tau} \tag{2}$$

with proportional action coefficient $K_m$, time constant $T_m$, and time delay (deadtime) $\tau$. The ratio

$$\eta := \frac{\tau}{T_m} \tag{3}$$

is called *degree of difficulty* [27]. Practical ranges of these parameters for room temperature processes can be found e. g. in [27] where one should keep in mind that variations could be larger, especially for $K_m$ caused by variations of flow (supply) temperature. Nevertheless, the proposed algorithm is not limited to this process type because it does not need to know or identify any time constant directly. The physics of rooms (room airflow) is such complex that it theoretically cannot be modeled adequately by a transfer function (or a differential equation) [28]. The proposed controller has to deal with these issues.

PI and PID controllers are the by far mostly used controllers in industry [29], [30]. The basic continuous-time PI controller is given by

$$R(s) = \frac{U_c(s)}{E_c(s)} = K_P\left(1+\frac{1}{T_I s}\right) \tag{4}$$

with proportional action coefficient $K_P$ and reset time $T_I$.

PI(D) controllers have also been used successfully in an event-based fashion [2], [7], [31]. The PI algorithm which is used in this paper is taken from [7], only enhanced by anti-reset windup. Derivative action has not been used. This will be explained later using results of the presented investigations.

A cost function which helps to design the adaptive controller is the product

$$J_{Prod} := N_{sc} \cdot J_{ISE} \tag{5}$$

of the number $N_{sc}$ of messages from the sensor to the controller and the control quality measured as Integral of Squared Error (ISE) $J_{ISE}$. The adaptation should reach small values of $J_{Prod}$ as this is a hint for a good trade-off between message number and control performance. More detailed reasons for this choice are discussed in [7].

## IV. Improved tuning rule

In [7] it has been shown that for minimzing $J_{Prod}$ at step responses, large oscillations should be avoided and—in an ideal case (no actuator saturation, FOLPD process)—a suitable tuning rule is

$$K_P = \frac{0.468}{K_m \cdot \eta}, \tag{6a}$$
$$T_I = T_m. \tag{6b}$$

But, typical challenges in room temperature control are actuator saturation, large time-variable (but not step-wise) disturbances, and processes of unknown order. As stated in [7], the tuning rule (6) is not optimal in these cases. Simulations confirm that ignoring these problems leads to poorly tuned control loops. This section thus presents some improvements over tuning rule (6).

### A. Oscillating step responses

As the goal is to avoid oscillating step responses, it is interesting to know for which $K_P$ that is possible at all. If the open-loop gain $K_o$, which is defined as

$$K_o := K_P \cdot K_m, \tag{7}$$

is greater than a limit $K_{o,max}(\eta)$, there are oscillations, independent of the selection of the reset time $T_I$, see an example in Fig. 2. Fig. 3 shows the maximum $K_{o,max}$ as a function of $\eta$, found by simulations. The simulation uses continuous-time control to reach idealized results, what is similar to an infinitesimally small threshold $\Delta_{lc}$. For numerical reasons a deadband around the set-point should be defined in which the control loop is allowed to oscillate for avoiding too conservative results. This has been set to 1 % of the step width.

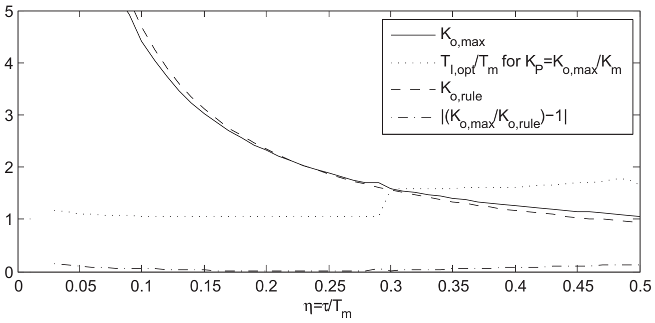

Fig. 3. $K_{o,max}$ as a function of $\eta$ for a deadband of 1 % and the optimal setting of $T_I$, normalized to $T_m$. Also $K_{o,rule}$ according to tuning rule (6) is shown as well as the ratio of $K_{o,max}$ and $K_{o,rule}$.

The conclusion for avoiding oscillating step responses is

$$K_P \overset{!}{\leq} \frac{K_{o,max}(\eta)}{K_m}. \tag{8}$$

$K_P$ according to (6a) lies near to the curve for a deadband of 1 % (see Fig. 3) and gives therefore nearly the fastest response with no more than 1 % overshoot.

### B. Actuator saturation

The immediate change of the controlled variable $u_p(t)$ caused by proportional action after a stepwise reference change $\Delta w$ can be calculated by

$$\Delta u_{prop} = K_P \cdot \Delta w. \tag{9}$$

Since in real applications $u_p(t)$ is bounded between 0 and 1 (valve fully closed to valve fully opened), it is useless to set $K_P$ higher than $1/\Delta w$ because of actuator saturation. That means

$$K_P \overset{!}{\leq} \frac{1}{|\Delta w|}. \tag{10}$$

An illustrative example: Assumed that the reference change for night setback is $\Delta w = -5\,\mathrm{K}$. So, each $K_P > 0.2$ would result in immediate actuator saturation. Of course, increasing $K_P$ does not degrade control performance at step responses (because it has little influence if the stability limit is not exceeded), but high $K_P$ will lead to many messages in "steady state" without improving control performance as will be discussed in section VII.

Note that the fulfillment of (10) does not guarantee that there is no actuator saturation, because that depends on the value of $u_p$ before the set-point change as well as on integral action.

Besides, derivative action (a PID controller) increases actuator action and hence also actuator saturation. Thus, it is at step responses reasonable to do without derivative action.

### C. New tuning rule

The proposed tuning rule for $K_P$ is the combination of (8) and (10)

$$K_P = \min\left(\frac{1}{|\Delta w|}, \frac{K_{o,max}(\eta)}{K_m}\right) \tag{11}$$

As (6a) approximates $K_{o,max}(\eta)/K_m$ quite well, the rule can be approximated by

$$K_P \approx \min\left(\frac{1}{|\Delta w|}, \frac{0.468}{K_m \cdot \eta}\right). \tag{12}$$

No rule for setting $T_I$ is given here because iterative optimization is used in the proposed adaptive controller.

## V. Proposed adaptation strategy

This section presents the new adaptation strategy.

### A. Used patterns

Only reference step responses are taken to analyze the process behavior. In a typical office building, reference changes occur twice a day: Once in the morning and once in the evening because of night setback. In residential buildings, there are often four reference changes because the set-point is higher only in the morning and in the evening. So, there are at least two step responses a day at which the controller parameters can be optimized.

The precondition for benefiting from an adaptive controller is that the process does not change faster than the adaptation can follow. Faster changes are regarded as belonging to the disturbances. However, the sources of process changes which have been itemized in section I do not change significantly during one day (or they change fast but only seldom, like on refurbishment). Only considering the variation of the flow temperature may be advantageous, what could be done via gain scheduling [3], [32].

Some other authors used also step-wise disturbances for updating the controller parameters [22], [24]. However, since significant step-wise load changes do not often occur in practical room temperature control, only set-point changes are considered here.

### B. Proportional action coefficient $K_P$

As

$$K_m = G(0) = \frac{Y_p(0)}{U_p(0)}, \tag{13}$$

and assuming a constant disturbance $d$, $K_m$ can be calculated from two pairs ($u_p[k]$, $y_p[k] + d$) measured in "steady state" with different values of $u_p[k]$. So, after each closed-loop step response, when the process is again in "steady state", $K_m$ is estimated by

$$K_m = \frac{(y_p(t_s) + d) - (y_p(t_0) + d)}{u_p(t_s) - u_p(t_0)} \approx \frac{y_c(t_s) - y_c(t_0)}{u_c(t_s) - u_c(t_0)} \tag{14}$$

where $t_0$ is the step time (or shortly before) and $t_s$ is the time when steady state is (assumed to be) reached after the step response. This method is relatively robust to measurement noise but in the case of slowly varying loads $d(t)$ the estimation gets inaccurate. If $(t_s - t_0)$ is chosen too small, the "steady state" may not yet have been reached, leading to more inaccurate estimation of $K_m$. Contrary, if $(t_s - t_0)$ is chosen too large, load changes can get more influence on the results. In the simulations of section VI $(t_s - t_0)$ has been set to one hour.

After estimating $K_m$, (12) is applied to compute $K_P$. Unfortunately, $\eta$ depends on $\tau$ and $T_m$ which are hard to estimate in closed loop under noisy conditions with time-variable load and significant threshold $\Delta_{lc}$. Instead, an upper limit $\eta_{max}$ can be used which is the greatest degree of difficulty which is expected to occur. According to [27], for room temperature control $\eta_{max}$ is 0.3. If $\eta$ of the real process is lower than $\eta_{max}$, $K_P$ is lower than necessary, but the reset time $T_I$ will be adjusted (reduced) to improve the control loop performance, see section V-C. The authors are working on more sophisticated solutions, but simulations show that this simple solution works well, too.

### C. Reset time $T_I$

As announced in section IV-C, an iterative method is used for updating $T_I$, i. e. the reset time is updated after each set-point change based on the measured overshoot. The overshoot $h_r$ is a monotonically decreasing function of $T_I$, see some examples in Fig. 4(a). This is intuitively clear because the higher the reset time $T_I$, the slower is the response and the less the set-point is exceeded before the controller can react on the overshoot. The basic idea for adaptation is:

- If there is (too much) overshoot, increase the reset time.
- If there is no (or too little) overshoot, decrease the reset time.

Because of (12) it is guaranteed that there is a setting of $T_I$ without oscillations (in the case of an ideal FOLPD process, continuous-time control and no disturbances).

The step width for updating $T_I$ must be defined. Simple learning algorithms (similar to first order low-passes) could be used, comparable to [13], [22], [24], but it is possible to apply more specific algorithms. An initial attempt is given in the following; more sophisticated solutions as well as theoretical analysis are part of current research of the authors.

Let $T_{I,opt}$ define the smallest possible reset time without overshoot. Fig. 4(a) shows some examples for the overshoot $h_r$ as a function of $T_I/T_{I,opt}$ using continuous-time control. The qualitative curves of Fig. 4(b) substantiate the assumption that the overshoot can be approximated by

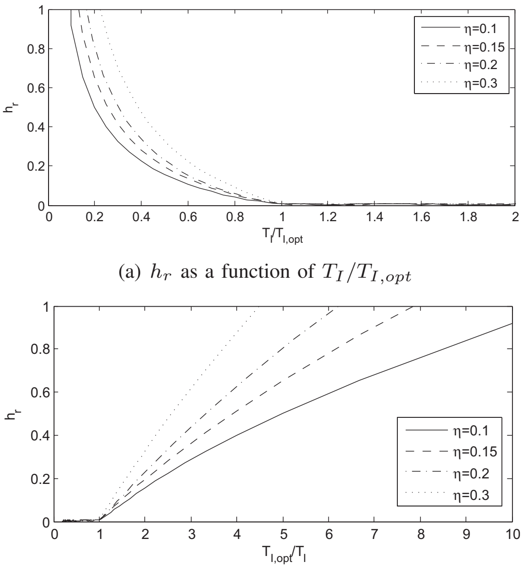
$$h_r \approx \begin{cases} \gamma \cdot \left(\frac{T_{I,opt}}{T_I} - 1\right), & \text{if } T_I < T_{I,opt} \\ 0, & \text{otherwise,} \end{cases} \tag{15}$$

The proportionality constant $\gamma$ is discussed later.

Equation (15) can be used to calculate $T_{I,opt}$ based on the measured overshoot $h_{r,old} > 0$ and the appropriate reset time $T_{I,old}$:

$$T_{I,new} = T_{I,opt} = \left(1 + \frac{h_{r,old}}{\gamma}\right) \cdot T_{I,old}. \tag{16}$$

If there is no overshoot, it is only known that the reset time should be reduced, but not how much. However, from (15) a maximum step width can be calculated with the requirement that the overshoot after the update must not exceed a given limit $h_{r,max}$. The important case is $T_{I,old} = T_{I,opt}$, because a reduction of $T_I$ will then result in the highest overshoot. The rule for updating is



(a) $h_r$ as a function of $T_I/T_{I,opt}$

(b) $h_r$ as a function of $T_{I,opt}/T_I$

Fig. 4. Overshoot $h_r$ as a function of reset time $T_I$, normalized to $T_{I,opt}$ (and inverse) for several $\eta$ and $K_o = 1.5$.

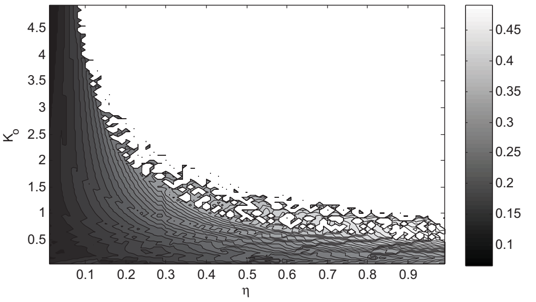


Fig. 5. $\gamma$ as a function of $\eta$ and $K_o$ for idealized conditions: Continuous-time control, FOLPD process, no disturbances, no actuator saturation.

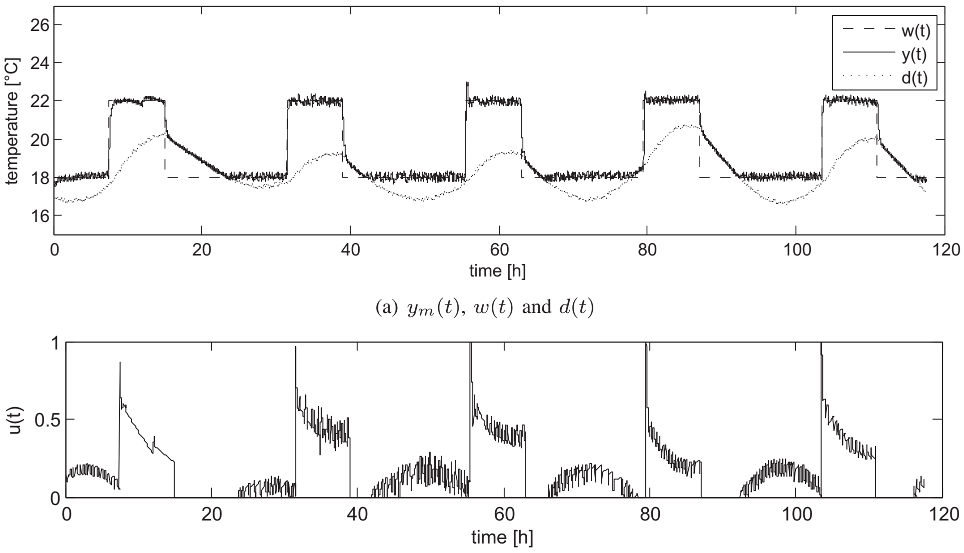
$$T_{I,new} = \frac{1}{1 + \frac{h_{r,max}}{\gamma}} \cdot T_{I,old}. \tag{17}$$

The greater $h_{r,max}$ is chosen, the faster the algorithm converges to less conservative settings. $h_{r,max}$ can be reduced after finding a rough estimation of $T_{I,opt}$, e. g. after the first step-response with overshoot happened.

The remaining task is to find the appropriate value of $\gamma$. This parameter depends on $\eta$, $K_o$, $\Delta_{lc}$, the real process order, and actuator limits. Additionally, the measured overshoot $h_{r,old}$ can be adulterated with disturbances and other effects, in particular when using level-crossing sampling where the exact overshoot cannot be measured. Similarly to [22] a low-pass filter could be used for reducing influences of disturbances, but filter design is difficult if the process parameters can vary over a wide range, especially with nonuniform sampling. Fortunately, it is not very important to know an exact value



(a) $y_m(t)$, $w(t)$ and $d(t)$

(b) $u_p(t)$

Fig. 6. Simulation over five days with level-crossing sampling and measurement noise.

of $\gamma$ because of the iterative method—if $\gamma$ is chosen too high, only the convergence rate is degraded. Thus, a worst case estimation is enough. Fig. 5 shows $\gamma$ as a function of $K_o$ and $\eta$ under the idealized assumptions of continuous-time control, a FOLPD process, no disturbances and no actuator saturation. According to this graphic and assuming that in room temperature control $\eta < 0.3$ holds [27], the worst case to be expected is $\gamma \approx 0.3$. This value has also been found to work well in simulations.

Step responses with too little overshoot *and* actuator saturation must not be used for updating $T_I$, because the too little overshoot may result from actuator saturation and not from sluggish tuning. This is no problem, since the controller knows whether the actuator limits (0 or 1) have been reached in the last step response.

This iterative method allows adaptation without estimating $\tau$ and $T_m$ what would be difficult with level-crossing sampling and disturbances. It also improves the tuning results in the case of unknown process order where (6) leads to suboptimal results [7].

### D. Initial settings

The initial settings of $K_P$ and $T_I$ should be based on the most critical process to be expected. This is the maximum of each parameter $\eta$, $K_m$, and $\tau$, i. e. for room temperature control according to [27] $\eta = 0.3$, $\tau = 0.05\,\mathrm{h}$, and $K_m = 10\,\mathrm{K}$. $K_P$ can then be set using (12) and (with regard to [7]) $T_I$ to $T_m$, i. e. $T_I = 0.5\,\mathrm{h}$.

In result, the first step response is stable. In most cases (all but the most critical case) the response will be too sluggish. After each step response, $K_P$ is updated using (12) and (14) as well as $T_I$ is reduced according to (16). The responses get faster until overshoots occur. Then $T_I$ is increased using (17).

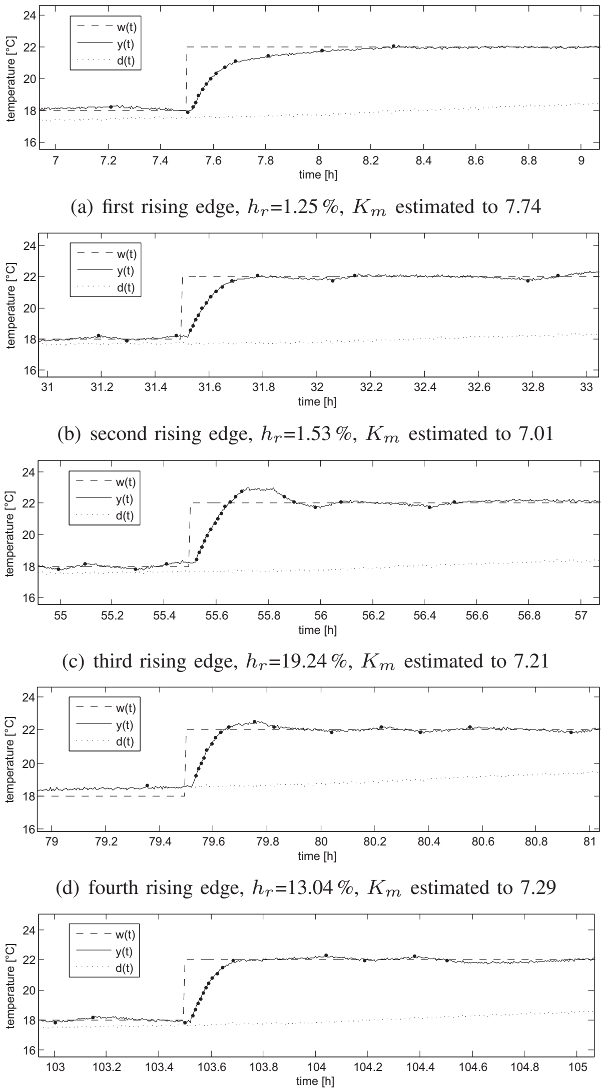
## VI. Simulations

Fig. 6 presents a simulation over five days using a process with $T_m = 0.15\,\mathrm{h}$, $K_m = 7\,\mathrm{K}$, and $\tau = 0.01\,\mathrm{h}$. The disturbances (this is the room temperature without heating, i. e. $u_p(t) \equiv 0$) are based on measurements taken from an office building which was built in 2005, having a heat energy consumption of 34 kWh/m$^2$a. By setting $\Delta_{lc}$ to 0.3 K (see section VII) and applying night setback of 4 K, an overshoot of 7.5 % (0.3K/4K) must be accepted because of level-crossing sampling. The internal sampling period of the sensor is 0.005 h.

As this is not the "most critical" of expectable processes, the first step response is slower than necessary, shown detailed in Fig. 7(a). Fighting against that, the adaptation algorithm estimates $K_m$, updates $K_P$ and reduces $T_I$. The negative set-point changes cannot be used for pattern recognition, because actuator saturation without overshoot occurs (the valve is fully closed). The second rising edge is significantly faster than the first, Fig. 7(b). The third even has (too much) overshoot, Fig. 7(c). So, the adaptation algorithm increases the reset time. The fourth step response has less overshoot, Fig. 7(d), but due to the inexact adaptation method, also this step response has too much overshoot and the reset time is further increased. The fifth set-point change is as desired.

## VII. Disturbance compensation

The tuning rules (6) and (12) are exclusively based on step responses. But, it is interesting how the parameters should be chosen in "steady state" when only disturbances have to be compensated. To the authors knowledge, until now only limit cycles have been studied in several publications (e. g. [2], [33]). Limit cycles are periodic movements of the controlled variable between two or more sampling levels which often occur in "steady state", especially because of integral action,



(a) first rising edge, $h_r$=1.25 %, $K_m$ estimated to 7.74

(b) second rising edge, $h_r$=1.53 %, $K_m$ estimated to 7.01

(c) third rising edge, $h_r$=19.24 %, $K_m$ estimated to 7.21

(d) fourth rising edge, $h_r$=13.04 %, $K_m$ estimated to 7.29

(e) fifth rising edge, $h_r$=7.12 %, $K_m$ estimated to 9.53

Fig. 7. The five first rising edge step responses with level-crossing sampling and measurement noise. The dots are sampling instants, i. e. level crossings.

and that results in an unpleasant high message rate without improving control performance. But, if disturbances lead to level crossings (and therefore messages) anyhow, the importance of avoiding limit cycles is reduced.

The disturbance is equal the room temperature without heating or cooling, i. e. $u_p(t) \equiv 0$. The main reasons for disturbances are time-varying heat flows to or from the outside which depend on the outside temperature, sunlight, and room utilization (how many persons and machines are creating heat). These influences do not lead to any step-wise changes of the room temperature. It is well known from experience and measured in the office building considered in section VI that without heating the room temperature is a slowly varying signal, usually periodic with the minimum after midnight and the maximum after noon. The amplitude depends on the outside temperature, sunlight, and room utilization and does thus change from day to day. In this section, for theoretical investigations disturbances are assumed to be of the form

$$d(t) = A \cdot \sin\left(\frac{t}{24\,\mathrm{h}}\right), \tag{18}$$

that means a sinus curve with a period of one day and an amplitude $A$.

Simulations show that the PI controller parameter settings minimizing (5) depend on the ratio $a$ of the disturbance amplitude $A$ and the threshold $\Delta_{lc}$ which is defined as

$$a := \frac{A}{\Delta_{lc}}. \tag{19}$$

The practical bounds of $a$ are of interest. Since humans usually do not feel temperature changes smaller than 0.3 K there is no need to set $\Delta_{lc}$ significantly smaller than this value—even if it would allow a smaller value for the cost function (5) because of smaller ISE, the occupants would not notice it while the message rate (and therefore energy consumption) would be unnecessarily high, and also the costs for a sensor measuring such exactly would be high. Besides, the temperature variations inside one room because of stratification and bordering spaces are significantly greater than 0.3 K [28]. The amplitude $A$ can be expected to be lower than 5 K (very old buildings with poor insulation), for modern, well insulated buildings lower than 1.5 K. So, $a$ can be expected to be lower than 17 (5 K/0.3 K), often lower than 5 (1.5 K/0.3 K).

Simulations show that for such small values of $a$ the cost function (5) can be optimized by considerably reducing $K_P$ compared to the value got by (6a) because reducing $K_P$ increases the period of limit cycles and hence decreases the message number and energy consumption. As the temperature set-point trajectory correlates roughly with the disturbance (at noon higher than at midnight) the necessary control action is further reduced.

This fact can be used to improve the tuning rule in "steady state" by simply adding a factor $\kappa$, getting

$$K_P = \frac{0.468 \cdot \kappa}{K_m \cdot \eta}. \tag{20}$$

Optimal values of $\kappa$ as a function of $a$ and $\eta$ found by simulations can be seen in Fig. 8. The optimal $\kappa$ rises with $a$ because for higher $a$ a higher $K_P$ can improve the ISE more significantly than for lower values of $a$.

$\kappa$ could be realized in the controller by using a second degree of freedom (set-point weighting).

Note that using derivative action of a PID controller would lead to stronger actuator action and faster oscillations (more messages) without improving control performance.

Unfortunately, since $a$ and $\eta$ are neither known a priori nor estimated on-line, the formula cannot be applied. Automatically finding values of $\kappa$ suitable for each controlled room is another part of current research of the authors. Additional sensors, e. g. for outdoor temperature, room occupancy, and illumination, can help estimating $a$. Weather forecasts promise even better results. However, these solutions are much more

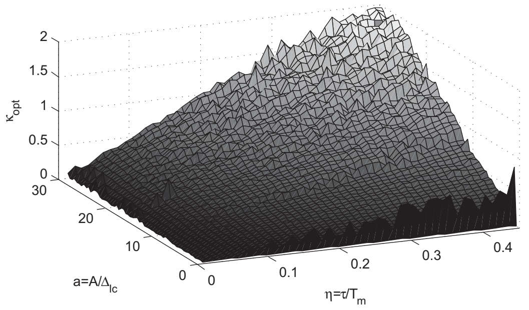


Fig. 8. Optimal setting of $\kappa$ in (20) as a function of degree of difficulty $\eta$ and disturbance to threshold ratio $a$. Simulation parameters are $T_m = 0.3\,\mathrm{h}$, $K_m = 10$, $T_I = T_m$ and $\Delta_{lc} = 0.3\,\mathrm{K}$. Minimum inter sample intervals [7] and actuator saturation have not been taken into account.

expensive than a simple single-loop controller like the proposed one.

## VIII. Conclusion

A pattern-based adaptive controller designed for level-crossing sampling and room temperature control has been presented. Simulations show that the algorithm can deal with typical problems of this kind of control loop. Also several points for future research have been pointed out, including practical improvements, theoretical analysis and less conservative assumptions.

*Abstract*—**Although the Wireless Sensor and Actuator Networks (WSANs) have many advantages than the wired networks, the nature of sharing wireless media and the complicated behavior of Media Access Control (MAC) introduce adverse impacts on the control system. In contrast to most work on networked control systems using simplified models of network induced delays, this paper considers the study the random access delay caused by a contention-based MAC scheme slotted ALOHA in WSANs. An improved fault detection observer with access delay compensation is proposed to improve the fault detection performance against the MAC delays.**

## I. Introduction

As one of the main challenges in Wireless Sensor Actuator Networks (WSANs) and Networked Control Systems (NCSs), the network-induced delay degrades the fault detection performance [1], [2],[3], [4] and much of attention have been paid on designing a fault detection system robust to network-induced delays [5], [6]. In most existing studies, the characteristics of a communication network are usually represented by simplified analytical models without considering the details of different communication protocols. For instance, it is popular to adopt a finite state Markov chain to represent the dynamics of the network-induced delays $\{\tau_k\}$, without consideration of the complicated behaviours of various communication protocols. As a result, the control system is modelled as a Markov Jumping System (MJS) [7] and various methods were proposed to design the fault detection filters, including Riccati equation methods [3] and linear matrix inequalities (LMIs) for $H_\infty$ fault detection observer design. In [8], [3], a Takagi-Sugeno (T-S) is built to represent network-induced delays and a fuzzy fault detection observer is proposed. [9] models the delay as a stochastic process with known mean and variance, and treats the impacts of delay as a parameter change in the framework of stochastic systems. Paper [10] used the Taylor approximation to analysis the impacts of delay and proposed a parity space-based residual generator. Eigen-decomposition and the Pade approximation were used in [11] under the assumption that the state matrix is diagonal.

However, the communication network is a complicated dynamic system and the simplified model of network delays cannot represent the communication network behaviour very well. The network-induced delays are caused by many reasons and there have been studies on the estimate the packet delays in a network [12]. For instance, paper [13] adopted the network calculus theory to determine the bounds of delays and adjust the threshold of fault detection observer's residual accordingly. In wireless networks, the contention-based MAC schemes are widely adopted to support multiple access. Unfortunately, it is still not clear how a random MAC scheme and its associated delay statistics influence the FD performance of NCSs. To bridge this gap between the communication protocols and fault detection observer designs, this paper brings the statistical properties of the access time of a contention-based MAC scheme (the so-called slotted-ALOHA) into the FD observer design. The main contribution of this paper are, (1) According to the analysis of the slotted ALOHA MAC scheme and its associated access delay (namely MAC-delay), a statistical estimation of the MAC-delay in slotted ALOHA induced is proposed. (2) With the estimate of MAC-delays, a new FD observer is proposed to compensate the MAC-delay such that the adverse impacts of the delays are attenuated and the fault detection performance is improved.

The rest of this paper is organized as follows: Section II is an introduction to a industrial WSAN. The slotted ALOHA is analyzed and its MAC-delay is estimated in Section III, followed by the proposal of a novel FD observer design with MAC-delay compensation in Section IV. The fault detection performance is then optimised in Section V. Finally, Section VI evaluates the performance of the proposed FD observer on a MATLAB/OMNeT hybrid simulation platform.

## II. System Model and Problem Formulation

As shown in Fig. 1, this paper considers a WSAN consisting of a set of distributed sensors and controllers organized in a group of control loops, an access point (AP) linking together the wireless network and the wired Ethernet and a Fault Detection (FD) system. All controllers and sensors are connected through the wireless network with a star topology, and the wireless network takes two non-overlapped radio channels, namely uplink and downlink channels, in 2.4G ISM band.

Fig. 1. A wireless sensor actuator network for supervisory control

Consider a plant working at some operation point

$$\begin{cases} \dot{x}(t) = Ax(t) + Bu(t) + B_f f(t) + B_d d(t) \\ y(t) = Cx(t) + v(t) \end{cases} \tag{1}$$

where $x(t) \in \mathbb{R}^n$ is the state variable of the plant, $u(t) \in \mathbb{R}^m$ the input, $y(t) \in \mathbb{R}^p$ the output. $v(t)$ and $d(t)$ are unknown inputs with appropriate dimensions. $f(t) \in \mathbb{R}^q$ is the fault to be detected. $A, B, C, B_f$ and $B_d$ are known constant matrices with appropriate dimensions, and $C$ is of full row rank.

The output $y_k$ measured by the sensor at sampling interval $T_s$ is sent to the AP through the uplink channel by using the slotted ALOHA media access protocol [12]. Once receiving a packet of $y_k$, the AP forwards it to the corresponding controller (via downlink channel) and to the remote FD system (via Ethernet). And the controllers reply with its control signal $u_k$ to the AP. When a packet of $u_k$ arrives from a controller through the downlink channel, the AP forwards it to the FD system only. The sensors $S_i$ are time-driven with local sampling interval $T_s$ and the controllers $Ctr_i$ is event-driven.

*Remark 1* The uplink is shared by all sensors, and a sensor has to compete for the use of the uplink channel. Several sensors may send their packets at the same time, which results in a 'collision'. Thus the transmission fails, re-transmission has to be scheduled and some delay is introduced. As one of the widely used random access scheme, a slotted ALOHA protocol is considered in this paper. In the downlink communication, however, the access to the downlink is fully coordinated by the AP, there is no competition for the use of downlink and the collision is avoided.

It is further assumed that the disturbances and fault components have slow dynamics $f(t) = f_k$, $d(t) = d_k$ and $v(t) = v_k$ for all $t \in [kT_s, (k+1)T_s]$. Similar to the discretization of dynamic system, at the $k$-th sampling instants, an equivalent discrete system of (1) can be represented by [10][14]

$$\begin{cases} x_{k+1} = \bar{A}x_k + B_0(\tau_k)u_k + B_1(\tau_k)u_{k-1} + \bar{B}_f f_k + \bar{B}_d d_k \\ y_k = Cx_k + v_k \end{cases} \tag{2}$$

where $\bar{A}$, $B_0(\tau_k)$, $B_1(\tau_k)$, $\bar{B}_f$ and $\bar{B}_d$ are defined in a similar way as [10].

Let

$$\bar{B} = \int_0^{T_s} e^{At} B dt = B_0(\tau_k) + B_1(\tau_k), \tag{3}$$

and

$$\Delta u_k = u_k - u_{k-1}, \tag{4}$$

system (2) can be rewritten under the following form:

$$\begin{cases} x_{k+1} = \bar{A}x_k + \bar{B}u_k - B_1(\tau_k)\triangle u_k + \bar{B}_f f_k + \bar{B}_d d_k \\ y_k = Cx_k + v_k \end{cases} \tag{5}$$

Note that $B_1(\tau_k) \in \mathbb{R}^{n \times m}$ is a matrix of functions with respect to $\tau_k$. Due to the fact that $\tau_k$ is a stochastic process determined by the communication network behaviors, the input matrix $B_1(\tau_k)$ varies at different time instants and the system under consideration actually behaves as a stochastic system,

## III. MAC Delay Analysis and Estimation

The network-induced delay $\tau_k$ is the delay relating the sensor sending out $y_k$ to the controller receiving it. Due to the nature of media sharing in wireless communication, if two or more devices sends their packet to the radio media during the transmission, a collision occurs, the receiver cannot receive the packet successfully, and the packets have to be re-transmitted. Thus a significant delay is induced. Such a delay is refereed to as 'MAC delay' or 'access delay'. In this section, it is our main interests to study the characteristics of MAC delay, and to estimate its mean value.

Let $\tau_1$ denote the MAC-delay in the uplink, $\tau_1$ is a stochastic variable and can be decomposed into two parts:

$$\tau_1 = E(\tau_1) + \Delta\tau_1 \tag{6}$$

where $E(\tau_1)$ is the mean value of the MAC-delay, and $\Delta\tau_1$ represents the jitter (the variation in the time between packets arriving at the AP). Generally, $\Delta\tau_1$ is a stochastic process with zero mean and variance $var(\Delta\tau_1) = \sigma^2$. Considering the reality of canceling re-transmissions in case of a too many re-transmissions, $\Delta\tau_1$ will be bounded.

Since the access to the downlink is fully coordinated by the AP, the delay from the AP to controllers consists of the transmission delay and data processing delay only. Let $\tau_2$ denote the downlink delay from the AP to controllers, $\tau_2$ is a deterministic constant value.

$$\tau_2 \approx T \tag{7}$$

where $T$ is the transmission time of a packet. Here, we have implicitly assumed that the the sum of processing time at the AP and corresponding controller is smaller and can be ignored. When this is not true, only a fixed constant term needs to be added to the final delay expression.

Let $\tau_k$ denote the network-induced delay relating the sensor to the actuator during sampling period $[kT_s, (k+1)T_s)$, $\tau_k$ can be expressed as

$$\tau_k \approx \tau_1 + T = T + E(\tau_1) + \Delta\tau_1 \tag{8}$$

and the mean value of the network-induced delay is

$$\bar{\tau} = E(\tau_k) \approx T + E(\tau_1) \tag{9}$$

In the followings, the focus is on the analysis of the slotted ALOHA scheme and the estimation of the mean value of access delay $\tau_1$ in the uplink channel. Borrowing the models and notations of the slotted ALOHA scheme in [12], the slotted ALOHA MAC protocol is summarized as follows:

1) When a sensor generates a new packet $y_k$, it accesses the uplink channel at the beginning of the next slot. This is called immediate-first transmission (IFT). Let $D_0$ be the access delay from the sampling time to the end of the initial transmission.
2) All packets are of the same size with transmission time $T$ and the length of a time slot is equal to $T$.
3) For a given sampling interval $T_s$, the total number of available slots for packet re-transmission $n$ is determined by:
$$n = \lfloor \frac{T_s}{T} \rfloor - 3 \tag{10}$$
4) A retransmission is scheduled after a random *backoff delay*, when a packet transmission fails. Let $W_i$ be the $i$-th backoff delay in unit of slots, that is refereed to as *backoff window size*. Then, the $i$-th retransmission takes place at the beginning of the $W_i$-th available slot. Note that $W_i \geqslant 1$. In this paper, a *uniform backoff* (UB) policy is adopted. That is all $W_i$'s are uniformly distributed in the same range , say $[1, w]$. The statistics of $W_i$ under UB policy are
$$\begin{aligned} P\{W_i = j\} &= \frac{1}{w}, \quad j = 1, 2, \ldots, w && (11)\\ E[W_i] &= \frac{1+w}{2} && (12)\\ \text{var}[W_i] &= \frac{[w^2-1]}{12} && (13) \end{aligned}$$
5) Let $R$ denote the number of retransmission needed for a successful packet transmission, and $D_i$ be the delay time due to the $i$-th unsuccessful transmission.

Thus, the access delay $\tau_1$ in the uplink is the time duration from its generation to the moment it is successfully transmitted to the AP, that is

$$\tau_1 = \sum_{i=0}^{R} D_i \tag{14}$$

and

$$D_i = (W_i + 1)T, \qquad i = 1, 2, ... \tag{15}$$

As required by the control criteria, the total network-induced delay should be less than $T_s$, that is $\tau_1 + \tau_2 < T_s$. Since the delay $\tau_2$ in the downlink is always $T$, the access delay $\tau_1$ should less than $T_s - T$. This requirement implies that the up bound of the access delay in the slotted ALOHA is $D_0 + nT$, where $n$ is given by (10). Hence, the value of $\tau_1$ can only be selected from the following set

$$\{D_0,\ D_0 + 2T,\ D_0 + 3T, \ldots, D_0 + nT\} \tag{16}$$

It is worth noting that $\tau_1$ can not be $D_0 + T$, because at least two slots are required for retransmission. According to the delay distributions of Slotted ALOHA [12] with some modification, the mean value of the access delay $\tau_1$ with the upper bound $D_0 + nT$ can be estimated as

$$\mathrm{E}(\tau_1) = D_0 + \frac{-1 + \sum_{i=1}^{n} \mathrm{P}\{\tau_1 \geqslant D_0 + iT\}}{\mathrm{P}\{\tau_1 \leqslant D_0 + nT\}} + 1 \tag{17}$$

where $\mathrm{P}\{\bullet\}$ represents the possibility of an event. For instance, $\mathrm{P}\{\tau_1 \leqslant D_0 + nT\}$ denote the possibility of $\tau_1 \leqslant D_0 + nT$ [12].

Hence, by selecting a proper initial backoff window size $w$, the distribution of the re-transmission $R$ can be calculated and the mean value of the access delay $E(\tau_1)$ in the uplink channel can be computed as (17). Thus the mean value of the total network-induced delay can be estimated as

$$\hat{\bar{\tau}} = T + E(\tau_1) \tag{18}$$

## IV. Fault Detection Observer design

Recalling the model of delay (4), one can rewrite (2c) as

$$\begin{aligned} B_1(\tau_k) &= \int_{T_s - \bar{\tau} - \Delta\tau_k}^{T_s} e^{At} B dt \\ &= A^{-1}[I - e^{-A(\bar{\tau} + \Delta\tau_k)}] e^{AT} \cdot B && (19) \end{aligned}$$

Applying the Taylor approximation of $e^{At} = [I + At] + g(t)$ to (19) gives

$$\begin{aligned} B_1(\tau_k) &= A^{-1}\big[I - [I - A(\bar{\tau} + \Delta\tau_k) + g(\bar{\tau} + \Delta\tau_k)]\big] \bar{A} \cdot B \\ &= \bar{A}(\bar{\tau} + \Delta\tau_k) - g(\tau_k)] \cdot B \\ &= \bar{A} \cdot \bar{\tau} \cdot B + \bar{A} \cdot \Delta\tau_k \cdot B - \bar{A} g(\tau_k) \cdot B \\ &= \bar{A}B \cdot \bar{\tau} + \bar{A}B \cdot \Delta\tau_k - \bar{A} g(\tau_k) B && (20) \end{aligned}$$

Substitute (20) into the state equation of (5), the system model can be written as

$$\begin{cases} x_{k+1} = \bar{A}x_k + [\bar{B} \quad -\bar{A}B\bar{\tau}] \begin{pmatrix} u_k \\ \Delta u_k \end{pmatrix} \\ \qquad\qquad +[-\bar{A}B\Delta u_k \quad \bar{B}_d\ ] \begin{pmatrix} \Delta\tau_k \\ d_k \end{pmatrix} + \bar{B}_f f_k + \bar{g}(\tau_k) \\ y_k = Cx_k + D_2 v_k \end{cases}$$

where $\bar{g}(\tau_k) = -\bar{A}g(\tau_k)B\Delta u_k$ denotes modeling errors due to the approximation. Define

$$\begin{array}{ll} \Gamma(\bar{\tau}) = [\bar{B} \quad -\bar{A}B\bar{\tau}], & \bar{u}_k = \begin{pmatrix} u_k \\ \Delta u_k \end{pmatrix} \\ \Gamma_d = [-\bar{A}B\Delta u_k \quad \bar{B}_d], & \bar{d}_k = \begin{pmatrix} \Delta\tau_k \\ d_k \end{pmatrix} \end{array}, \tag{21}$$

the system model now is expressed in the following form:

$$\begin{cases} x_{k+1} = \bar{A}x_k + \Gamma(\bar{\tau})\bar{u}_k + \Gamma_d\ \bar{d}_k + \bar{B}_f f_k + \bar{g}(\tau_k) \\ y_k = Cx_k + v_k \end{cases} \tag{22}$$

A networked fault detection observer in the following discrete Luenberger observer form is used:

$$\begin{cases} \hat{x}_{k+1} = \bar{A}x_k + \Gamma(\hat{\bar{\tau}})\bar{u}_k + L(y_k - \hat{y_k}) \\ \hat{y}_k = C\hat{x}_k \\ r_k = W(y_k - \hat{y}_k) \end{cases} \tag{23}$$

where $r_k \in \mathbb{R}^l$ is the so-called residual for indicating the fault occurrence, $L \in \mathbb{R}^{n\times p}$ and $W \in \mathbb{R}^{l\times p}$ are the observer gain matrix and weighting matrix to be designed, respectively.

Let the observer error be $e_k = x_k - \hat{x_k}$ and $\hat{\bar{\tau}}$ the estimation of $\bar{\tau}$, the the overall dynamics of residual generator (23) is governed by

$$\begin{cases} e_{k+1} = (\bar{A} - LC)e_k + (\Gamma(\bar{\tau}) - \Gamma(\hat{\bar{\tau}}))\bar{u}_k \\ \qquad\qquad +\Gamma_d\bar{d}_k + \bar{B}_f f_k - Lv_k + \bar{g}(\tau_k) \\ r_k = WCe_k + Wv_k \end{cases} \tag{24}$$

In equation (24), it appears that the residual dynamics depends on the amplitude of the terms $\Gamma(\bar{\tau})$, $\Gamma(\hat{\bar{\tau}})$ and $\Delta\tau_k$ which are functions of network-induced delay $\tau_k$.

Recalling $\Gamma(\bar{\tau}) = [\bar{B} \quad -\bar{A}B\bar{\tau}]$ in (21), one can get

$$\begin{array}{rl} & [(\Gamma(\bar{\tau}) - \Gamma(\hat{\bar{\tau}}))]\bar{u}_k \\ = & [[\bar{B} \quad -\bar{A}B\bar{\tau}] - [\bar{B} \quad -\bar{A}B\hat{\bar{\tau}}]] \begin{bmatrix} u_k \\ \Delta u_k \end{bmatrix} \\ = & \begin{bmatrix} 0 & \bar{A}B(\hat{\bar{\tau}} - \bar{\tau}) \end{bmatrix} \Delta u_k \\ = & \bar{A}B(\hat{\bar{\tau}} - \bar{\tau}) \cdot \Delta u_k \end{array} \tag{25}$$

Then $(\Gamma(\bar{\tau}) - \Gamma(\hat{\bar{\tau}}))\bar{u}_k + \Gamma_d\bar{d}_k$ in (24) can be re-formed as

$$[\bar{A}B\Delta u_k \quad \bar{A}B\Delta u_k \quad \bar{B}_d] \begin{bmatrix} (\hat{\bar{\tau}} - \bar{\tau}) \\ \Delta\tau_k \\ d_k \end{bmatrix}, \tag{26}$$

and the state estimation error (24) now is

$$\begin{cases} e_{k+1} = (\bar{A} - LC)e_k + [\bar{A}B \quad \bar{A}B \quad \bar{B}_d] \begin{bmatrix} (\hat{\bar{\tau}} - \bar{\tau})\Delta u_k \\ \Delta\tau_k\Delta u_k \\ d_k \end{bmatrix} \\ \qquad\qquad +\bar{B}_f f_k - Lv_k + \bar{g}(\tau_k) \\ r_k = WCe_k + Wv_k \end{cases} \tag{27}$$

It shows that the network-induced delay introduces an extra unknown input $\begin{bmatrix} (\hat{\bar{\tau}} - \bar{\tau})\Delta u_k \\ \Delta\tau_k\Delta u_k \end{bmatrix}$ into the dynamics of the residual generator, and the residual may deviate from zero even if no fault has happened. If this unknown input is not carefully taken into account in the fault detection observer design, residual $r_k$ could not reflect the fault's occurring properly. This phenomenon causes either false alarms or failure to detect faults.

Different from the decoupling unknown inputs in some fault detection observer designs, in this paper, the FD observer design problem is turned into an eigenvalue assignment and performance optimization problem. The objectives are to select an gain matrix $L \in \mathbb{R}^{n\times p}$, such that the following three criteria are met:

- Stability: The poles of $\bar{A} - LC$ in (27) is within the unit circle in the $z$-plane;
- Sensitivity to faults: The residual $r_k$ should be sensitive to faults $f_k$, that is the transfer function matrix (TFM) relating $f_k$ to $r_k$ should be maximized;
- Robustness to disturbances and delays: The residual $r_k$ should be insensitive to disturbances $d_k$ and network-induced delays $\tau_k$. That is the TFM relating $d_k$ and $\tau_k$ to $r_k$ should be minimized.

## V. Fault Detection Performance Optimisation

In the following, the impacts of the delays on the residual $r_k$ is analyzed in terms of TFMs and an the gain matrix $L$ in (27) is optimised to ensure the residual's sensitivity to the faults and enhance the robustness against the delays.

The $z$-transform of (27) gives the following transfer function matrices (TFMs)

$$\begin{cases} G_1(z) = G_2(z) = C(zI - \bar{A} + LC)^{-1}\bar{A}B \\ G_f(z) = C(zI - \bar{A} + LC)^{-1}B_f \end{cases} \tag{28}$$

where $G_1(G_2)$ and $G_f$ are TFM relating $r_k$ to $(\hat{\bar{\tau}} - \bar{\tau})\Delta u_k$, $(\Delta\tau_k\Delta u_k)$ and $f_k$ , respectively.

### A. Optimization in the frequency domain

As shown in the FD problem definition, there are two objective functions, namely sensitivity index and robustness index. Considering the access delays of the ALOHA in section III, we propose the following two performance indices.

*1) Robustness Index:* Observe that the TFMs $G_1(G_2)$ relating $r_k$ to $\Delta\tau_k\Delta u_k$ ($[\hat{\bar{\tau}} - \bar{\tau}]\Delta u_k$) are the same, but the signals $\Delta\tau_k$ and $(\hat{\bar{\tau}} - \bar{\tau})$ have different characteristics in the frequency domain. By optimizing the fault detection performance at the frequency of interest, instead of the whole frequency range, our observer is tailored for attenuating the network-induced delay.

$$\min_L J_1 = \sum_{z\in\Omega} \|\beta(z)G_1(z)\| \tag{29}$$

where $\Omega$ is the frequency range of interest, and $\beta(z)$ is a weighting function for $G_1(z)$ over the frequency range $\Omega$. $\Omega$ and $\beta(z)$ depend on the frequency characteristics of the MAC-delay $\tau$ and the the difference between successive input samples $\Delta u$. Generally, since it is the residual we are interested in, $\Omega$ and $\beta(z)$ are determined by finding the significant frequency components of $r_k$.

*2) Sensitivity Index:* Not like a random noise, a fault signal is usually associate with some pattern, and, its energy distribution is not uniformly distributed over the whole frequency range of interest. In general, two common faults are considered, namely, the incipient fault (a ramp signal) and the abrupt fault (a step signal). A ramp fault mainly consists of low-frequency components. For an abrupt fault, high-frequency contents exist only at the time instant when the fault starts, and it is almost constant (zero frequency) content thereafter. In order to increase the fault significance in residual $r$, it is proposed that the sensitivity index is maximized at $z = 1$ (corresponding to zero frequency in the continuous frequency domain).

$$\max_L J_2 = \|G_f(z)\|_{z=1} \tag{30}$$

Combining robustness index (29) and sensitivity index (30) yields the performance index

$$\min_{Q,\Lambda} J = \frac{J_1}{J_2} = \frac{\sum_{z\in\Omega}\|\beta(z)G_1(z)\|}{\rho + \|G_f(z)\|_{z=1}} \tag{31}$$

where $\rho$ is an arbitrary small positive number to ensure a non-zero denominator. Since the frequency information has now incorporated into the new index (31), the resulting FD observer is optimal for attenuating the negative impacts caused by the MAC-delay. In most applications, such a FD observer has a better performance in terms of attenuating the MAC-delay induced disturbance.

## VI. Simulation Platform and Results Analysis

In order to demonstrate the the proposed delay compensation approach, the hybrid simulation platform and fault detection results are presented in this section. The control system and the FD system are programmed in MATLAB/SIMULINK, and the wireless network is emulated by using OMNeT++. Compared with MATLAB/SIMULINK, the open source OMNeT++ platform is able to mimic the detailed behaviour of a wireless network, and imitate the features, such as SNIR(Singal-Noise-Interference-Ratio), SNR(Singal-Noise-Ratio), MAC-delay and packet loss due to either low SNR or collision.

In the simulation, the system matrices of the plant are as follows:

$$A = \begin{bmatrix} 30.7643 & 36.0164 \\ -30.8287 & -35.9486 \end{bmatrix}, \quad B = \begin{bmatrix} 2.2991 \\ -0.0668 \end{bmatrix},$$

$C = [1 \quad 0]$ and $B_d = B_f = B$. The sampling interval $T_s = 0.03\ sec$. The control input and plant output are subject to input disturbances $d_k$ and output measurement noises $v_k$, respectively, where $d_k$ and $v_k$ are independent bounded noises uniformly distributed between $[-0.2, 0.2]$ and $[-2, 2]$. Two kind of faults are concerned in the simulation, namely, step fault and slope fault. The step fault associated with the actuator occurs at time $t_1 = 10s$ with magnitude 0.2, and the slope fault starts at 10 s with slope rate 0.05.

As shown in Figure 1, we consider a networked control system composed with five local control loops in total and one AP. The total number of clock-driven sensors is ten and there are five event-driven controllers. A FD observer is to be designed for one of the control loops. All the communication devices works at 2Mbps on 2.4GHz ISM band. Data, either from sensors or from controllers, is transmitted with a single packet whose length is 1712 bits including physical premier(192 bits), protocol header length (272bits for MAC, 32bits for Network layer), which gives an air frame with a transmission duration of $856us$.

The simulation results of packet delay given by OMNeT++ are shown in Figure 2. The mean value of the packet delay from sensor to controller is $\bar{\tau} = 0.0136$s. With the aid of the MAC-delay estimate, a MAC-delay compensated FD observer can be constructed as (23) and the optimisation of index (31) yields the optimal gain matrix

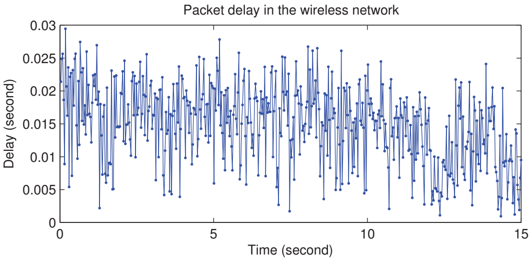

Fig. 2. Packet delay $\tau_k$ from sensor to controller

$$L = \begin{bmatrix} 0.1123 \\ -0.1027 \end{bmatrix} \tag{32}$$

The residuals of the proposed FD observer are given by Figure 3 (for step fault) and Figure 4 (for slope fault), respectively. From Figure 3-4, one can seen that the proposed delay compensation techniques is able to detect these faults clearly.

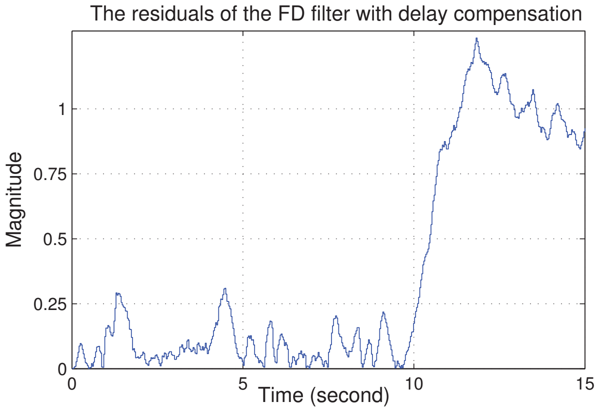

Fig. 3. Residuals $r_k$ subject to step fault occurring at 10 second with step size 0.2

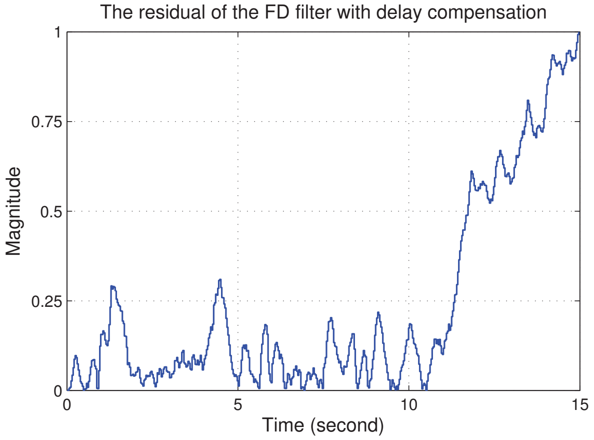

Fig. 4. Residuals $r_k$ subject to slope fault occurring at 10 second with rate of 0.05

## VII. Conclusions

This paper addresses the fault detection problem of WSANs-based wireless networked control systems, where the MAC-access delay of the slotted ALOHA is considered. With the aid of the MAC-access delay estimation, a FD observer with MAC-delay compensation is proposed. These advantages of the proposed FD observer with MAC delay compensation have been demonstrated through extensive computer simulations. As to future work, it is certainly possible to extend our cross-discipline analytical approach by considering more sophisticated MAC schemes (such as Carrier Sense Multiple Access(CSMA) and 802.11 Distributed Coordination Function), random backoff policies (such as geometric backoff and binary exponential backoff) and physical channel models.

*Abstract*—**This article is concerned with stability analysis of a linear discrete-time dynamic quantizer system with packet loss. First, several modifications are made to the original dynamic quantizer to make it easier to realize. Then communication channel subject to packet loss of Bernoulli distribution from the quantizer to the plant input is considered. Moreover, based on Lyapunov function approach, a sufficient condition for mean square stability of the closed-loop system is derived. Finally, a numerical simulation is given for effectiveness of the proposed method.**

***Keywords-Discrete-time; Dynamic quantizer; Mean square stability; Linear discrete system; Pactket loss;***

## I. Introduction

In the past few years, quantized control has been of great significance in the research field of control systems. In practical discrete-time systems, owing to limited network bandwidth, extensive use of encoders and decoders, command-driven actuators and discrete-level sensors, it becomes necessary for the signals to be quantized before transmission.

Numerous results on this subject have been obtained in recent years. Early studies of quantized control systems mainly focus on construction of static quantizers which can guarantee the stability of the system. For example, global asymptotic stabilization of continuous-time systems is considered in [1], [9], where a special uniform quantizer with scaling factor is used for quantization. Stabilization of the given system with the coarsest quantization density is analyzed in [2], [3], [7] using the sector bound approach. Furthermore, stabilization problem for systems with one-dimensional input using quantized feedback with a memory structure is analyzed in [4]-[6], focusing on the tradeoff between static quantizer complexity and system performance. And the least amount of information needs to be communicated between the quantizer and the controller in order to stabilize an unstable linear system is addressed in [8], [10]-[13]. Moreover, the coarsest quantization density to stabilize the system with networked packet losses is considered in [17]-[18], and input-to-state stability of systems with time-varying delays is analyzed in [19] in terms of LMIs.

For early works of quantized control systems, the parameters of quantizers stay invariant as the system evolves, which will generate large quantized error. This means that part of the system performance has to be sacrificed to cope with such a quantized error. For this reason, in [14], [15], a novel optimal dynamic quantizer was given whose parameters can vary as the system evolves, which is able to handle such problem. The optimal dynamic quantizer in [14], [15] is constructed to minimize the quantized error according to the output of the plant, which can sacrifice fewer system's performance. In further study of this work in [16], the stability problem was considered under a dynamic quantized LFT system in terms of the poles/zeros. However, these works cannot deal with networked problems such as packet losses and time-delays effectively.

In this paper, stability of optimal dynamic quantized system is analyzed based on Lyapunov function approach. Besides, networked packet loss of the closed-loop system is also taken into consideration, which cannot be effectively solved in the LFT form. Moreover, some modifications are made to the original dynamic quantizer. The static part of the dynamic quantizer is replaced by the static quantizer with scaling factor and saturation value, which makes it easier to be realized and can guarantee smaller quantized error when the state comes close to the equilibrium point.

The whole paper is organized as follows. In section 2, we review the original dynamic quantized system and introduce the improved dynamic quantizers used in this paper. Next in section 3, main result on stability analysis is derived. A numerical simulation is given in section 4 and section 5 concludes this article.

## II. Problem Formulation and Preliminaries

### A. Original Dynamic Quantized System

Consider the discrete-time systems shown in Fig.1, where the linear plant $P$ is given by

$$P:\begin{cases} x(k+1)=Ax(k)+Bv(k) \\ y(k)=Cx(k) \end{cases} \tag{1}$$

where $x\in R^n$ is the state, $v\in R^m$ is the control input, $y\in R^p$ is the output, $A\in R^{n\times n}$, $B\in R^{n\times m}$, and $C\in R^{p\times n}$ are system matrices. The initial state of the plant $P$ is

This work was supported by the National Natural Science Foundation of China (Grant No. 61104097, No. 61120106010), Research Fund for the Doctoral Program of Higher Education of China (Grant No. 20111101120027).

$x(0)=x_0$ for $x_0 \in R^n$ , the pair $(A,B)$ is stabilizable and $A$ is unstable. Assume the following assumption holds:

**Assumption 1.** The plant $P$ satisfies that the dimensions of $v$ and $y$ are the same $(m=p)$ and the matrix $CB$ is nonsingular.

The original optimal dynamic quantizer $Q$ in Fig.1 ( $\Sigma^{**}$ ) is given by [14]

$$Q:\begin{cases}\xi(k+1)=A\xi(k)-Bu(k)+Bv(k)\\ v(k)=q(-(CB)^{-1}CA\xi(k)+u(k))\end{cases} \tag{2}$$

where $\xi \in R^n$ , $u \in R^m$ , and $v \in R^m$ are the state, input, and output of this quantizer respectively, $A,B$ and $C$ of the quantizer are the same as the plant $P$ , $q: R^m \to R^m$ is a static uniform quantizer.

The static uniform quantizer $q$ in (2) satisfies that

$$q(x)=\left\lfloor \frac{x}{\Delta}+\frac{1}{2}\right\rfloor \Delta \tag{3}$$

that is

$$abs(q(x)-x)=abs(x-q(x))\le \frac{\Delta}{2} \tag{4}$$

where $\tilde{a}=\lfloor a \rfloor$ denotes the biggest integer satisfying $\tilde{a}\le a$ , and $\Delta$ is the quantized interval of the quantizer.

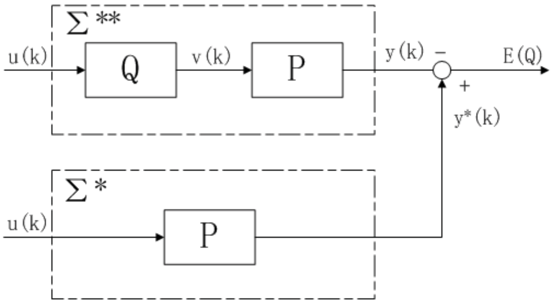

Figure 1. Two controlled plants: ( $\Sigma^{*}$ ) usual controlled plant; ( $\Sigma^{**}$ ) controlled plant with dynamic quantizer

**Remark 1.** The dynamic quantizer $Q$ in Fig.1 ( $\Sigma^{**}$ ) has been proved to be an optimal quantizer according to the output of the plant in [14]. Which indicates the parameters of the dynamic quantizer $Q$ are chosen such that the output error $E(Q)=\sup_{k\in Z_+}\left\| y(k)-y^{*}(k)\right\|$ between the system $\Sigma^{**}$ and $\Sigma^{*}$ is minimized. For the static quantizer $q$ , the quantized error is $\frac{\Delta}{2}$ as (4) indicates. It is clear that such open-loop dynamic quantized system cannot always guarantee stability of the whole system for the quantizer itself may not be stable.

*B. Closed-loop System*

In this paper, consider that packet losses occur with probability $\alpha$ in the input channel of the plant as is shown in Fig.2. The plant is described as

$$P:\begin{cases}x(k+1)=Ax(k)+B\theta(k)v(k)\\ y(k)=Cx(k)\end{cases} \tag{5}$$

where $\theta(k)$ is a Bernoulli random variable with a probability distribution given by

$$\Pr(\theta(k)=i)=\begin{cases}\alpha, & i=0,\\ 1-\alpha, & i=1,\end{cases} \quad 0\le\alpha<1 \tag{6}$$

Consider the closed-loop system $\Sigma$ in Fig.2 using sate feedback control law $u(k)$ which is given by

$$u(k)=Kx(k) \tag{7}$$

where $K \in R^{m\times n}$ is the feedback gain.

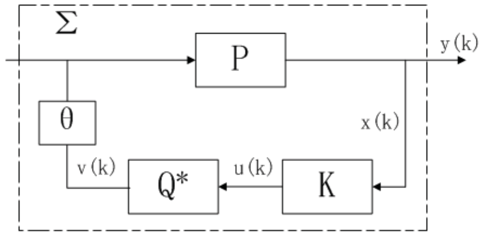

Figure 2. Dynamic quantized system $\Sigma$ with packet loss

In this paper we replace static uniform quantizer $q$ in (2) with $q_\mu$

$$q_\mu(x)=\begin{cases}\mu(k)M, & if \dfrac{x}{\mu(k)}>M-\dfrac{1}{2}\Delta\\ -\mu(k)M, & if \dfrac{x}{\mu(k)}\le -M+\dfrac{1}{2}\Delta\\ \left\lfloor \dfrac{x}{\Delta\mu(k)}+\dfrac{1}{2}\right\rfloor \Delta\mu(k), & if \dfrac{|x|}{\mu(k)}\le M-\dfrac{1}{2}\Delta\end{cases} \tag{8}$$

where $\mu(k)$ is the scaling factor, M is the saturation value and $\Delta$ is the sensitivity.

Obviously, the following conditions can be obtained according to the quantizer:

Ⅰ.If $|x|\le M\mu(k)$ , then $|q_\mu(x)-x|\le\frac{\Delta\mu(k)}{2}$ ;

Ⅱ.If $|x|>M\mu(k)$ , then $|q_\mu(x)|>M\mu(k)-\frac{\Delta\mu(k)}{2}$ .

**Remark 2.** The uniform quantizer $q_\mu$ here is different from quantizer $q$ in that it brings in a scaling factor $\mu(k)$ , and a saturation value $M$ . The former can guarantee $q_\mu$ not saturate by adjusting scaling factor $\mu(k)$ properly, which will be considered in next section. The latter makes the static part of the dynamic quantizer easier to realize. Moreover, it is clear that by bringing in this scaling factor $\mu(k)$ , when the quantizer does not meet with saturation, the quantized error varies according to $\mu(k)$ .

Therefore, an improved dynamic quantizer $Q^*$ in Fig.2 is given by

$$Q^*:\begin{cases}\xi(k+1)=A\xi(k)-Bu(k)+Bv(k)\\ v(k)=q_\mu(-(CB)^{-1}CA\xi(k)+u(k))\end{cases} \tag{9}$$

**Remark 3.** It should be noticed that although the static quantizer $q_\mu$ used here is different from $q$ in [14], the dynamic quantizer $Q^*$ is still the optimal quantizer for the system $\Sigma$ . It has been proved in [14] that for the dynamic quantizer (2) with static quantizer (3), minimum value of output error $E(Q)$ can be given as

$$E(Q)=\|abs(CB)\|\frac{\Delta}{2}$$

where for the matrix $M:=\{M_{ij}\}$ , $abs(M):=\{|M_{ij}|\}$ .

When it comes to $q_\mu$ for our system, the quantized error becomes $\frac{\Delta\mu(k)}{2}$ , obviously, similar conclusion can be expressed as

$$E(Q)=\|abs(CB)\|\frac{\Delta\overline{\mu}}{2}$$

where $\overline{\mu}=\sup_{k\in Z_+}(\mu(k))$ is upper bound of $\mu(k)$ . As a result, the improved dynamic quantizer is still optimal dynamic quantizer for the system.

Therefore, the closed-loop system $\Sigma$ in Fig.2 can be written as

$$\begin{cases}\begin{bmatrix}x(k+1)\\ \xi(k+1)\end{bmatrix}=\begin{bmatrix}A+BK & -\theta B(CB)^{-1}CA\\ 0 & A-B(CB)^{-1}CA\end{bmatrix}\begin{bmatrix}x(k)\\ \xi(k)\end{bmatrix}\\ \qquad\qquad+\begin{bmatrix}\theta B\\ B\end{bmatrix}\left[q_\mu(\phi)-\phi\right]\\ y(k)=[C\quad 0]\begin{bmatrix}x(k)\\ \xi(k)\end{bmatrix}\end{cases} \tag{10}$$

where $\phi=-(CB)^{-1}CA\xi(k)+Kx(k)$ .

Rewrite the closed-loop system $\Sigma$ as

$$\begin{cases}z(k+1)=\overline{A}z(k)+\overline{B}e(\Gamma z(k))\\ y(k)=\overline{C}z(k)\end{cases} \tag{11}$$

where $z(k)=\left[x(k)\quad \xi(k)\right]^T$ , $e(\Gamma z(k))=q_\mu(\phi)-\phi$ denotes the quantized error, and $\Gamma=\left[-(CB)^{-1}CA\quad K\right]$ .

Matrices $\overline{A}\in R^{2n\times 2n}$ , $\overline{B}\in R^{2n\times m}$ , $\overline{C}\in R^{p\times 2n}$ are defined as

$$\overline{A}=\begin{bmatrix}A+\theta BK & -\theta B(CB)^{-1}CA\\ 0 & A-B(CB)^{-1}CA\end{bmatrix},\overline{B}=\begin{bmatrix}\theta B\\ B\end{bmatrix},\overline{C}=[C\quad 0].$$

When $\theta(k)=1$ , we let

$$A_1=\overline{A}=\begin{bmatrix}A+BK & -B(CB)^{-1}CA\\ 0 & A-B(CB)^{-1}CA\end{bmatrix},B_1=\overline{B}=\begin{bmatrix}B\\ B\end{bmatrix}.$$

When $\theta(k)=0$ , we can get

$$A_2=\overline{A}=\begin{bmatrix}A & 0\\ 0 & A-B(CB)^{-1}CA\end{bmatrix},B_2=\overline{B}=\begin{bmatrix}0\\ B\end{bmatrix}.$$

**Definition 1.** System (11) is said to be mean square stable if

$$\lim_{k\to\infty}E\left\{\left|z(k)\right|^2\right\}=0 \tag{12}$$

for any initial state $z(0)\in R^{2n}$ .

**Lemma 1.** The following inequality holds for any positive definite matrix $G$ and matrices $E$ and $F$

$$E^TGF+F^TGE\le E^TGE+F^TGF \tag{13}$$

## III. STABILITY ANALYSIS

The following theorem presents a sufficient condition for the stability of the closed-loop system $\Sigma$ :

**Theorem 1.** For a given feedback gain $K$ and packet loss probability $\alpha$ , if there exists a positive definite symmetric matrix $P$ satisfying that

$$(1-\alpha)A_1^TPA_1+\alpha A_2^TPA_2-\frac{1}{2}P<0 \tag{14}$$

then the system (11) is mean square stable under control law $u(k)=Kx(k)$ .

*Proof*: The closed-loop system (11) can be expressed as

$$\begin{cases}z(k+1)=(1-\alpha)\left(A_1z(k)+B_1e(\Gamma z(k))\right)\\ \qquad\qquad+\alpha\left(A_2z(k)+B_2e(\Gamma z(k))\right)\\ y(k+1)=\overline{C}z(k)\end{cases} \tag{15}$$

Choose a Lyapunov function, $V(z(k))=z^T(k)Pz(k)$ , where $P\in R^{2n\times 2n}$ is a positive definite matrix, $\Delta V(z(k))$ is given by the following expression

$$\Delta V(z(k))=E\{V(z(k+1))\}-V(z(k))$$

by using Lemma 1, we can get

$$\begin{aligned}
&\Delta V(z(k)) \\
&= E\left\{z^T(k+1)Pz(k+1)\right\} - z^T(k)Pz(k) \\
&= (1-\alpha)[z^T(k)(A_1^T PA_1 - P)z(k) + z^T(k)A_1^T PB_1 e(\Gamma z(k)) \\
&\quad + e^T(\Gamma z(k))B_1^T PA_1 z(k) + e^T(\Gamma z(k))B_1^T PB_1 e(\Gamma z(k))] + \\
&\quad + \alpha[z^T(k)(A_2^T PA_2 - P)z(k) + z^T(k)A_2^T PB_2 e(\Gamma z(k)) \\
&\quad + e^T(\Gamma z(k))B_2^T PA_2 z(k) + e^T(\Gamma z(k))B_2^T PB_2 e(\Gamma z(k))] \\
&\le 2z^T(k)[(1-\alpha)A_1^T PA_1 + \alpha A_2^T PA_2 - \frac{1}{2}P]z(k) \\
&\quad + 2e^T(\Gamma z(k))[(1-\alpha)B_1^T PB_1 + \alpha B_2^T PB_2]e(\Gamma z(k)) \\
&\le 2z^T(k)[(1-\alpha)A_1^T PA_1 + \alpha A_2^T PA_2 - \frac{1}{2}P]z(k) \\
&\quad + 2e^T(\Gamma z(k))B^{*T} PB^* e(\Gamma z(k))
\end{aligned} \tag{16}$$

where $B^* = \left\{\overline{B} : \max(B_1^T PB_1, B_2^T PB_2)\right\}$.

Define $D = -\left[(1-\alpha)A_1^T PA_1 + \alpha A_2^T PA_2 - \frac{1}{2}P\right]$, if the matrix $D$ is positive definite, (14) can be obtained directly, and (16) can be rewritten as

$$\begin{aligned}
&\Delta V(z(k)) \\
&\le -2z^T(k)Dz(k) + 2e^T(\Gamma z(k))B^{*T} PB^* e(\Gamma z(k)) \qquad (17) \\
&\le -2\left[\lambda_{\min}(D)|z(k)|^2 - \left\|B^{*T} PB^*\right\| \Delta^2 \mu^2(k)\right]
\end{aligned}$$

The last expression of (17) is negative if the state of $\Sigma$ is outside the ball

$$H = \left\{z(k) : z(k) \le \Theta\Delta\mu(k)\right\} \tag{18}$$

where $\Theta = \sqrt{\dfrac{\left\|B^{*T} PB^*\right\|}{\lambda_{\min}(D)}}$.

Define the scaling factor $\Omega$ as

$$\Omega = \sqrt{\frac{\lambda_{\max}(P)}{\lambda_{\min}(P)}}\sqrt{\Theta^2 + \varepsilon}\,\|\Gamma\|\Delta M^{-1} \tag{19}$$

where $\varepsilon > 0$ is a fixed real number.

We will analyze the control strategy by two stages according to the variation of the scaling factor $\mu(k)$ as [1], [9]:

The "zooming-out" stage of the quantizer.

Set $u(k) = 0$, $\mu(0) = 1$, $\mu(k) = \|A\|^k$ and increase $k$ fast enough, then a positive integer $k$ can be found such that

$$\left|\frac{\Gamma z(k)}{\mu(k)}\right| \le M\sqrt{\frac{\lambda_{\min}(P)}{\lambda_{\max}(P)}} - 2\Delta$$

In the view of condition Ⅰ in the former section

$$\left|q_\mu\left(\frac{\Gamma z(k)}{\mu(k)}\right)\right| \le \left|\frac{\Gamma z(k)}{\mu(k)}\right| + \Delta \le M\sqrt{\frac{\lambda_{\min}(P)}{\lambda_{\max}(P)}} - \Delta$$

Define

$$k_0 = \min\left\{k \ge 1 : \left|q_\mu\left(\frac{\Gamma z(k)}{\mu(k)}\right)\right| \le M\sqrt{\frac{\lambda_{\min}(P)}{\lambda_{\max}(P)}} - \Delta\right\} \tag{20}$$

Hence it follows that

$$\left|\frac{\Gamma z(k_0)}{\mu(k_0)}\right| \le \left|q_\mu\left(\frac{\Gamma z(k_0)}{\mu(k_0)}\right)\right| + \Delta \le M\sqrt{\frac{\lambda_{\min}(P)}{\lambda_{\max}(P)}}$$

Therefore

$$|\Gamma z(k_0)| \le M\mu(k_0)\sqrt{\frac{\lambda_{\min}(P)}{\lambda_{\max}(P)}}$$

Which means

$$|z(k_0)| \le \frac{M}{\|\Gamma\|}\mu(k_0)\sqrt{\frac{\lambda_{\min}(P)}{\lambda_{\max}(P)}}$$

Hence $z(k_0)$ belongs to an ellipsoid

$$R_1 = \left\{z(k) : z^T(k)Pz(k) \le \frac{M^2}{\|\Gamma\|^2}\mu^2(k)\lambda_{\min}(P)\right\} \tag{21}$$

It is obvious that $\Gamma z(k) \le M\mu(k)$ holds with $\mu(k) = \mu(k_0)$ for all $z(k) \in R_1$.

Take $M$ and $\Delta$ in (19) properly to guarantee $\Omega < 1$, it follows that $R_1 \supset H$. Moreover, if $k \ge k_0$, $z(k)$ will never leave $R_1$.

The "zooming-in" stage of the quantizer.

Define

$$\tilde{\tau} = \frac{M^2\lambda_{\min}(P) - \Delta^2\Theta^2\|T\|^2\lambda_{\max}(P)}{\|T\|^2\lambda_{\min}(D)\Delta^2\varepsilon} \tag{22}$$

We can have $\tilde{\tau} > 0$ as $\Omega < 1$. Define $\tau = \lceil\tilde{\tau}\rceil$, where $\lceil\tilde{\tau}\rceil$ denotes the smallest integer satisfy $\tau \ge \tilde{\tau}$, $\tau \in Z_{0+}$.

Assume an inequality can be get according to $\tau \in Z_{0+}$

$$E[z^T(k_0+\tau)Pz(k_0+\tau)] \le \Delta^2\mu^2(k_0)(\Theta^2+\varepsilon)\lambda_{\max}(P) \tag{23}$$

Suppose (23) is not true, then we can have that

$$E[z^T(k_0+\tau)Pz(k_0+\tau)] > \Delta^2\mu^2(k_0)(\Theta^2+\varepsilon)\lambda_{\max}(P) \tag{24}$$

That is

$$E[|z(k_0+\tau)|^2] > \Delta^2\mu^2(k_0)(\Theta^2+\varepsilon) \tag{25}$$

for all $k \in [k_0, k_0+\tau]$.

Based on (18) and $\Omega < 1$, it is clear that

$$\begin{aligned} &\Delta V[z(k_0+\tau-1)] \\ &= E[z^T(k_0+\tau)Pz(k_0+\tau)] - \\ &\quad E[z^T(k_0+\tau-1)Pz(k_0+\tau-1)] \qquad (26) \\ &\le -\lambda_{\min}(D)E[|z(k_0+\tau-1)|^2] + \lambda_{\min}(D)\Theta^2\Delta^2\mu^2(k_0) \\ &< -\lambda_{\min}(D)\Delta^2\mu^2(k_0)\varepsilon \end{aligned}$$

Furthermore, it can be obtained that

$$\begin{aligned} &\Delta V[z(k_0+\tau-i)] \\ &= E[z^T(k_0+\tau-i+1)Pz(k_0+\tau-i+1)] - \\ &\quad E[z^T(k_0+\tau-i)Pz(k_0+\tau-i)] \qquad (27) \\ &\le -\lambda_{\min}(D)E[|z(k_0+\tau-i)|^2] + \lambda_{\min}(D)\Theta^2\Delta^2\mu^2(k_0) \\ &< -\lambda_{\min}(D)\Delta^2\mu^2(k_0)\varepsilon \end{aligned}$$

where $i \in \{1,2,3,\cdots,\tau\}$.

Then we have

$$\begin{aligned} &E[z^T(k_0+\tau)Pz(k_0+\tau)] - z^T(k_0)Pz(k_0) \\ &< -\lambda_{\min}(D)\Delta^2\mu^2(k_0)\varepsilon\,\tau \\ &\le -\lambda_{\min}(D)\Delta^2\mu^2(k_0)\varepsilon\,\tilde{\tau} \qquad (28) \\ &= \lambda_{\max}(P)\Delta^2\Theta^2\mu^2(k_0) - \frac{M^2}{\|\Gamma\|^2}\lambda_{\min}(P)\mu^2(k_0) \end{aligned}$$

However, the following inequality can be obtained from (21) and (24)

$$\begin{aligned} &E[z^T(k_0+\tau)Pz(k_0+\tau)] - z^T(k_0)Pz(k_0) \\ &\ge \Delta^2\mu^2(k_0)(\Theta^2+\varepsilon)\lambda_{\max}(P) - \mu^2(k_0)\frac{M^2}{\|\Gamma\|^2}\lambda_{\min}(P) \qquad (29) \\ &\ge \lambda_{\max}(P)\Delta^2\Theta^2\mu^2(k_0) - \frac{M^2}{\|\Gamma\|^2}\lambda_{\min}(P)\mu^2(k_0) \end{aligned}$$

Obviously (28) and (29) contradict with each other, which implies the validity of (23).

Based on (23) and $\Omega < 1$, it follows that

$$\begin{aligned} E[z^T(k_0+\tau)Pz(k_0+\tau)] &\le \Delta^2\mu^2(k_0)(\Theta^2+\varepsilon)\lambda_{\max}(P) \\ &< (\Omega\mu(k_0))^2\frac{M^2}{\|\Gamma\|^2}\lambda_{\min}(P) \qquad (30) \end{aligned}$$

Thus it is clear that $z(k_0+\tau)$ belongs to

$$R_2 = \left\{ z(k) : E[z^T(k)Pz(k)] \le (\Omega\mu(k))^2\frac{M^2}{\|\Gamma\|^2}\lambda_{\min}(P) \right\} \qquad (31)$$

Let $\mu(k) = \Omega\mu(k_0)$ for $k_0+\tau \le k \le k_0+2\tau$, a similar result can be obtained

$$E[z^T(k_0+2\tau)Pz(k_0+2\tau)] < (\Omega^2\mu(k_0))^2\frac{M^2}{\|\Gamma\|^2}\lambda_{\min}(P) \qquad (32)$$

Let $\mu(k) = \Omega^{i-1}\mu(k_0)$ for $k_0+(i-1)\tau \le k \le k_0+i\tau$, it can be given as

$$E[z^T(k_0+i\tau)Pz(k_0+i\tau)] < (\Omega^i\mu(k_0))^2\frac{M^2}{\|\Gamma\|^2}\lambda_{\min}(P) \qquad (33)$$

By repeating this procedure, we can obviously obtain that $\mu(k) \to 0$ as $k \to \infty$, and $\lim_{k\to\infty} E[|z(k)|^2] \to 0$, which means the closed-loop system $\Sigma$ is mean square stable.

## IV. A NUMERICAL EXAMPLE

In this section, a numerical example is given to show the effectiveness of the proposed method. Consider the following system

$$P: \begin{cases} x(k+1) = \begin{bmatrix} 1.1 & \\ & 0.5 \end{bmatrix} x(k) + \begin{bmatrix} 1 \\ 2 \end{bmatrix} \theta(k)v(k) \\ y(k) = \begin{bmatrix} 1 & 0.2 \end{bmatrix} x(k) \end{cases}$$

where $\theta(k)$ is a Bernoulli random variable with probability distribution given by

$$\Pr(\theta(k) = i) = \begin{cases} 0.2, & i = 0 \\ 0.8, & i = 1 \end{cases}$$

which means the packet-loss rate is 0.2.

Obviously, the plant $P$ is unstable as one of its eigenvalues is 1.1. And it is stabilizable as $rank[B\ AB] = 2$. Set the feedback gain $K = [-1.53\ 0.13]$. The dynamic quantizer is given as

$$Q: \begin{cases} \xi(k+1) = \begin{bmatrix} 1.1 & \\ & 0.5 \end{bmatrix} \xi(k) - \begin{bmatrix} -1.53 & 0.13 \\ -3.06 & 0.26 \end{bmatrix} x(k) \\ \qquad + \begin{bmatrix} 1 \\ 2 \end{bmatrix} v(k) \\ v(k) = q_\mu(\begin{bmatrix} -0.7857 & 0.0714 \end{bmatrix} \xi(k) \\ \qquad + \begin{bmatrix} -1.53 & 0.13 \end{bmatrix} x(k)) \end{cases}$$

whose parameters are determined by the plant $P$ and the feedback gain $K$.

The closed-loop system $\Sigma$ can be expressed as

$$\begin{cases} z(k+1) = \begin{bmatrix} -0.43 & 0.13 & -0.7857\theta & -0.0714\theta \\ -3.06 & 0.76 & -1.5714\theta & -0.1429\theta \\ & & 0.3143 & -0.0714 \\ & & -1.5714 & 0.3571 \end{bmatrix} z(k) \\ \qquad + \begin{bmatrix} \theta & 2\theta & 1 & 2 \end{bmatrix}^T e(\Gamma z(k)) \\ y(k+1) = \begin{bmatrix} 1 & 0.2 & 0 & 0 \end{bmatrix} z(k) \end{cases}$$

We can find there is a positive definite matrix

$$P=\begin{bmatrix} 7.7602 & -1.2269 & 2.1796 & -0.4196 \\ -1.2269 & 0.3699 & -0.5016 & 0.1113 \\ 2.1796 & -0.5016 & 9.8224 & 0.1117 \\ -0.4196 & 0.1113 & 0.1117 & 0.5190 \end{bmatrix}$$

satisfying (14), then the system is mean square stable under control law (7).

The static quantizer is given by

$$q_\mu(x)=\begin{cases} 4\mu(k), & if\, x>3.95\mu(k) \\ -4\mu(k), & if\, x\le -3.95\mu(k) \\ \left\lfloor \dfrac{x}{\mu(k)}+0.05 \right\rfloor \mu(k), & if\, |x|\le 3.95\mu(k) \end{cases}$$

with $M=4$ and $\Delta=0.1$.

Set $\varepsilon=0.1$, we can get $\Omega=0.7497<1$. Let the initial state of the system be $z(0)=[5\ \ 7\ \ 8\ \ 6]^T$. Then the trajectories of state $z(k)$ are shown in Fig.3, where $z(i)$ denotes the $i$ -th component of $z(k)$. It is clear that system (11) is mean square stable as $z(k)\to 0$ when $k\to\infty$.

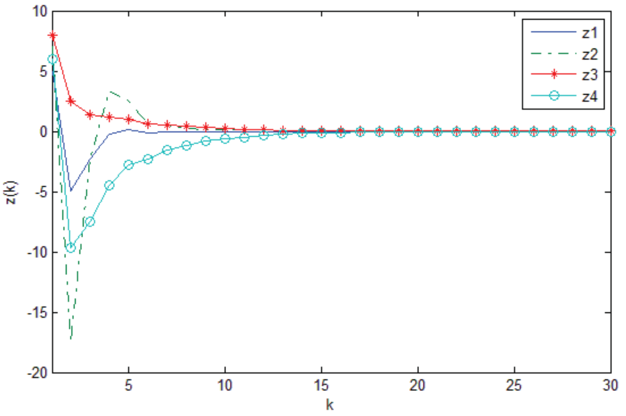

Figure 3. Trajectories of state $z(k)$

## V. Conclusion

This paper has discussed the stability of the optimal dynamic quantizer system with packet loss subject to Bernoulli distribution. In order to make the quantizer more practical and have better performance, traditional optimal dynamic quantizer has been improved here by replacing its static part with another one which contains saturation value and scaling factor. The communication channel has been considered subject to packet loss from the quantizer to the plant input. Based on Lyapunov function approach, a sufficient condition for mean square stability of the closed-loop system has been given.

# Design and simulation of fuzzy controller based (IPM) converter fed DC Motors

Abdallah A. Ahmed, Yuanqing Xia and Bo Liu

*Abstract*—**This paper proposes a DSPF2812 based 32-bit micro-controller is used to to generate PWM waveform required to switch IPM_DRIVE, by using fuzzy logic controller to control dc motor fed by AC/DC (IPM) converter. The fuzzy controller is designed in such a way that it can be implemented in a micro-controller or DSP processor based embedded system. The system designed consists of an inner ON/OFF current controller and an outer fuzzy speed controller. The fuzzy speed controller is used to change the duty cycle of the(IPM) converter and thereby, the voltage fed to the DC motor regulates its speed. The performance in respect of load variation and speed change has been reported. Simulations results are presented to demonstrate the proposed performance and then, compared with the reported results and found that the performance of fuzzy based IPM_DRIVE drive for DC motors is improved.**

*Index Terms*—**Fuzzy controller, DC motors, IPM_DRIVE converter, speed control.**

## I. INTRODUCTION

Since the first successful application of the fuzzy concept into the control of a dynamic plant several decades ago, there has been a considerable world wide interest in fuzzy controller. It has been known that it is possible to control many complex systems effectively by skilled operators who have no knowledge of their underlying dynamics, while it is difficult to achieve the same with conventional controllers [1][2]. They are used in several applications ranging from the control of power converters to speed control of motors [3]. It's suitable for applications such as the speed control of a dc motor which has nonlinearities. It is this fact which has ultimately made the fuzzy controller is more powerful to handle those un-modeled uncertainties. Meanwhile, the motion control applications can be found in almost every sector of industry, from factory automation and robotics to high-tech computer hard disk drives. They are used to regulate mechanical motions in terms of position, velocity, acceleration and/or to coordinate the motions of multiple axes or machine parts. Furthermore, DC motors drives have been widely used in such applications where the accurate speed tracking is required, and in spite of the fact that AC motors are rugged, cheaper and lighter, DC motors are still a very popular choice in particular applications. It is known as a typical plant in the teaching on the control theory and research, and many methods have been developed for DC motors, for example, see [4], [5]-[10]. In conventional control strategies were used and it comprises of fixed arrangement with fixed parameter design. Hence the tuning and optimization of these controllers is a challenging and difficult task, particularly, under varying load conditions, parameter changes, abnormal modes of operation.

[11] has demonstrated and reported the separately excited dc motor fed by a chopper (DC to DC converter) and controlled by a fuzzy logic controller. It has been reported that the fuzzy logic controller controls the duty cycle of the chopper, there by the voltage fed to the motor for regulating the speed. The experimental setup has improved the performance over PI controller. It is seen that the separately excited dc drive have low starting torque which limits its applications.

H.A.Yousef and H.M.Khalil [12] have demonstrated the dc series motor drive fed by a single phase controlled rectifier (AC to DC converter) and controlled by fuzzy logic. It has been concluded that the fuzzy logic controller provides better control over the classical PI controller which has improved the performance. It is also reported that the settling time and maximum overshoot can be reduced. Due to the inherent limitations, AC to DC converter fed drive introduces unwanted harmonic ripples in the output.

[13] has reported the dc series motor drive fed by a single phase full-bridge converter (DC to DC converter) controlled by fuzzy logic. It has been reported that the motor performance was simulated for different controllers like simplify fuzzy logic model (SFL), PI type fuzzy controller (FPI) and classical PI controller. The simulation result shows that the SFI provides superior performance over other controllers. It is found from the analysis that only the speed error has been taken as fuzzy input. There are some important achievements in fuzzy controller for closed loop control of DC drive (see, for example [14]-[20]).

The proposed system deals development of a speed for a dc motor fed by AC/DC (IPM) converter, utilizes the fuzzy logic controller and IPM_DRIVE (IPM power modules). The fuzzy logic based speed command is followed even under load torque disturbances.

The paper is structured as follows. Section II describes the mathematical model formulation of the proposed DC motors, while Section III presents the design of Fuzzy Logic Control . Section IV, gives a simulation results and discussion. Conclusion is given in Section V.

## II. Mathematical Model of DC Motors

The goal in the development of the mathematical model is to relate the voltage applied to the armature to the velocity or position of the motor. Two balance equations can be developed by considering the electrical and mechanical characteristics of the system. Because of the complexity of dynamic-system problems, idealizing assumptions will be made. These assumptions are:

**Assumption 2.1:** The brushes are narrow, and commutation is linear.

**Assumption 2.2:** The armature is assumed to have no effect on the total direct-axis flux because the armature-wave is perpendicular to the field axis.

**Assumption 2.3:** The effects of the magnetic saturation will be neglected [21].

The electric circuit of the armature and the free body diagram of the rotor are shown in Fig.1, where

$V_t$ - Motor terminal voltage
$Ra$ - Armature resistance
$La$- Armature inductance
$J$ - Moment of inertia
$B$-Friction coefficient
$T_l$ - Load torque
$\omega$ -Angular speed
$\theta$-Angular displacement
$K_T$- Torque constant and
$K_b$- Back emf constant.

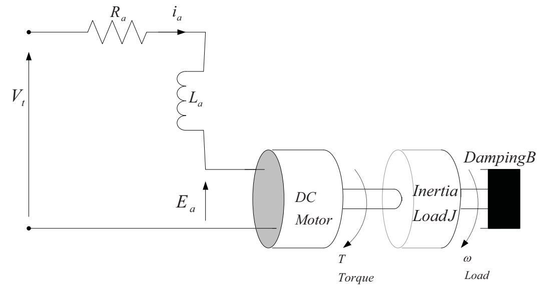

Fig. 1: DC Motor Equivalent Circuit.

By choosing $i_a$, $\omega$ and $\theta$ as the state variables and $V_t$ as input. The output is chosen to be $\omega$, and define the system matrices $A_c$, $B_c$ and $C_c$ as follows

$$A_c = \begin{bmatrix} \frac{-R_a}{L_a} & \frac{-K_b}{L_a} & 0 \\ \frac{K_T}{J} & \frac{-B}{J} & 0 \\ 0 & 1 & 0 \end{bmatrix}, \tag{1}$$

$$B_c = \begin{bmatrix} \frac{1}{L_a} \\ 0 \\ 0 \end{bmatrix}, C_c = \begin{bmatrix} 0 & 1 & 0 \end{bmatrix}, \tag{2}$$

we have the following state space description of DC motors dynamic

$$\left\{ \begin{array}{lcl} \dot{x}_t & = & A_c x_t + B_c u_t \\ y_t & = & C_c x_t \end{array} \right. \tag{3}$$

where state variables are

$$x = [i_a \ \omega \ \theta]^T \tag{4}$$

Sampling this system with step time $T_s$ yields

$$\left\{ \begin{array}{lcl} x_{k+1} & = & Ax_k + Bu_k \\ y_k & = & Cx_k \end{array} \right. \tag{5}$$

where

$$A = e^{A_c T_s}, \quad B = \int_0^{T_s} e^{A_c(T_s-\tau)} B_c d\tau, \ C = C_c \tag{6}$$

## III. Fuzzy Logic Control (FLC)

Fig.2 shows the block diagram of the complete proposed system. The proposed system consists of DC motor, IPM_DRIVE (IPM power modules) for driving the dc motor. A tacho generator(optical encoder) is used to measure the speed and which used for speed feedback. A DSPF2812 based 32-bit microcontroller is used to to generate PWM waveform required to switch Intelligent Power Module (IPM), during the experimental setup. Firstly, Matlab/simlink model of the DC motor and the IPM_Drive power converter is developed and simulated, and then, fuzzy logic controller is designed by using fuzzy toolbox, finally, the closed loop operation is simulated.

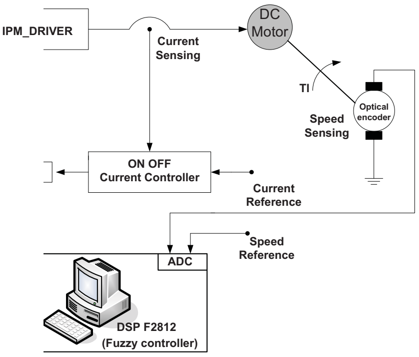

Fig. 2: Black diagram of proposed system.

**Intelligent Power Module:** Intelligent Power Module (IPM) is advanced hybrid power devices that combine high speed, low loss IGBTs with optimized gate drive and protection circuitry. System reliability is further enhanced by the IPM's integrated over temperature and under voltage lock out protection. Compact, automatically assembled Intelligent Power Modules are designed to reduce system size, cost, and time. In this paper, we use AC/DC converter based on Intelligent Power Module (IPM module, IRAM10UP60B-2) to driver DC motor, equivalent circuit of the IPM is shown in Fig.3.

The function of a fuzzy controller is to convert linguistic control rules based on expert knowledge into control strategy [23]. The effective and efficient control using fuzzy logic has emerged as a tool to deal with uncertain, imprecise or qualitative decision making problems [24]-[30]. The FLC consists of mainly four stages, namely Fuzzification, Rule-base, Inference engine and Defuzzification. The Takagi- Sugeno type controller is performed for present control for DC motor because it has singleton membership in the output variable. Moreover, it can be easily implemented and number of calculations can be reduced and works well with optimization and adaptive techniques which makes it very attractive in control problems, particularly for dynamic nonlinear systems [31]. General structure of the fuzzy controller is shown in Fig. 4, and the simulink model developed is given in Fig.5.

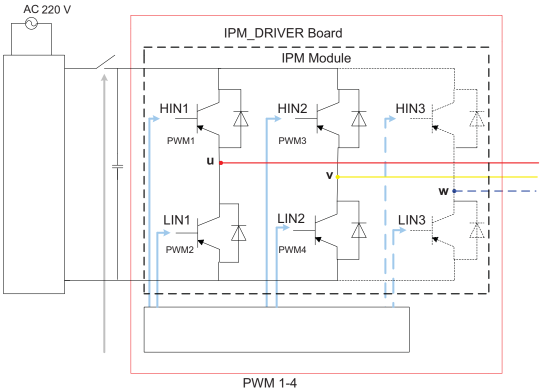

Fig. 3: Equivalent circuit of the IPM.

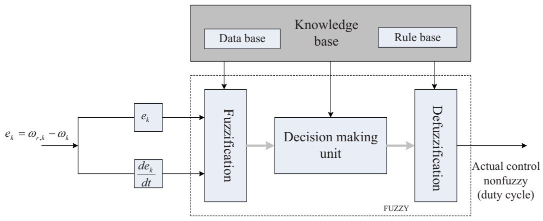

Fig. 4: General structure of the fuzzy controller .

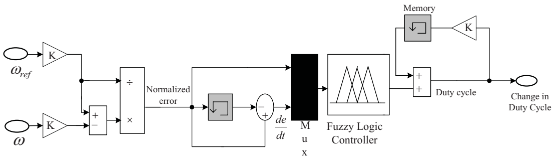

Fig. 5: Simulink scheme of the fuzzy controller.

## *A. Fuzzification*

In this work, the motor variables considered are speed $\omega$ and current $i_a$. The speed $\omega$ is the control object of FLC. Let $\omega_r$ denote the reference speed, then the definitions for error $e_k$ and change in error $\Delta e_k$ are given in (7) and (8).

$$e_k = \omega_{r,k} - w_k \tag{7}$$

$$\Delta e_k = e_k - e_{k-1} \tag{8}$$

TABLE I: Rule based of the system

| E<br>CE | NB | NS | O | PS | PB |
|---|---|---|---|---|---|
| NB | NB | NB | NB | NS | Z |
| NS | NB | NB | NS | Z | PS |
| O | NB | NS | Z | PS | PS |
| PS | NS | Z | PS | PB | PB |
| PB | Z | PS | PB | PB | PB |

Five linguistic variables are used for fuzzificating the input variable $e_k$ and $\Delta e_k$ as follows, Negative Big $(NB)$, Negative Small $(NS)$, Zero $(Z)$, Positive Small $(PS)$ and Positive Big $(PB)$. In this work only five membership functions are used for the input, i.e. error and change in error. In order to reduce the number of membership function the width of the membership functions are kept different. The membership function width for the center membership functions is considered narrow and wide towards outer.

### B. defuzzification

After fuzzy reasoning we have a linguistic output variable which needs to be translated into a crisp value. The objective is to derive a single crisp numeric value that best represents the inferred fuzzy values of the linguistic output variable. The linguistic variables are converted in to a numerical variable [32]. The defuzzified output is the duty cycle $dc_k$. The change in duty cycle $\Delta dc_k$ can be obtained by adding the pervious duty cycle $pdc_k$ with the duty cycle $dc_k$ which is given in Eq.(9).

$$\Delta dc_k = dc_k + pdc_k \tag{9}$$

### C. Rule table and Inference Engine

The Inference Mechanism provides the mechanism for invoking or referring to the rule base such that the appropriate rules are fired. The control rules related to the fuzzy output to the fuzzy inputs are derived from general knowledge of the system behavior, also the perception and experience. However, some of the control rules are developed using “trial and error” method [14]. The general rule can be written as “If $e(k)$ is $X$ and $\Delta e(k)$ is $Y$ then $\Delta dc(k)$ is $Z$”, where $X, Y$and $Z$ are the fuzzy variable for $e(k)$, $\Delta e(k)$ and $\Delta dc(k)$ respectively . The rule table for the designed fuzzy controller is given in the Table I [33].

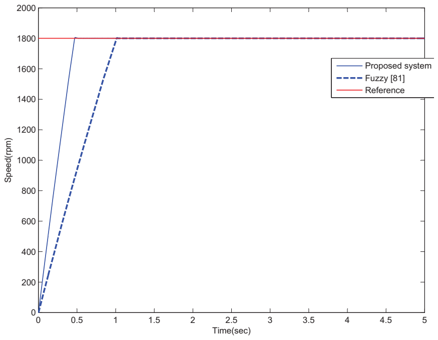

Fig. 6: Comparisons between the proposed system and fuzzy controller reference [34] for $\omega_r = 1800$ rpm .

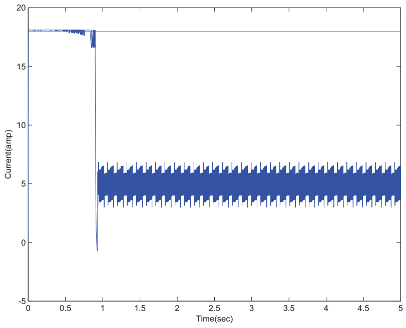

Fig. 7: Current variation with respect to time .

## IV. Simulation and Discussion of the Proposed System

In this section, the effectiveness of proposed model has been simulated using Matlab/simulink toolbox, the designed fuzzy controller (FC) and AC/DC converter based on Intelligent Power Module is tested. The simulation results of the proposed fuzzy controller(FC) are compared with fuzzy controller (FC) [34]. Fig.6 shows the comparisons between the proposed system fuzzy controller and fuzzy controller reference [34] for $\omega_r = 1800$ rpm , and Fig.7 is shown Current Variation respect to time. We can observed that, the current variation includes some harmonics due to AC to DC converter. In order to show the robustness of the proposed system, performance comparisons of the proposed system with reference [12] and reference [34] for the speed $\omega_r = 1800$ rpm is shown in the Table II.

The simulated result of speed regulation for a step change in load torque of 50% and 100% applied at $t = 2.5sec$ are shown in Fig. 8 and Fig. 9 respectively.

Form these figures, we can observed that the load

TABLE II: The performance comparisons of the proposed system with reference [12] and reference [34] .

| Controller | [12] | [34] | current |
|---|---|---|---|
| Setting time | 1.7 sec | 1sec | 0.7 |
| Max.over shoot | 3.2% | 0.36% | 0.30% |

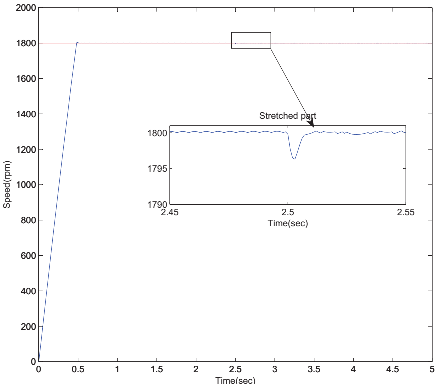

Fig. 8: Speed variation for the step change in load torque $(\Delta T_l = 50\%)$ applied at t= 2.5 sec for $\omega_r = 1800$ rpm.

influences the performance of the controller. Furthermore, it is also observed that the motor speed is function of the load torque and it seen that when load is applied the motor takes it is sufficient time to reach the reference speed.

In order to validate the proposed method, the compared between proposed method and fuzzy controller (FC) [34] for speed $\omega_r = 1800$ rpm and load torque $\Delta T_l = 5N.m$ applied at time $t = 2.5sec$ is shown in Fig. 10. Furthermore, the comparison of the proposed system with reference [12] and reference [34] for the speed $\omega_r = 1800$ rpm and $\Delta T_l = 5N.m$ applied at $t = 2.5sec$ is shown in the Table III. Fig. 11 shown current variation for step change in load torque $(\Delta T_l = 5N.M)$ applied at t= 2.5 sec for $\omega_r = 1800$

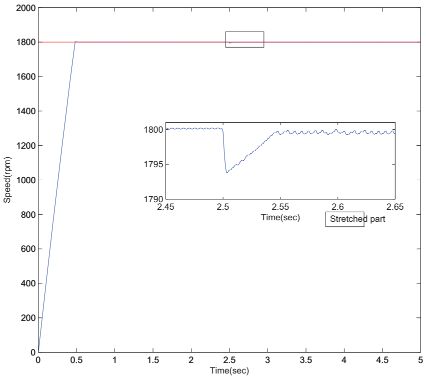

Fig. 9: Speed variation for the step change in load torque $(\Delta T_l = 100\%)$ applied at t= 2.5 sec for $\omega_r = 1800$ rpm.

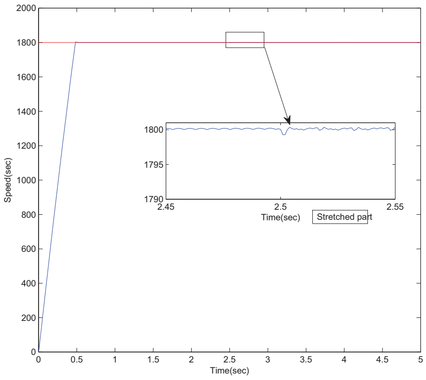

Fig. 10: Speed variation for the step change in load torque $(\Delta T_l = 5N.M)$ applied at t= 2.5 sec for $\omega_r = 1800$ rpm.

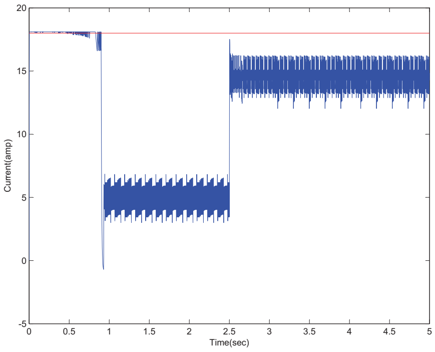

Fig. 11: Current variation for the step change in load torque $(\Delta T_l = 5N.m)$ applied at t= 2.5 sec for $\omega_r = 1800$ rpm.

## V. Conclusion

This paper consider the fuzzy logic controller for control DC motor. In the proposed method, the mathematic model of DC motor is applied to evaluate the fuzzy logic controller, and a IPM_DRIVE (IPM power modules) is used to fed dc motor . The effective results show that the

TABLE III: Comparison of the proposed system with reference [12] and reference [34] speed $\omega_r = 1800$ rpm at $\Delta T_l = 5N.m$ applied at $t = 2.5sec$ .

| Controller | [12] | [34] | Current |
|---|---|---|---|
| Max.over shoot | 3.2% | 0.36% | 0.30% |
| Max. speed drop | 3.5% | 0.36% | 0.25% |
| Recovery time | 2.4 sec | 0.01 sec | 0.007 sec |

performance of DC motor controller has obtained better results by using Fuzzy Logic Controller and (IPM power modules) fed the proposed system. The designed fuzzy logic controller also is implemented in a micro-controller.

*Abstract*—**In this paper, the design of the a web-based Smart Home system is introduced. The proposed system provides a web interface through which users are able to check the home status and control the domestic appliance remotely as long as they have a PC system connected to the Internet. In order to give users a more vivid way to access the Smart Home system, a web based 3D interface with virtual reality technology is proposed in this paper. The rooms, appliances and furniture are reconstructed in the web-based interface. Users can "look around" in the virtual home remotely. They are able to check the security alarms, control the appliances in the 3D virtual reality similar as they do in real homes.**

***Keywords-smart home; web-based interface; 3D virtual reality; wireless network***

## I. INTRODUCTION

Recently, smart home has emerged as a hot spot both in academic and industrial communities [1]. Smart Home is the term commonly used to define a residence that integrates technology and services through home networking to enhance power efficiency and improve the quality of living. With the advent of the smart devices including Smart TV and smart pad, the various types of service [2] for smart home are expected to appear in the market.

A lot of smart home features such as home entertainments, surveillance and access control, resource effective management [3], home appliances automation, environmental control, assistive computing and healthcare came into birth so that lead to a promising industrial market in last two decades [4].

Today's Internet is evolving into an "Internet of things," as soon there will be more than one trillion connected devices. By 2013, 1.2 billion connected consumer electronics devices are expected in the more than 800 million homes with broadband connections.

With the rapid development of the Internet, new smart homes are moved out from the home onto the network where users are able to monitor and control the domestic appliances remotely check the status of the home from any place any where as long as they have Internet access.

In recent years, web-based 3D technologies have been widely used in many applications such as online games [5], urban management [6], remote experimentation [7] and GIS [8] *etc*. 3D objects can be imported and rendered in web browsers. If the homes can be reconstructed in web based virtual reality world, the users can access their homes remotely in a more vivid way.

In this paper, the design of a web-based smart home is introduced. It can be accessed remotely using web browsers. Web-based 3D technology is adopted in the design to provide a more vivid remote access interface. They are able to "walk around" in the virtual homes and control the appliances freely as if they are at home.

## II. STRUCTURE OF SMART HOME

### A. General Strucrue

It is a trend that telephone, television and computer networks merging in one optical fiber network with the development communication technology. The proposed Smart Home system is based on the Triple Play communication architecture as shown in Figure 1.

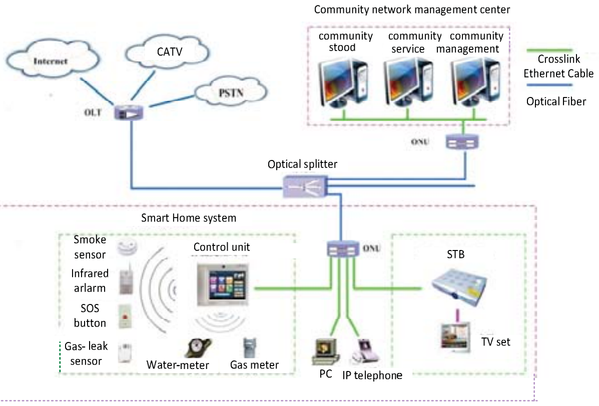

Figure 1. Typical structure of smart home with triple play communication architecture

The proposed Smart Home system uses wireless communication to control various domestic appliances in order to reduce the cost of cabling and increase the flexibilities. Small wireless communication modules are installed on domestic appliances, meters and security sensors so they can be accessed by the control unit through wireless communication.

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

The Control Unit is also connected to a central web server located in the community center. The users are able to control the appliances, monitor the real-time images and check the power consumption at home through the web server remotely. Moreover, if any security alarm is trigged, the message is also transmitted to the central web server where a text message is sent to the corresponding user's mobile phone automatically.

### *B. Structure of the Hardware*

The network architecture of smart home system inside the home consists of two parts, as shown in Figure 2. The Control Unit is the central device of the system. It mainly consists of the main board, LCD screen, CMOS camera, wireless module, microphone and speaker. The main board is based on Samsung's S3C6410 ARM11 processor and integrates various functions such as video signal processing, camera control, USB, SD card, LCD screen, Ethernet. It is also equipped with a buzzer, a temperature sensor, a back-up lithium battery holder to ensure that the system time is not lost after power failure and other equipments.

In addition to the control unit, smart home system has many kinds of modules, such as security modules, domestic appliances control modules, smart meter modules. The security modules include window and door magnetic sensor, smoke sensor, gas leak sensor, infrared sensor, SOS button, etc. The domestic appliances control modules are used to control appliances, including light, air conditioner, curtain *etc*. The smart meter modules are used to collect the real time reading of the electricity, water and gas meters. The environmental monitoring modules are used to monitor the environment in house, including temperature and humidity. In addition, the smart socket can measure the real time status of the appliances, including voltage, current and power. These modules are connected to the central Control Unit using wireless communication. The status of the domestic devices is transmitted to the control unit in real time.

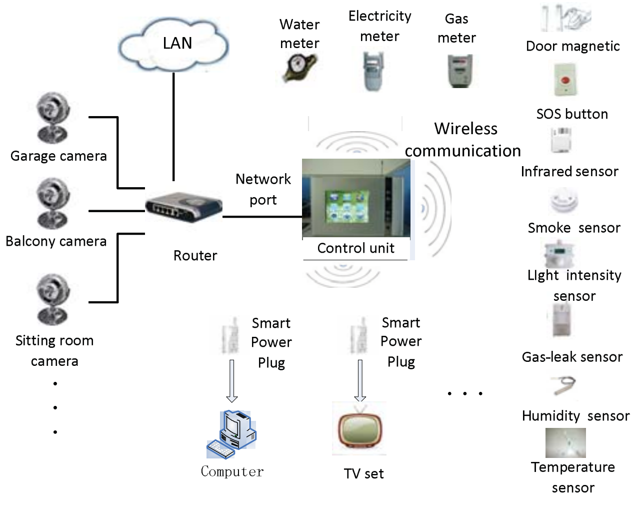

Figure 2. Structure of the Smart Home system

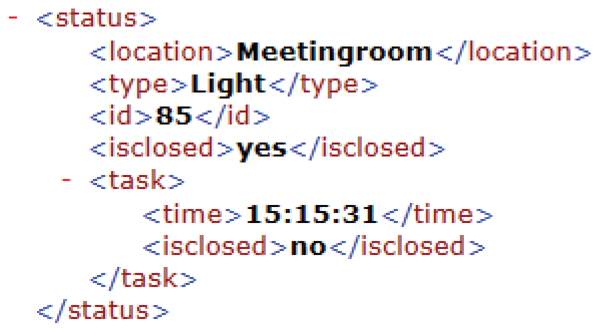
The Smart Home System uses wireless network to establish the communication between the control unit and home devices (such as appliances, security alarms and smart meters *etc*). The wireless module communicates with a variety of sensor modules, domestic appliances control modules, data acquisition modules by a nRF905 single-chip wireless transceiver which operates at 433MHz band. The use of the wireless network has simplified the system structure and reduced the cost of cabling greatly comparing with the wired solutions.

## III. SOFTWARE STRUCTURE OF THE CONTROL UNIT

The operating system running in the Control Unit is Linux and the embedded software is developed using Qt which is a cross-platform application and UI framework. The device table represented in XML (Extensible Markup Language) form is the data core of the Control Unit software. Each device such as domestic appliances, security sensors has a corresponding element in the XML, where its, id, type, locations and status etc are specified. The control Unit can operate on the devices through wireless communication according to information stored in the XML device table. Figure 3 is an example of a light represented in the XML table. The XML elements are synchronized with the real devices. Every time an operation is implemented on a device or the status of a device changes, the corresponding XML elements are modified.



```
- <status>
    <location>Meetingroom</location>
    <type>Light</type>
    <id>85</id>
    <isclosed>yes</isclosed>
  - <task>
      <time>15:15:31</time>
      <isclosed>no</isclosed>
    </task>
  </status>
```

Figure 3. An example of device table

Figure 4 shows the software structure of Control Unit. The network communication module establishes TCP connection channels with central web server. It get the information of the home devices from the XML table and transmit them to the web sever. The wireless communication module keeps connection with home devices. It receives the real time information from the home devices and implements the corresponding modification on the XML table.

If one of the security sensors is trigged, it sends a message to the Control Unit through wireless communication. The corresponding status of the XML is modified. Then the alarm message is transmitted to the central server where a text message is sent to the user's mobile phone.

Another important function of the Control Unit is to control and monitor domestic appliances. If provide a unified user interface to control all the appliances. For example, if a user wants to operate a certain appliance on the Control Unit such as tuning on a light, the Control Unit will send a command to the corresponding appliance through wireless communication and modify the XML document at the mean time.

Figure 4. Software structure of control unit

## IV. WEB-BASED REMOTE ACCESS INTERFACE

The Smart Home system provides a web-based remote interface for users. By a simple click of the mouse on web application, users are able to remotely and conveniently operate and control domestic appliances.

Web-based smart home remote control platform adopts B/S structure with a three-tier structure, as shown in Figure 5. In the overall architecture, Tomcat web server and MySQL database are deployed in the central server located in the community center. Three software modules are designed and implemented in the web server. The Communication Module is responsible for data communication between the wireless devices and Control Unit through the TCP protocol. JSP and Servlets are deployed to dynamically generate web interface for users to remotely manipulate the domestic electronics.

MySQL database is deployed as the middle layer which is the kernel data structure of the web server. All the information such as the user list, device list and security alarm record are stored in the database.

Web services server consists of database server and local servers, it communicates with the Control Unit through TCP connections. A variety of data provided by the Control Unit is sent to the server in XML form. Security alarm status, power consumption information and indoor environment information are packed in XML document and sent to the server.

Web Services server has played the role of a bridge in the whole system. It can not only obtain data form the Control Unit, but also pass the commands (such as tuning on or off a appliance) to from the web client to the Control Unit. These commands are also packed in XML which can be parsed and executed by the Control Unit.

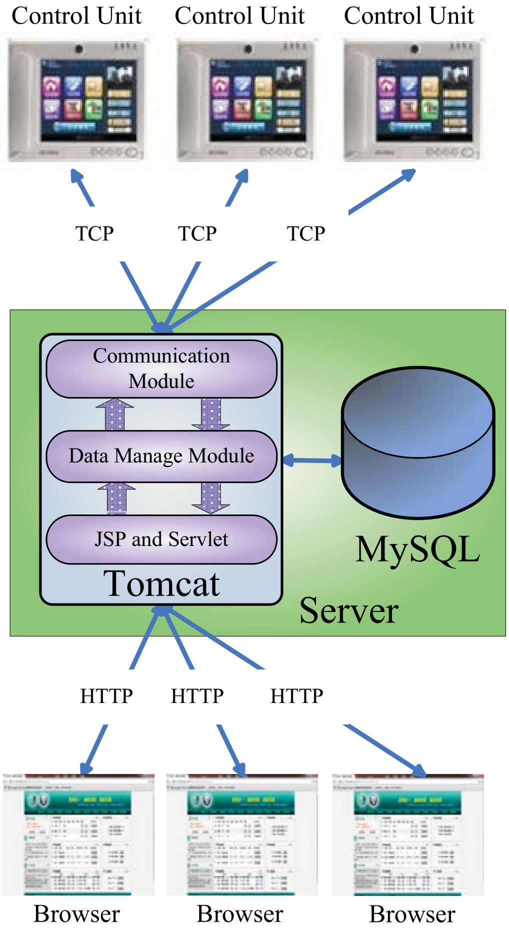

Figure 5. Overall architecture

The web-based Smart Home interface is shown in Figure 6. It can be seen that the main page containing user information, home appliance control, power monitoring, alarm monitoring, indoor environment, video monitoring, meter information *etc*.

Figure 6. Main Page

The web pages for the Smart Home system are different from conventional ones, which are mainly based on information publication. Ajax engine is introduced into the web so that the client browser uses asynchronous mode to communicate with the server. The web-based interface keeps requesting the status of the Smart Home devices from the web server. Therefore, every time there are changes (such as that an alarm is trigged) happened on the web server, if can be reflected on the web based interface immediately.

## V. WEB-BASED 3D VIRTUAL REALITY

The web-based 3D virtual reality technology is adopted for the design of the smart home systems. When users login in their home remotely using their web browser, a web-based 3D interface is also provided for them. Their homes are reconstructed in the web browsers using 3D virtual reality. They can "walk into" their virtual homes and control the appliances remotely similar to the way they do in their real homes.

### *A. 3D Modeling*

Components (appliances, furniture and rooms) of the smart homes must be modelled in 3D before it can be imported into the web-based user interface. There are many commercial software available for the 3D model design, such as 3DS Max, Solid Works and Pro/E *etc.* The original 3D models to be displayed in the web-based interface are firstly designed using the software and then converted into a common format which can be recognised and decoded by Flash 3D engines.

In this case, 3DS Max is selected as the 3D model development tool. The models designed in the 3DS Max are exported into the Wavefront .obj format for the Flash 3D engine. Figure 7 is an example which shows the 3D model of room being designed in the 3DS Max environment.

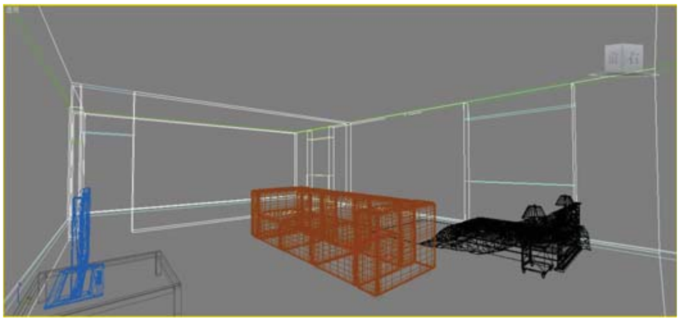

Figure 7. A 3D room designed in 3DS Max

When designing the 3D models, the complexity of these models must be considered carefully. The quality and the complexity of the 3D models have to be balanced. Even though the most powerfully 3D Flash is more than capable of processing tens thousands triangles, too complex models always result in big target files. In the internet environment, the long wait for downloading these files to the web browsers should be avoided as much as possible.

### *B. 3D Rendering*

3D models in can not be displayed in the web browser directly. It must be imported and rendered in Flash Controls. There are several 3D Flash engines available and most of them are open source software. Paperverion3D, Away3D and Sandy3D are examples. However, some early version of 3D engines only support software rendering. Without GPU (Graphic Processing Unit) acceleration, only relatively simple 3D applications can be implemented in the web-based interface, which had significantly limited the growth of the web-based 3D technologies.

The release of Flash 11 had changed the situation. Flash 11.0 starts to support hardware accelerated 3D rendering, which makes it possible to designed more complex 3D applications. Stage 3D which is a set of 3D API in Flash 11 enables advanced 3D capabilities on both PC and mobile platforms. In order to help developers to quickly design 3D web-based applications, Proscenium which is an ActionScript code library built on the top of Stage 3D has also been released. Using Proscenium, models designed in 3D design software can be easily imported and rendered into Flash Controls. The structure of a 3D Flash Controls is depicted in Figure 8.

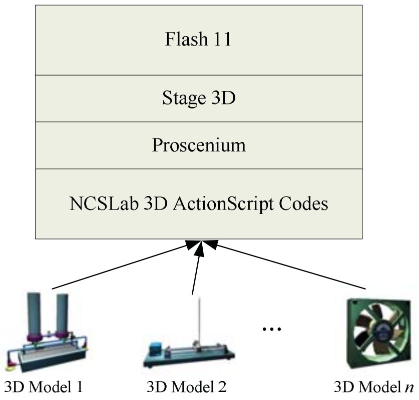

Figure 8. Structure of a 3D Flash Control

Using the resources provided by Stage 3D and Proscenium, 3D models designed in the 3DS Max environment are imported into Flash Controls which are embedded into web browser. Therefore, they can be embedded and displayed in the web-based interface. Apart from the 3D engine, some supporting codes are also designed. These codes are able to communicate with the Web Server and dynamically control the animations of the 3D components.

### *C. Web-based 3D Interface*

Figure 9 shows the structure about how the 3D models are displayed in the web-based interface. The Tomcat Web Servers create the NCSLab web pages dynamically using JSP/Servlet Technology. These pages are downloaded to the web browsers and generate the web-based interface.

On the user's web browser, AJAX scripts embedded in the HTML codes are designed to deploy the 3D Flash Controls in the web-based interface. These codes download and the corresponding 3D Flash Controls and embed them into the web browser. The 3D Flash Controls are also able to obtain real-time data from the web server. The motions of the 3D models can be manipulated according to the real-time experimental data collected from the web server, which gives the synchronization between the animations and real test rigs.

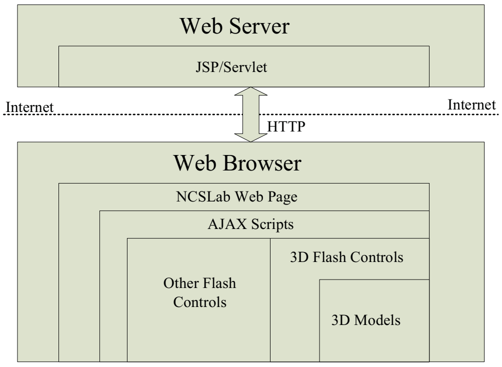

Figure 9. Structure of 3D web-based interface

Even the same 3D Flash Controls running in different circumstance may have different configurations. These configurations are generated dynamically in the XML form by the JSP/Servlet codes running on the web servers. The AJAX scripts pass the XMLs to the 3D Flash Controls where the 3D components are displayed properly according to these configurations.

Figure 10 shows a virtual home reconstructed in the web browser. The real home is displayed in the 3D virtual environment. Users are able to look around in the “virtual home” freely using the mouse the keyboards. They can check the security alarms, control the appliance freely similar to the way they do in real homes.

## VI. Conclusions

In this paper, a web-based smart home system with 3D virtual reality is introduced. In this system, wireless network is used to establish communication between the Control Unit and home devices. Comparing with the wired solution, it is able to simplify the system structure and save the cabling cost greatly. A web server is deployed in the community center. Therefore, users are able to login the web server and access their homes remotely using web-based interface. 3D virtual reality technologies are also used in the system. Rooms, appliances and furniture are reconstructed in the 3D web-based interface. Users can “look around” in the virtual home remotely. They are able to check the security alarms, control the appliances in the 3D virtual reality similar as they do in real homes.

# New stability criteria for linear systems with time-varying interval delay

Jian Sun, Jie Chen, *Member, IEEE*, G.P. Liu, *Fellow, IEEE*,

*Abstract*— **This paper is concerned with the problem of stability of systems with time-varying delay in a given interval. A novel Lyapunov-Krasovskii functional is proposed to obtain new stability conditions. Some triple integral terms are introduced in the Lyapunov-Krasovskii functional and the information on the lower bound on the delay are sufficiently used. New delay-dependent stability criteria are derived using integral inequalities and formulated in terms of linear matrix inequality (LMI). Comparing numerical examples show that the proposed criteria yield a larger upper bound on the delay for a given lower bound on the delay than existing results.**

## I. INTRODUCTION

During the past few years, time-delay systems have been an active research area. Much attention has been paid to the stability and stabilization of time-delay systems. In a practical system, time-delay often deteriorates the performance of the system and even causes instability. Especially, in networked control systems, there exist time-delays in both the forward channel and the feedback channel, which poses a negative effect on the stability and performance of the systems and makes the systems difficult to analyze and synthesize [1], [2], [3], [4], [5].

Stability criteria for time-delay systems in the literature can be roughly classified into two categories. One is delay-independent and the other is delay-dependent. Generally speaking, delay-dependent stability conditions are less conservative than delay-independent ones. So, many researchers specialize in developing less conservative stability criteria for time-delay systems and some important results have been obtained [6], [7], [8], [9], [10], [11], [12], [13], [14], [15], [16]. Based on some model transformations, some stability conditions for time-delay systems have been obtained in [17], [18]. A descriptor system method was proposed in [19], [20], [21] where a time-delay system is presented in the form of a descriptor system. Combining the descriptor system method with Park's inequality [22] or Moon et. al's inequality [23] can yield much less conservative results. In order to further reduce the conservatism of stability criteria, a free-weighting matrices method was proposed by He et. al [24], [25], [26]. Some free-weighting matrices are introduced by Leibniz–Newton formula to estimate the upper bound of the derivative of the Lyapunov-Krasovskii functional. Numerical examples illustrated that this method can yield less conservative results than the descriptor system method. In order to reduce the decision variables in the stability criteria, Jensen's inequality [27] was used to derive stability results for time-delay systems. It has been proved that results obtained by Jensen's inequality are generally equivalent to those obtained by descriptor system method or free-weighting matrices method [28]. For the systems with time-varying delay, [29], [30] reported that some useful terms are ignored when estimating the upper bound of the derivative of the Lyapunov functional, which can introduce significant conservatism. Inspired by this observation, some less conservative results were proposed in [29], [30], [31] by taking into these useful terms account.

In the literature, the time-varying delay is often assumed belong to a given interval, that is,

$$0 < h_1 \leqslant d(t) \leqslant h_2 \tag{1}$$

However, the information on the lower bound of the delay is not sufficiently used in the Lyapunov functional. For example, $\int_{t-h_2}^{t} x^T(s)Qx(s)ds$ and $\int_{t-d(t)}^{t} x^T(s)Rx(s)ds$ are often used as a part of the Lyapunov functional. The integral upper limits of these terms are all $t$ but not $t-h_1$, which may cause some conservatism just as proved in our previous work [32]. Similarly, some double integral terms such as $\int_{-h_2}^{-h_1}\int_{t+\theta}^{t} \dot{x}^{\mathrm{T}}(s)Z\dot{x}(s)dsd\theta$ are often used as a part of the Lyapunov functional. The inner integral upper limit is $t$ but not $t-h_1$ which may also introduce some additional conservatism. Observing this fact, a new Lyapunov functional is proposed in this paper where the information on the lower bound of the delay is sufficiently used, that is, some terms like $\int_{-h_2}^{-h_1}\int_{t+\theta}^{t-h_1} \dot{x}^{\mathrm{T}}(s)Z\dot{x}(s)dsd\theta$ are used in the Lyapunov functional. Furthermore, it has been shown in [32] that introducing some triple-integral terms in Lyaounov functional can significantly reduce the conservatism of the obtained results. In this paper, a triple integral term like $\int_{-h_2}^{-h_1}\int_{\theta}^{-h_1}\int_{t+\lambda}^{t-h_1} \dot{x}^{\mathrm{T}}(s)R\dot{x}(s)dsd\lambda d\theta$ is introduced in the Lyapunov functional. It should be noted that the upper limits of $s$, $\lambda$ and $\theta$ are $t-h_1$, $-h_1$ and $-h_1$, respectively. In this paper, a novel Lyapunov-Krasovskii functional which contains some new triple-integral terms and sufficiently uses the information on the lower bound of the delay is proposed. Some new delay-dependent stability criteria are obtained using some integral inequalities. Numerical examples illustrates

that results in this paper are significant improvements over existing ones.

*Notations:* Throughout this paper, the superscripts '-1' and 'T' stand for the inverse and transpose of a matrix, respectively; $\mathbb{R}^n$ denotes an n-dimensional Euclidean space; $\mathbb{R}^{m\times n}$is the set of all $m\times n$ real matrices; $P>0$ means that the matrix $P$ is symmetric positive definite; $I$ is an appropriately dimensional identity matrix.

## II. PROBLEM FORMULATION AND PRELIMINARIES

Consider the following linear system with time-varying interval delay:

$$\begin{aligned} &\dot{x}(t)=Ax(t)+A_1x(t-\tau(t)), \quad t>0 \\ &x(t)=\phi(t), \quad t\in[-\tau_2,\ 0] \end{aligned} \tag{2}$$

where $x(t)\in\mathscr{R}^n$ is the state vector; $A\in\mathscr{R}^{n\times n}$ and $A_1\in\mathscr{R}^{n\times n}$ are constant system matrices with appropriate dimensions; The initial condition $\phi(t)$ is a continuously differentiable vector-valued function; $\tau(t)$ is a time-varying differentiable function and satisfies

$$0<\tau_1\leqslant\tau(t)\leqslant\tau_2 \tag{3}$$

$$\dot{\tau}(t)\leqslant\mu \tag{4}$$

where $0<\tau_1<\tau_2$, and $0\leqslant\mu$ are constants.

Before moving on, the following integral inequalities are introduced.

*Lemma 1:* [27], [32] For any constant matrix $Z>0$ and scalars $\tau_2>\tau_1>0$ such that the following integrations are well defined, then

(1)

$$\begin{aligned} &-\int_{t-\tau_2}^{t-\tau_1} x^{\mathrm{T}}(s)Zx(s)ds \\ &\qquad\leqslant -\tau_{12}^{-1}\int_{t-\tau_2}^{t-\tau_1} x^{\mathrm{T}}(s)dsZ\int_{t-\tau_2}^{t-\tau_1} x(s)ds \end{aligned}$$

(2)

$$\begin{aligned} &-\int_{-\tau_2}^{-\tau_1}\int_{t+\theta}^{t-\tau_1} x^{\mathrm{T}}(s)Zx(s)dsd\theta \\ &\leqslant -2\tau_{12}^{-2}\int_{-\tau_2}^{-\tau_1}\int_{t+\theta}^{t-\tau_1} x^{\mathrm{T}}(s)dsd\theta Z\int_{-\tau_2}^{-\tau_1}\int_{t+\theta}^{t-\tau_1} x(s)dsd\theta \end{aligned}$$

where $\tau_{12}=\tau_2-\tau_1$.

The objective of this paper is to derive less conservative delay-dependent stability conditions for system (2). Using the obtained results, one can obtain a larger maximum upper bound of the delay for a given lower bound of the delay.

## III. MAIN RESULTS

In this section, some less conservative stability criteria are developed. Before presenting the main results, we define $\xi(t)=col\{x(t),x(t-\tau(t)),x(t-\tau_1),x(t-\tau_2),\dot{x}(t-\tau_1),\dot{x}(t-\tau_2),\ \int_{t-\tau_1}^{t}x(s)ds,\ \int_{t-\tau(t)}^{t-\tau_1}x(s)ds,\ \int_{t-\tau_2}^{t-\tau(t)}x(s)ds\}$, and $e_i$ $(i=1,2,\cdots,9)$ are block entry matrices. For example, $e_7^{\mathrm{T}}=[0\ \ 0\ \ 0\ \ 0\ \ 0\ \ 0\ \ I\ \ 0\ \ 0]$.

*Theorem 1:* Given scalars $0<\tau_1<\tau_2$, and $0\leqslant\mu$, if there exist matrices $P=[P_{ij}]_{5\times5}>0$, $Q=[Q_{ij}]_{2\times2}>0$, $X=[X_{ij}]_{2\times2}>0$, $S>0$, $Z_j>0$, $j=1,\cdots,4$, $R_1>0$, and $R_2>0$ with appropriate dimensions such that the following LMIs hold, then system (2) with a time-varying delay satisfying (3) and (4) is asymptotically stable.

$$\begin{aligned} \Theta_1 =\ &\Phi P\Upsilon^{\mathrm{T}}+\Upsilon P\Phi^{\mathrm{T}}+\Lambda+\Gamma^{\mathrm{T}}Y\Gamma+\Gamma^{\mathrm{T}}Q_{12}^{\mathrm{T}}e_1^{\mathrm{T}} \\ &+e_1Q_{12}\Gamma-\begin{bmatrix} e_4 & e_6\end{bmatrix}X\begin{bmatrix} e_4^{\mathrm{T}} \\ e_6^{\mathrm{T}}\end{bmatrix} \\ &+\begin{bmatrix} e_3 & e_5\end{bmatrix}(X-Q)\begin{bmatrix} e_3^{\mathrm{T}} \\ e_5^{\mathrm{T}}\end{bmatrix} \\ &-(e_1-e_3)Z_1(e_1^{\mathrm{T}}-e_3^{\mathrm{T}}) \\ &-2(e_2-e_4)Z_2(e_2^{\mathrm{T}}-e_4^{\mathrm{T}})-(e_3-e_2)Z_2(e_3^{\mathrm{T}}-e_2^{\mathrm{T}}) \\ &-e_8Z_4e_8^{\mathrm{T}}-2e_9Z_4e_9^{\mathrm{T}}-(\tau_1e_1-e_7)R_1(\tau_1e_1^{\mathrm{T}}-e_7^{\mathrm{T}}) \\ &-(\tau_{12}e_3-e_8-e_9)R_2(\tau_{12}e_3^{\mathrm{T}}-e_8^{\mathrm{T}}-e_9^{\mathrm{T}})<0 \end{aligned} \tag{5}$$

$$\begin{aligned} \Theta_2 =\ &\Phi P\Upsilon^{\mathrm{T}}+\Upsilon P\Phi^{\mathrm{T}}+\Lambda+\Gamma^{\mathrm{T}}Y\Gamma+\Gamma^{\mathrm{T}}Q_{12}^{\mathrm{T}}e_1^{\mathrm{T}} \\ &+e_1Q_{12}\Gamma-\begin{bmatrix} e_4 & e_6\end{bmatrix}X\begin{bmatrix} e_4^{\mathrm{T}} \\ e_6^{\mathrm{T}}\end{bmatrix} \\ &+\begin{bmatrix} e_3 & e_5\end{bmatrix}(X-Q)\begin{bmatrix} e_3^{\mathrm{T}} \\ e_5^{\mathrm{T}}\end{bmatrix} \\ &-(e_1-e_3)Z_1(e_1^{\mathrm{T}}-e_3^{\mathrm{T}}) \\ &-(e_2-e_4)Z_2(e_2^{\mathrm{T}}-e_4^{\mathrm{T}})-2(e_3-e_2)Z_2(e_3^{\mathrm{T}}-e_2^{\mathrm{T}}) \\ &-2e_8Z_4e_8^{\mathrm{T}}-e_9Z_4e_9^{\mathrm{T}}-(\tau_1e_1-e_7)R_1(\tau_1e_1^{\mathrm{T}}-e_7^{\mathrm{T}}) \\ &-(\tau_{12}e_3-e_8-e_9)R_2(\tau_{12}e_3^{\mathrm{T}}-e_8^{\mathrm{T}}-e_9^{\mathrm{T}})<0 \end{aligned} \tag{6}$$

where

$$\begin{aligned} &\Phi=[e_1\ \ e_3\ \ e_4\ \ e_7\ \ e_8+e_9] \\ &\Upsilon=\left[\Gamma^{\mathrm{T}}\ \ e_5\ \ e_6\ \ e_1-e_3\ \ e_3-e_4\right] \\ &\Lambda=\mathrm{diag}\{Q_{11}+\tau_1Z_3,\ -(1-\mu)S,\ +S+\tau_{12}^2Z_4,\ 0 \\ &\qquad \tau_{12}^2Z_2+\frac{\tau_{12}^4}{4}R_2,\ 0,\ -Z_3,\ 0,\ 0\} \\ &\Gamma=[A\ \ A_1\ \ 0\ \ 0\ \ 0\ \ 0\ \ 0\ \ 0\ \ 0] \\ &Y=Q_4+\tau_1^2Z_1+\frac{\tau_1^4}{4}R_1 \end{aligned}$$

*Proof:* Choose a Lyapunov functional as follows:

$$\begin{aligned} V(x_t)=\ &\rho^{\mathrm{T}}(t)P\rho(t)+\int_{t-\tau_1}^{t}\zeta^{\mathrm{T}}(s)Q\zeta(s)ds \\ &+\int_{t-\tau_2}^{t-\tau_1}\zeta^{\mathrm{T}}(s)X\zeta(s)ds \\ &+\int_{t-\tau(t)}^{t-\tau_1}x^{\mathrm{T}}(s)Sx(s)ds \\ &+\int_{-\tau_1}^{0}\int_{t+\theta}^{t}\tau_1\dot{x}^{\mathrm{T}}(s)Z_1\dot{x}(s)dsd\theta \\ &+\int_{-\tau_2}^{-\tau_1}\int_{t+\theta}^{t-\tau_1}\tau_{12}\dot{x}^{\mathrm{T}}(s)Z_2\dot{x}(s)dsd\theta \\ &+\int_{-\tau_1}^{0}\int_{t+\theta}^{t}\tau_1x^{\mathrm{T}}(s)Z_3x(s)dsd\theta \\ &+\int_{-\tau_2}^{-\tau_1}\int_{t+\theta}^{t-\tau_1}\tau_{12}x^{\mathrm{T}}(s)Z_4x(s)dsd\theta \end{aligned}$$

$$+\int_{-\tau_1}^{0}\int_{\theta}^{0}\int_{t+\lambda}^{t}\frac{\tau_1^2}{2}\dot{x}^{\mathrm{T}}(s)R_1\dot{x}(s)dsd\lambda d\theta$$
$$+\int_{-\tau_2}^{-\tau_1}\int_{\theta}^{-\tau_1}\int_{t+\lambda}^{t-\tau_1}\frac{\tau_{12}^2}{2}\dot{x}^{\mathrm{T}}(s)R_2\dot{x}(s)dsd\lambda d\theta \quad (7)$$

where $\rho(t) = col\{x(t), x(t-\tau_1), x(t-\tau_2), \int_{t-\tau_1}^{t} x(s)ds, \int_{t-\tau_2}^{t-\tau_1} x(s)ds\}$, $\zeta(s) = col\{x(s), \dot{x}(s)\}$.
Taking the derivative of $V(x_t)$ along the trajectory of system (2) yields

$$\begin{aligned}
\dot{V}(x_t) = & 2\rho^{\mathrm{T}}(t)P\dot{\rho}(t) \\
& + \zeta^{\mathrm{T}}(t)Q\zeta(t) - \zeta^{\mathrm{T}}(t-\tau_1)Q\zeta(t-\tau_1) \\
& + \zeta^{\mathrm{T}}(t-\tau_1)X\zeta(t-\tau_1) - \zeta^{\mathrm{T}}(t-\tau_2)X\zeta(t-\tau_2) \\
& + x^{\mathrm{T}}(t-\tau_1)Sx(t-\tau_1) \\
& - (1-\mu)x^{\mathrm{T}}(t-\tau(t))Sx(t-\tau(t)) \\
& + \tau_1^2\dot{x}^{\mathrm{T}}(t)Z_1\dot{x}(t) - \tau_1\int_{t-\tau_1}^{t}\dot{x}^{\mathrm{T}}(s)Z_1\dot{x}(s)ds \\
& + \tau_{12}^2\dot{x}^{\mathrm{T}}(t-\tau_1)Z_2\dot{x}(t-\tau_1) \\
& - \tau_{12}\int_{t-\tau_2}^{t-\tau_1}\dot{x}^{\mathrm{T}}(s)Z_2\dot{x}(s)ds \\
& + \tau_1^2 x^{\mathrm{T}}(t)Z_1x(t) - \tau_1\int_{t-\tau_1}^{t}x^{\mathrm{T}}(s)Z_3x(s)ds \\
& + \tau_{12}^2 x^{\mathrm{T}}(t-\tau_1)Z_4x(t-\tau_1) \\
& - \tau_{12}\int_{t-\tau_2}^{t-\tau_1}x^{\mathrm{T}}(s)Z_4x(s)ds \\
& + \frac{\tau_1^4}{4}\dot{x}^{\mathrm{T}}(t)R_1\dot{x}(t) \\
& - \frac{\tau_1^2}{2}\int_{-\tau_1}^{0}\int_{t+\theta}^{t}\dot{x}^{\mathrm{T}}(s)R_1\dot{x}(s)dsd\theta \\
& + \frac{\tau_{12}^4}{4}\dot{x}^{\mathrm{T}}(t-\tau_1)R_2\dot{x}(t-\tau_1) \\
& - \frac{\tau_{12}^2}{2}\int_{-\tau_2}^{-\tau_1}\int_{t+\theta}^{t-\tau_1}\dot{x}^{\mathrm{T}}(s)R_2\dot{x}(s)dsd\theta \quad (8)
\end{aligned}$$

Using Lemma 1, it can be obtained that

$$\begin{aligned}
-\tau_1 & \int_{t-\tau_1}^{t}\dot{x}^{\mathrm{T}}(s)Z_1\dot{x}(s)ds \\
& \leq -\xi^{\mathrm{T}}(t)(e_1-e_3)Z_1(e_1^{\mathrm{T}}-e_3^{\mathrm{T}})\xi(t) \quad (9)
\end{aligned}$$

$$\begin{aligned}
-\tau_1 & \int_{t-\tau_1}^{t}x^{\mathrm{T}}(s)Z_3x(s)ds \\
& \leq -\int_{t-\tau_1}^{t}x^{\mathrm{T}}(s)dsZ_3\int_{t-\tau_1}^{t}x(s)ds \quad (10)
\end{aligned}$$

$$\begin{aligned}
-\frac{\tau_1^2}{2} & \int_{-\tau_1}^{0}\int_{t+\theta}^{t}\dot{x}^{\mathrm{T}}(s)R_1\dot{x}(s)dsd\theta \\
& \leq -\xi^{\mathrm{T}}(t)(\tau_1e_1-e_7)R_1(\tau_1e_1^{\mathrm{T}}-e_7^{\mathrm{T}})\xi(t) \quad (11) \\
-\frac{\tau_{12}^2}{2} & \int_{-\tau_2}^{-\tau_1}\int_{t+\theta}^{t-\tau_1}\dot{x}^{\mathrm{T}}(s)R_2\dot{x}(s)dsd\theta \\
& \leq -\xi^{\mathrm{T}}(t)(\tau_{12}e_3-e_8-e_9)R_2(\tau_{12}e_3^{\mathrm{T}}-e_8^{\mathrm{T}}-e_9^{\mathrm{T}})\xi(t)(12)
\end{aligned}$$

let $\alpha = (\tau(t)-\tau_1)/\tau_{12}$ and use the similar method as in [31]

$$\begin{aligned}
-\tau_{12} & \int_{t-\tau_2}^{t-\tau_1}\dot{x}^{\mathrm{T}}(s)Z_2\dot{x}(s)ds \\
= & -\tau_{12}\int_{t-\tau_2}^{t-\tau(t)}\dot{x}^{\mathrm{T}}(s)Z_2\dot{x}(s)ds \\
& - \tau_{12}\int_{t-\tau(t)}^{t-\tau_1}\dot{x}^{\mathrm{T}}(s)Z_2\dot{x}(s)ds \\
= & -(\tau_2-\tau(t))\int_{t-\tau_2}^{t-\tau(t)}\dot{x}^{\mathrm{T}}(s)Z_2\dot{x}(s)ds \\
& - (\tau(t)-\tau_1)\int_{t-\tau_2}^{t-\tau(t)}\dot{x}^{\mathrm{T}}(s)Z_2\dot{x}(s)ds \\
& - (\tau(t)-\tau_1)\int_{t-\tau(t)}^{t-\tau_1}\dot{x}^{\mathrm{T}}(s)Z_2\dot{x}(s)ds \\
& - (\tau_2-\tau(t))\int_{t-\tau(t)}^{t-\tau_1}\dot{x}^{\mathrm{T}}(s)Z_2\dot{x}(s)ds \\
\leq & -\xi^{\mathrm{T}}(t)(e_2-e_4)Z_2(e_2^{\mathrm{T}}-e_4^{\mathrm{T}})\xi(t) \\
& - \xi^{\mathrm{T}}(t)(e_3-e_2)Z_2(e_3^{\mathrm{T}}-e_2^{\mathrm{T}})\xi(t) \\
& - \alpha\xi^{\mathrm{T}}(t)(e_2-e_4)Z_2(e_2^{\mathrm{T}}-e_4^{\mathrm{T}})\xi(t) \\
& - (1-\alpha)\xi^{\mathrm{T}}(t)(e_3-e_2)Z_2(e_3^{\mathrm{T}}-e_2^{\mathrm{T}})\xi(t) \quad (13)
\end{aligned}$$

Similarly,

$$\begin{aligned}
-\tau_{12} & \int_{t-\tau_2}^{t-\tau_1}x^{\mathrm{T}}(s)Z_4x(s)ds \\
& \leq -\xi^{\mathrm{T}}(t)\left[e_8^{\mathrm{T}}Z_4e_8+e_9^{\mathrm{T}}Z_4e_9\right]\xi(t) \\
& \quad - \alpha\xi^{\mathrm{T}}(t)e_9^{\mathrm{T}}Z_4e_9\xi(t) \\
& \quad - (1-\alpha)\xi^{\mathrm{T}}(t)e_8^{\mathrm{T}}Z_4e_8\xi(t) \quad (14)
\end{aligned}$$

From (8)-(14), one can obtain

$$\dot{V}(x_t) \leqslant \xi^{\mathrm{T}}(t)\left[\alpha\Theta_1+(1-\alpha)\Theta_2\right]\xi(t) \quad (15)$$

Since $0 \leq \alpha \leq 1$, $\alpha\Theta_1+(1-\alpha)\Theta_2$ is a convex combination of $\Theta_1$ and $\Theta_2$. Therefore, $\alpha\Theta_1+(1-\alpha)\Theta_2 < 0$ is equivalent to $\Theta_1 < 0$ and $\Theta_2 < 0$. If (5)-(6) are satisfied, then system (2) is asymptotically stable. ■

*Remark 1:* A new kind of augmented Lyapunov functional is proposed in this paper to develop new delay-interval-dependent stability criteria. Being distinguished from existing Lyapunov functionals, the one in this paper contains some triple-integral terms which has been proved able to reduce the conservatism of the obtained results effectively. Furthermore, the information on the lower bound of the delay is sufficiently used in the Lyapunov functional by including the terms $\int_{-\tau_2}^{-\tau_1}\int_{t+\theta}^{t-\tau_1}\tau_{12}\dot{x}^{\mathrm{T}}(s)Z_2\dot{x}(s)dsd\theta$ and $\int_{-\tau_2}^{-\tau_1}\int_{\theta}^{-\tau_1}\int_{t+\lambda}^{t-\tau_1}\frac{\tau_{12}^2}{2}\dot{x}^{\mathrm{T}}(s)R_2\dot{x}(s)dsd\lambda d\theta$. It can be seen that the integral upper limits of these terms are $t-\tau_1$ or $-\tau_1$. To the best knowledge of the authors', this kind of Lyapunov functional has been never used in the literature. Numerical examples will be given in the next section to show that such a kind of Lyapunov functional can yield less conservative results.

*Remark 2:* Using some integral inequalities and the idea of the convex combination, new delay-interval-dependent stability criteria are obtained without introducing any free-weighting matrices. Therefore, the method proposed in this paper may involve much less variables than the well-known free-weighting matrices method and the descriptor system method.

In some circumstances, the information on the derivative of the delay may not be always available or the delay is not differentiable. For this case, the following corollary can be derived from Theorem 1 by setting $S = 0$.

*Corollary 1:* Given scalars $0 < \tau_1 < \tau_2$, and $0 \leqslant \mu$, if there exist matrices $P = [P_{ij}]_{5\times5} > 0$, $Q = [Q_{ij}]_{2\times2} > 0$, $X = [X_{ij}]_{2\times2} > 0$, $Z_j > 0$, $j = 1, \cdots, 4$, $R_1 > 0$, and $R_2 > 0$ with appropriate dimensions such that the following LMIs hold, then system (2) with a time-varying delay satisfying (3) is asymptotically stable.

$$\begin{aligned}
\hat{\Theta}_1 = {} & \Phi P \Upsilon^{\mathrm{T}} + \Upsilon P \Phi^{\mathrm{T}} + \hat{\Lambda} + \Gamma^{\mathrm{T}} Y \Gamma + \Gamma^{\mathrm{T}} Q_{12}^{\mathrm{T}} e_1^{\mathrm{T}} \\
& + e_1 Q_{12} \Gamma - \begin{bmatrix} e_4 & e_6 \end{bmatrix} X \begin{bmatrix} e_4^{\mathrm{T}} \\ e_6^{\mathrm{T}} \end{bmatrix} \\
& + \begin{bmatrix} e_3 & e_5 \end{bmatrix} (X - Q) \begin{bmatrix} e_3^{\mathrm{T}} \\ e_5^{\mathrm{T}} \end{bmatrix} \\
& - (e_1 - e_3) Z_1 (e_1^{\mathrm{T}} - e_3^{\mathrm{T}}) \\
& - 2(e_2 - e_4) Z_2 (e_2^{\mathrm{T}} - e_4^{\mathrm{T}}) - (e_3 - e_2) Z_2 (e_3^{\mathrm{T}} - e_2^{\mathrm{T}}) \\
& - e_8 Z_4 e_8^{\mathrm{T}} - 2 e_9 Z_4 e_9^{\mathrm{T}} - (\tau_1 e_1 - e_7) R_1 (\tau_1 e_1^{\mathrm{T}} - e_7^{\mathrm{T}}) \\
& - (\tau_{12} e_3 - e_8 - e_9) R_2 (\tau_{12} e_3^{\mathrm{T}} - e_8^{\mathrm{T}} - e_9^{\mathrm{T}}) < 0 \qquad (16)
\end{aligned}$$

$$\begin{aligned}
\hat{\Theta}_2 = {} & \Phi P \Upsilon^{\mathrm{T}} + \Upsilon P \Phi^{\mathrm{T}} + \hat{\Lambda} + \Gamma^{\mathrm{T}} Y \Gamma + \Gamma^{\mathrm{T}} Q_{12}^{\mathrm{T}} e_1^{\mathrm{T}} \\
& + e_1 Q_{12} \Gamma - \begin{bmatrix} e_4 & e_6 \end{bmatrix} X \begin{bmatrix} e_4^{\mathrm{T}} \\ e_6^{\mathrm{T}} \end{bmatrix} \\
& + \begin{bmatrix} e_3 & e_5 \end{bmatrix} (X - Q) \begin{bmatrix} e_3^{\mathrm{T}} \\ e_5^{\mathrm{T}} \end{bmatrix} \\
& - (e_1 - e_3) Z_1 (e_1^{\mathrm{T}} - e_3^{\mathrm{T}}) \\
& - (e_2 - e_4) Z_2 (e_2^{\mathrm{T}} - e_4^{\mathrm{T}}) - 2(e_3 - e_2) Z_2 (e_3^{\mathrm{T}} - e_2^{\mathrm{T}}) \\
& - 2 e_8 Z_4 e_8^{\mathrm{T}} - e_9 Z_4 e_9^{\mathrm{T}} - (\tau_1 e_1 - e_7) R_1 (\tau_1 e_1^{\mathrm{T}} - e_7^{\mathrm{T}}) \\
& - (\tau_{12} e_3 - e_8 - e_9) R_2 (\tau_{12} e_3^{\mathrm{T}} - e_8^{\mathrm{T}} - e_9^{\mathrm{T}}) < 0 \qquad (17)
\end{aligned}$$

where $\Phi$, $\Upsilon$, $Y$ and $\Gamma$ are the same as those defined in Therom 1, and $\hat{\Lambda} = \mathrm{diag}\{Q_{11} + \tau_1 Z_3,\ 0,\ \tau_{12}^2 Z_4,\ 0,\ \tau_{12}^2 Z_2 + \frac{\tau_{12}^4}{4} R_2,\ 0,\ -Z_3,\ 0,\ 0\}$.

*Remark 3:* When there are norm-bounded uncertainties in system (2), Theorem 1 and Corollary 1 can be extended to deal with this case following a similar method as in [9], [23].

## IV. NUMERICAL EXAMPLES

In this section, some numerical examples are given to show the effectiveness of the proposed method, that is, the method in this paper can yield less conservative results than exiting ones.

*Example 1:* Consider the following system [30], [31] with

$$A = \begin{bmatrix} -2 & 0 \\ 0 & -0.9 \end{bmatrix}, \quad A_1 = \begin{bmatrix} -1 & 0 \\ -1 & -1 \end{bmatrix}.$$

For various $\mu$ and unknown $\mu$, the maximum upper bounds of the delay (MUBDs), $\tau_2$, for given lower bound, $\tau_1$, are listed in Table I and II along with those obtained in [31], [32]. It is easy to see from Table I and II that our method can give less conservative results than those obtained in [31], [32].

TABLE I

MUBDs WITH GIVEN $\tau_1$ FOR DIFFERENT $\mu$ FOR EXAMPLE 1

| $\tau_1$ | Methods | $\mu = 0.3$ | $\mu = 0.5$ | $\mu = 0.9$ |
|---|---|---|---|---|
| 2 | [31] | 2.6972 | 2.5048 | 2.5048 |
| | [32] | 3.0129 | 2.5663 | 2.5663 |
| | Theorem 1 | 3.0168 | 2.6116 | 2.6116 |
| 3 | [31] | 3.2591 | 3.2591 | 3.2591 |
| | [32] | 3.3408 | 3.3408 | 3.3408 |
| | Theorem 1 | 3.3932 | 3.3932 | 3.3932 |
| 4 | [31] | 4.0744 | 4.0744 | 4.0744 |
| | [32] | 4.1690 | 4.1690 | 4.1690 |
| | Theorem 1 | 4.2054 | 4.2054 | 4.2054 |
| 5 | [31] | — | — | — |
| | [32] | 5.0275 | 5.0275 | 5.0275 |
| | Theorem 1 | 5.0440 | 5.0440 | 5.0440 |

TABLE II

MUBDs FOR VARIOUS $\tau_1$ AND UNKNOWN $\mu$ FOR EXAMPLE 1

| Methods | $\tau_1$ | 2 | 3 | 4 | 5 |
|---|---|---|---|---|---|
| [31] | $\tau_2$ | 2.5048 | 3.2591 | 4.0744 | — |
| [32] | $\tau_2$ | 2.5663 | 3.3408 | 4.1690 | 5.0275 |
| Corollary 1 | $\tau_2$ | 2.6116 | 3.3932 | 4.2054 | 5.0440 |

*Example 2:* Consider the following system [30], [31] with

$$A = \begin{bmatrix} 0 & 1 \\ -1 & -2 \end{bmatrix}, \quad A_1 = \begin{bmatrix} 0 & 0 \\ -1 & 1 \end{bmatrix}.$$

Given different lower bounds, our objective is to calculate MUBDs which keep the above system asymptotically stable. Table III lists the results for $\mu = 0.6$ and Table IV lists results for unknown $\mu$ comparing those obtained in [31], [32]. It can be seen that the results obtained in this paper are better than those in [31], [32].

*Example 3:* Consider the following system [29] with

$$A = \begin{bmatrix} -0.5 & -2 \\ 1 & -1 \end{bmatrix}, \quad A_1 = \begin{bmatrix} -0.5 & -1 \\ 0 & 0.6 \end{bmatrix}.$$

For various $\mu$, the MUBDs for given lower bound, $\tau_1$, are listed in Table V. In Table V results in [31], [32] are also listed. It is easy to see that our results are less conservative than those in [31], [32].

## V. CONCLUSIONS

In this paper, the problem of the stability of linear systems with time-varying interval delays has been investigated. New delay-interval-dependent criteria have been developed by introducing a new Lyapunov-Krasovskii functional and

using the integral inequality technique and the idea of the convex combination. Due to the new construction of the introduced Lyapunov-Krasovskii functional and the sufficient use of the information on the delay interval, our results are less conservative than the existing ones. Some numerical examples have illustrated that the method proposed in this paper is efficient.

***Abstract*—This paper concerns the observer-based pole placement control for MIMO time varying non-lexicographically-fixed discrete systems. If both of the reachability indices and the observability indices are non-lexicographically-fixed, augmented plant equation and augmented observer are needed. Design procedure of this control system is proposed and the stability and the separation principle of the total closed loop system is also shown.**

*Keywords - Pole Placement; Observer; Time Varying System; Descrete System; Non-Lexicographically-Fixed System*

## I. Introduction

It is well known that the pole placement control can be designed for linear time-varying system by using the controllability canonical form as in the time-invariant case [5], [6]. The linear time-varying multivariable system whose controllability indices or observability indices are not constant is called the non-lexicographically-fixed system. Valasec et. al. [7] proposed the pole placement design method for such a system by augmenting the system equation so that the augmented system is lexicographically-fixed. This paper concerns the pole placement and the observer design method for linear time-varying discrete non-lexicographically-fixed system. Using the Valasec's idea, the procedure to extend a discrete non-lexicographically-fixed system to a lexicographically-fixed augmented system will be presented. Then, the simple pole placement technique can be applied to the augmented system without transforming the system into any canonical form [12]. Further, using the property of the anti-causal dual system, it will be shown that the same design method can be used for the augmented observer for non-lexicographically-fixed systems. Finally, as for the time-invariant case, the stability and the separation principle of the total closed loop system are also shown for the case where both of the augmented pole placement controller and the augmented observer are used.

## II. Preliminaries

Consider the following linear time-varying m-input p-output MIMO discrete system.

$$\begin{aligned} x(k+1) &= A(k)x(k) + B(k)u(k) \qquad (1) \\ y(k) &= C(k)x(k) \qquad (2) \end{aligned}$$

where $x \in R^n$, $u \in R^m$, and $y \in R^p$ are the state variable, the input and output, respectively. $A(k) \in R^{n\times n}$, $B(k) \in R^{n\times m}$ and $C(k) \in R^{p\times n}$ are time-varying coefficient matrices.

*Definition 1:* System (1) is called "completely reachable in $n$ steps" if for any $x_1 \in R^n$ there exists a bounded input $u(j)$ $(j = k, \cdots, k+n-1)$ such that $x(k) = 0$ and $x(k+n) = x_1$ for all k.

The reachability matrix, $R(k)$, of this system is defined by

$$\begin{aligned} R(k) &= \left[ \; b_0^1(k) \quad \cdots \quad b_0^m(k) \; \right| \cdots \\ & \qquad \cdots \left| \; b_{n-1}^1(k) \quad \cdots \quad b_{n-1}^m(k) \; \right] \qquad (3) \end{aligned}$$

Here, $b_i^l(k) \in R^n$ is calculated by the following recurrence equations.

$$\begin{aligned} b_0^l(k) &= b^l(k+n-1) \\ b_{i+1}^l(k) &= A(k+n-1)b_i^l(k-1) \qquad (4) \\ & \qquad (i = 0, \cdots, n-2, \quad l = 1, \cdots, m \;) \end{aligned}$$

where, $b^l(k) \in R^n$ is the $l$-th column of $B(k)$.

If the system (1) is completely reachable in $n$ steps, the rank of $R(k)$ is $n$, from which we can define the nonsingular $n \times n$ matrix $\bar{R}(k)$ using the reachability indices $\mu_i (i = 1, 2, \cdots, m)$ as follows.

$$\begin{aligned} \bar{R}(k) &= \left[ \; b_0^1(k), \cdots, b_{\mu_1-1}^1(k) \right| \cdots \\ & \qquad \cdots \left| b_0^m(k), \cdots, b_{\mu_m-1}^m(k) \; \right] \qquad (5) \end{aligned}$$

The reachability indices satisfy that $\sum_{i=1}^m \mu_i = n$ and are assumed that $\mu_1 \geq \mu_2 \geq \cdots \geq \mu_m$ without loss of generallity.

Here, we state the definition of the observability in $n$ steps as a dual concept of the reachability in $n$ steps.

*Definition 2:* The system (1), (2) is said to be completely observable in $n$ steps if for any $k$, $x(k)$ is determined uniquely from $y(k)$, $y(k+1)$, $\cdots$, $y(k+n-1)$.

The following steps are the pole placement control design procedure proposed by the authors in [11] without using a transformation into any canonical form.

**STEP 1** Check the reachability of the system (1) and obtain $\bar{R}(k)$ and $\mu_i$ $(i=1,\cdots,m)$.

**STEP 2**

Calculate the new output signal, $\tilde{y}(k)$, by the following equation, so that the relative degree from $u(k)$ to $\tilde{y}(k)$ is the system degree, $n$.

$$\tilde{y}(k) = \tilde{C}(k)x(k) = W\bar{R}^{-1}(k-n)x(k) \tag{6}$$

where $W$ is the matrix defined by the following.

$$\begin{aligned} W &= diag(w_1, w_2, \cdots, w_m) \\ w_i &= \left[\begin{array}{cccc} 0 & \cdots & 0 & 1 \end{array}\right] \in R^{1\times\mu_i} \end{aligned} \tag{7}$$

**STEP 3** Let $q^i(z)$ be the ideal and stable characteristic polynomial for the closed-loop system of degree $\mu_i$, i.e.,

$$q^i(z) = z^{\mu_i} + \alpha^i_{\mu_i-1}z^{\mu_i-1} + \cdots + \alpha^i_1 z + \alpha^i_0 \tag{8}$$

Here, $z$ is the shift operator. Then, we have the following equation [11].

$$\left[\begin{array}{ccc} q_1(z) & & \\ & \ddots & \\ & & q_m(z) \end{array}\right]\tilde{y}(k) = F(k)x(k) + \Lambda(k)u(k) \tag{9}$$

where $\Lambda(k) \in R^{m\times m}$ is nonsingular. (See Appendix.)

**STEP 4** From (9), the state feedback

$$u(k) = D(k)x(k) = -\Lambda^{-1}(k)F(k)x(k) \tag{10}$$

makes the closed loop system

$$\left[\begin{array}{ccc} q_1(z) & & \\ & \ddots & \\ & & q_m(z) \end{array}\right]\tilde{y}(k) = 0 \tag{11}$$

This implies that the closed loop state equation

$$x(k+1) = \{A(k) + B(k)D(k)\}x(k) \tag{12}$$

is equivalent to the time invariant system with desired poles, i.e., there exists some transformation matrix, $P(k)$, that satisfies the following equation.

$$P(k+1)\{A(k) + B(k)D(k)\}P^{-1}(k) = A^* \tag{13}$$

where

$$\det(zI - A^*) = \prod_{i=1}^{m} q^i(z) \tag{14}$$

Then, if the matrix $P(k)$ is the Lyapunov transformation, the closed loop system is stable and equivalent to some time-invariant system that has the ideal and stable eigen values.

## III. Pole Placement of Non-Lexicographically-Fixed Systems

In the previous section, the reachability indices are supposed to be fixed. Such indices are said to be lexicographically-fixed. However, since the system has time-varying parameters, the reachability indices might be variable as well. Such indices are said to be non-lexicographically-fixed. In this section, we consider the pole placement control designing procedure for a system with non-lexicographically-fixed indices. Valasek et. al. proposed the pole placement design method for non-lexicographically-fixed multivariable continuous systems in [8]. In this paper, we apply this idea to the discrete system together with the new pole placement technique stated in the previous section.

Suppose that the system (1) is completely reachable in $n$ steps, and has non-lexicographically-fixed reachability indices. It is assumed that the maximum value of each reachability index $\mu_i$ is known, i.e.,

$$v_i = \max_k \mu_i(k) \qquad (i=1,\cdots,m) \tag{15}$$

Using $v_i$, we define $n_g$ by

$$n_g = \sum_{i=1}^{m} v_i \tag{16}$$

Define the augmented system by

$$x_g(k+1) = A_g(k)x_g(k) + B_g(k)u(k) \tag{17}$$

$$\left\{\begin{array}{l} x_g(k) = \left[\begin{array}{c} x(k) \\ x_e(k) \end{array}\right] \\ A_g(k) = \left[\begin{array}{cc} A(k) & 0 \\ A_2(k) & A_1(k) \end{array}\right], B_g(k) = \left[\begin{array}{c} B(k) \\ B_e(k) \end{array}\right] \end{array}\right.$$

where $x_g \in R^{n_g}$ and $x_e \in R^{n_g-n}$. $A_1(k) \in R^{(n_g-n)\times(n_g-n)}$, $A_2(k) \in R^{(n_g-n)\times n}$, and $B_e(k) \in R^{(n_g-n)\times m}$ are design parameter matrices so that the above augmented system has lexicographically-fixed reachability indices, $v_i$ $(i=1,\cdots,m)$.

The reachability matrix $R_g(k)$ of this augmented system is

$$\begin{aligned} R_g(k) = [\ & {b_g}^1_0(k) \ \cdots \ {b_g}^m_0(k) \ | \cdots \\ & \cdots \ | \ {b_g}^1_{n_g-1}(k) \ \cdots \ {b_g}^m_{n_g-1}(k) \ ] \end{aligned} \tag{18}$$

where ${b_g}^l_i(k) \in R^{n_g}$ is defined by the following recurrence equations.

$$\begin{aligned} {b_g}^l_0(k) &= {b_g}^l(k+n_g-1) \\ {b_g}^l_{i+1}(k) &= A_g(k+n_g-1){b_g}^l_i(k-1) \\ & \quad (i=0,\cdots,n_g-2, \quad l=1,\cdots,m\ ) \end{aligned} \tag{19}$$

Here, ${b_g}^l(k) \in R^{n_g}$ is the $l$-th column of $B_g(k)$.

For the augmented system to have lexicographically-fixed reachability indices, $v_i$, the following $n_g \times n_g$ matrix $\bar{R}_g(k)$ should be nonsingular for all $k$.

$$\begin{aligned} \bar{R}_g(k) \ = \ [\ & {b_g}^1_0(k), \cdots, {b_g}^1_{v_1-1}(k) | \cdots \\ & \cdots | {b_g}^m_0(k), \cdots, {b_g}^m_{v_m-1}(k)\ ] \end{aligned} \tag{20}$$

On the other hand, $\bar{R}_g(k)$ can be written as

$$\bar{R}_g(k) = \left[ \begin{array}{c} \bar{R}_v(k) \\ \bar{R}_e(k) \end{array} \right] \tag{21}$$

where $\bar{R}_v(k) \in R^{n \times n_g}$ and $\bar{R}_e(k) \in R^{(n_g - n) \times n_g}$ are

$$\begin{aligned} \bar{R}_v(k) &= [\ b_0^1(k), \cdots, b_{v_1-1}^1(k) | \cdots \\ &\qquad \cdots | b_0^m(k), \cdots, b_{v_m-1}^m \ ] \end{aligned} \tag{22}$$

$$\begin{aligned} \bar{R}_e(k) &= [\ {r_e}_0^1(k), \cdots, {r_e}_{v_1-1}^1(k) | \cdots \\ &\qquad \cdots | {r_e}_0^m(k), \cdots, {r_e}_{v_m-1}^m(k) \ ] \end{aligned} \tag{23}$$

Since, from the assumption, the rank of $\bar{R}_v(k)$ is $n$, there exists a matrix, $\bar{R}_e(k)$, such that $\bar{R}_g(k)$ is nonsingular for all $k$. The problem is to find $A_1(k)$, $A_2(k)$, and $B_e(k)$ that give such ${r_e}_i^l(k) \in R^{n_g - n}$.

From (20)-(23), we have

$$ {b_g}_0^l(k) = \left[ \begin{array}{c} b_0^l(k) \\ {r_e}_0^l(k) \end{array} \right] \tag{24}$$

then, using (17) and (24), the recurrence equation (19) can be modified as follows.

$$\begin{aligned} {b_g}_0^l(k) &= \left[ \begin{array}{c} b_0^l(k) \\ {r_e}_0^l(k) \end{array} \right] = \left[ \begin{array}{c} b^l(k + n_g - 1) \\ {b_e}^l(k + n_g - 1) \end{array} \right] \\ {b_g}_{i+1}^l(k) &= \left[ \begin{array}{c} b_{i+1}^l(k) \\ {r_e}_{i+1}^l(k) \end{array} \right] \\ &= \left[ \begin{array}{cc} A(k + n_g - 1) & 0 \\ A_2(k + n_g - 1) & A_1(k + n_g - 1) \end{array} \right] {b_g}_i^l(k - 1) \\ &= \left[ \begin{array}{c} A(k + n_g - 1) b_i^l(k - 1) \\ [\ A_2(k + n_g - 1) \quad A_1(k + n_g - 1)\ ] {b_g}_i^l(k - 1) \end{array} \right] \\ &\qquad (i = 0, 1, \cdots\ , \quad l = 1, \cdots, m\ ) \end{aligned} \tag{25}$$

Here, ${b_e}^l(k)$ is the $l$-th column of $B_e(k)$. From (25), the relation between ${r_e}_i^l(k)$ and $A_1(k)$, $A_2(k)$, and $B_e(k)$ is obtained as follows.

$$\begin{aligned} & B_e(k + n_g - 1) = [\ {r_e}_0^1(k) \quad \cdots, \quad {r_e}_0^m(k)\ ] \\ & [\ A_2(k + n_g - 1) \quad A_1(k + n_g - 1)\ ] \bar{R}_g(k - 1) \\ & \qquad = \bar{R}_{e+}(k) \end{aligned} \tag{26}$$

where $\bar{R}_{e+}(k)$ is defined by

$$\begin{aligned} \bar{R}_{e+}(k) = [\ & {r_e}_1^1(k) \quad \cdots \quad {r_e}_{v_1}^1(k) | \cdots \\ & \cdots \ | {r_e}_1^m(k) \quad \cdots \quad {r_e}_{v_m}^m(k)\ ] \end{aligned} \tag{27}$$

From the above, design parameter matrices such that the augmented plant (17) has lexicographically-fixed reachability indices, $v_i (i = 1, \cdots, m)$, can be calculated as follows. First, determine $\bar{R}_e(k)$ so that $\bar{R}_g(k)$ is nonsingular for all $k$. Then, using arbitrarily determined parameters ${r_e}_{v_1}^1(k), \cdots, {r_e}_{v_m}^m(k)$ in (26) and (27), and then, $A_1(k)$, $A_2(k)$ and $B_e(k)$ are obtained by

$$\begin{aligned} & B_e(k) = [\ {r_e}_0^1(k - n_g + 1) \quad \cdots, \quad {r_e}_0^m(k - n_g + 1)\ ] \\ & [\ A_2(k) \quad A_1(k)\ ] = \bar{R}_{e+}(k - n_g + 1) \bar{R}_g^{-1}(k - n_g) \end{aligned} \tag{28}$$

The state feedback for the pole placement can be obtained as the following form by applying the pole placement design procedure stated in the previous section to this augmented system.

$$u(k) = [D_x(k),\ D_e(k)] \left[ \begin{array}{c} x(k) \\ x_e(k) \end{array} \right] = D_g(k) x_g(k) \tag{29}$$

This implies that there exists the time-varying transformation matrix $P_g(k) \in R^{n_g \times n_g}$ that satisfies

$$P_g(k + 1) \{A_g(k) + B_g(k) D_g(k)\} P_g^{-1}(k) = A_g^* \tag{30}$$

Hence, if the transformation matrix $P_g(k)$ is the Lyapunov transformation, the closed loop system is stable and equivalent to some time-invariant system that has desired and stable constant eigenvalues.

## IV. Observer of Non-Lexicographically-Fixed Systems

In this section, we consider the design of the observer for the system that has non-lexicographically-fixed observability indices. Suppose that the system (1),(2) is completely observable in $n$ steps and has observability indices, $\nu_i (i = 1, \cdots, p)$, which are non-lexicographically-fixed. Further, it is assumed that the following $d_i$ are known.

$$d_i = \max_k \nu_i(k) \qquad (i = 1, \cdots, p) \tag{31}$$

Using these $d_i$, we define $n_s$ by

$$n_s = \sum_{i=1}^{m} d_i \tag{32}$$

If the system has lexicographically-fixed observability indices, its observer can be written as follows.

$$\begin{aligned} \hat{x}(k + 1) &= A(k) \hat{x}(k) + B(k) u(k) \\ &\quad - H(k)(y(k) - C(k) \hat{x}(k)) \end{aligned} \tag{33}$$

where $\hat{x}(k) \in R^n$ is the state estimation of $x(t)$. Then, the problem is to find the observer gain matrix $H(k) \in R^{n \times p}$. But, since the observability indices are non-lexicographically-fixed, we augment the observer system as follows.

$$\begin{aligned} \hat{x}(k + 1) &= A(k) \hat{x}(k) + B(k) u(k) \\ &\quad - H(k)(y(k) - C(k) \hat{x}(k)) \\ &\quad - (A_4(k) + H(k) C_e(k)) \epsilon(k) \end{aligned} \tag{34}$$

$$\begin{aligned} \epsilon(k + 1) &= A_3(k) \epsilon(k) + H_e(k)(y(k) - C(k) \hat{x}(k)) \\ &\quad + H_e(k) C_e(k) \epsilon(k) \end{aligned} \tag{35}$$

Here, $\epsilon(k) \in R^{n_s - n}$ is an auxiliary signal and $A_3(k) \in R^{(n_s - n) \times (n_s - n)}$, $A_4(k) \in R^{n \times (n_s - n)}$, and $C_e(k) \in R^{p \times (n_s - n)}$ are design parameter matrices determined later. Using the state estimation error, $e(k) = x(k) - \hat{x}(k)$ the following state error equation is obtained from (1), (2), (34), and (35).

$$e_s(k + 1) = A_s(k) e_s(k) + H_s(k) C_s(k) e_s(k) \tag{36}$$

where

$$\left\{\begin{array}{l} e_s(k) = \left[\begin{array}{c} e(k) \\ \epsilon(k) \end{array}\right], A_s(k) = \left[\begin{array}{cc} A(k) & A_4(k) \\ 0 & A_3(k) \end{array}\right] \\ H_s(k) = \left[\begin{array}{c} H(k) \\ H_e(k) \end{array}\right], C_s(k) = \left[\begin{array}{cc} C(k) & C_e(k) \end{array}\right] \end{array}\right. \tag{37}$$

From this, the observer design problem is to find $H_s(k)$ so that $A_s(k) + H_s(k)C_s(k)$ is equivalent to some constant matrix which has desired constant eigenvalues.

For this purpose, consider the following anti-causal system as a dual system of the system $(A_s(k),\ C_s(k))$.

$$\begin{array}{l} \xi_s(k-1) = A_s^T(k)\xi_s(k) + C_s^T(k)v(k) \\ A_s^T = \left[\begin{array}{cc} A^T(k) & 0 \\ A_4^T(k) & A_3^T(k) \end{array}\right],\ C_s^T(k) = \left[\begin{array}{c} C^T(k) \\ C_e^T(k) \end{array}\right] \end{array} \tag{38}$$

Since the system $(A(k)$,$C(k))$ is completely observable in $n$ steps and has the observability indices, $\nu_i (i = 1, \cdots, p)$, its dual system is completely reachable in $n$ steps and has reachability indices, $\nu_i$.

The reachability matrix, $R_s(k)$, of the augmented dual system (38) can be written as

$$\begin{array}{r} R_s(k) = \left[\ c_s{}_0^1(k) \quad \cdots \quad c_s{}_0^m(k)\ \middle|\ \cdots \right. \\ \left. \cdots\ \middle|\ c_s{}_{n_s-1}^1(k) \quad \cdots \quad c_s{}_{n_s-1}^m(k)\ \right] \end{array} \tag{39}$$

where $c_s{}_i^l(k) \in R^{n_s}$ is defined by the following recurrence equations.

$$\begin{array}{rcl} c_s{}_0^l(k) & = & c_s{}^l(k - n_s + 1) \\ c_s{}_{i+1}^l(k) & = & A_s^T(k - n_s + 1)c_s{}_i^l(k+1) \\ & & (i = 0, \cdots, n_s - 2, \quad l = 1, \cdots, m\ ) \end{array} \tag{40}$$

Here, $c_s{}^l(k) \in R^{n_s}$ is the $l$-th column of $C_s^T(k)$.

For the augmented system to have lexicographically-fixed reachability indices, $d_i$, the following $n_s \times n_s$ matrix, $\bar{R}_s(k)$, should be nonsingular for all $k$.

$$\begin{array}{rcl} \bar{R}_s(k) & = & [\ c_s{}_0^1(k), \cdots, c_s{}_{d_1-1}^1(k)| \cdots \\ & & \cdots |c_s{}_0^m(k), \cdots, c_s{}_{d_m-1}^m(k)\ ] \end{array} \tag{41}$$

$\bar{R}_s(k)$ can be written as

$$\bar{R}_s(k) = \left[\begin{array}{c} \bar{R}_d(k) \\ \bar{R}_h(k) \end{array}\right] \tag{42}$$

where, $\bar{R}_d(k) \in R^{n \times n_s}$ and $\bar{R}_h(k) \in R^{(n_s - n) \times n_s}$ are defined by

$$\begin{array}{rcl} \bar{R}_d(k) & = & [\ c_0^1(k), \cdots, c_{v_1-1}^1(k)| \cdots \\ & & \cdots |c_0^m(k), \cdots, c_{d_m-1}^m\ ] \end{array} \tag{43}$$

$$\begin{array}{rcl} \bar{R}_h(k) & = & [\ r_h{}_0^1(k), \cdots, r_h{}_{d_1-1}^1(k)| \cdots \\ & & \cdots |r_h{}_0^m(k), \cdots, r_h{}_{d_m-1}^m(k)\ ] \end{array} \tag{44}$$

Since, the anti-causal dual system is reachable in $n$ steps, the rank of $\bar{R}_d(k)$ is $n$, and, hence, there always exists the matrix, $\bar{R}_h(k)$, such that the rank of $\bar{R}_s(k)$ is $n_s$ for all $k$. Thus, as the previous section, $C_e^T(k)$, $A_3^T(k)$, and $A_4^T(k)$ can be obtained by

$$\begin{array}{l} C_e^T(k) = [\ r_h{}_1^0(k + n_s - 1) \quad \cdots \quad r_h{}_m^0(k + n_s - 1)\ ] \\ [\ A_4^T(k) \quad A_3^T(k)\ ] = \bar{R}_{h+}(k + n_s - 1)\bar{R}_s^{-1}(k + n_s). \end{array} \tag{45}$$

Here, $\bar{R}_{h+}(k)$ is defined by

$$\begin{array}{r} \bar{R}_{h+}(k) = [\ r_h{}_1^1(k) \quad \cdots \quad r_h{}_{d_1}^1(k)| \cdots \\ \cdots |r_h{}_1^m(k) \quad \cdots \quad r_h{}_{d_m}^m(k)\ ] \end{array} \tag{46}$$

where $r_h{}_{d_1}^1(k)$,$\cdots$, $r_h{}_{d_m}^m(k)$ are arbitrarily determined parameters.

From the above, the anti-causal augmented dual system, (38), has lexicographically-fixed reachability indices, $d_i$. Thus, using the pole placement technique stated in the section 2, the matrix $H_s^T(k)$ can be obtained so that $A_s^T(k) + C_s^T(k)H_s^T(k)$ is equivalent to some constant matrix $A_o^{*T}$ which has desired constant eigenvalues. i.e., there exists some transformation matrix, $Q_s(k) \in R^{n_s \times n_s}$, such that

$$Q_s(k+1)\{A_s(k) + C_s(k)H_s(k)\}Q_s^{-1}(k) = A_o^* \tag{47}$$

Hence, if $Q_s(k)$ is the Lyapunov transformation, (34) and (35) becomes the augmented observer, and $e(k)$ and $\epsilon(k)$ converge to 0.

## V. Stability of the Total Closed Loop

If the system (1), (2) has both of non-lexicographically-fixed reachability indices and non-lexicographically-fixed observability indices, the augmented plant and the augmented observer are needed for the observer based pole placement. In this section, for such a system, the stability of the total closed loop system and the separation principle are considered.

The augmented plant is (17), and the augmented observer is (34), (35). Then, for the observer based pole placement, the state feedback (29) is modified to

$$u(k) = \left[\begin{array}{cc} D_x(k) & D_e(k) \end{array}\right] \left[\begin{array}{c} \hat{x}(k) \\ \hat{x}_e(k) \end{array}\right] \tag{48}$$

where $\hat{x}(k)$ is the state estimation. In this state feedback, $\hat{x}_e(k)$ is used instead of $x_e(k)$, because, in the second equation of (17), $x(t)$ should be replaced by $\hat{x}(k)$.

Hence, the total closed loop system for this case becomes as follows.

$$\begin{array}{l} \left[\begin{array}{c} x(k+1) \\ \hat{x}_e(k+1) \\ \hat{x}(k+1) \\ \epsilon(k+1) \end{array}\right] = \left[\begin{array}{cc} A & BD_e \\ 0 & A_1 + B_eD_e \\ -HC & BD_e \\ H_eC & 0 \end{array}\right. \\ \left.\begin{array}{cc} BD_x & 0 \\ A_2 + B_eD_x & 0 \\ A + BD_x + HC & -A_4 - HC_e \\ -H_eC & A_3 + H_eC_e \end{array}\right] \left[\begin{array}{c} x(k) \\ \hat{x}_e(k) \\ \hat{x}(k) \\ \epsilon(k) \end{array}\right] \end{array} \tag{49}$$

Using the transformation matrix

$$T = \left[\begin{array}{cc|cc} I & 0 & 0 & 0 \\ 0 & I & 0 & 0 \\ \hline I & 0 & -I & 0 \\ 0 & 0 & 0 & I \end{array}\right] \qquad (50)$$

the total system (49) is transformed into

$$\begin{bmatrix} x(k+1) \\ \hat{x}_e(k+1) \\ e(k+1) \\ \epsilon(k+1) \end{bmatrix} = \begin{bmatrix} A+BD_x & BD_e & -BD_x & 0 \\ A_2+B_eD_x & A_1+B_eD_e & -A_2-B_eD_x & 0 \\ 0 & 0 & A+HC & A_4+HC_e \\ 0 & 0 & H_eC & A_3+H_eC_e \end{bmatrix} \begin{bmatrix} x(k) \\ \hat{x}_e(k) \\ e(k) \\ \epsilon(k) \end{bmatrix}$$

$$= \begin{bmatrix} A_g+B_gD_g & E \\ 0 & A_s+C_sH_s \end{bmatrix} \begin{bmatrix} x(k) \\ \hat{x}_e(k) \\ e(k) \\ \epsilon(k) \end{bmatrix} \qquad (51)$$

where

$$E(k) = \begin{bmatrix} -B(k)D_x(k) & 0 \\ -A_2(k)+B_e(k)D_x(k) & 0 \end{bmatrix}. \qquad (52)$$

In (49) and (51), the symbol "(k)" is omitted because of the small space.

From the above, using the transformation matrix

$$\Phi(k) = \begin{bmatrix} P_g(k) & 0 \\ 0 & Q_s(k) \end{bmatrix} \qquad (53)$$

the following relation is obtained.

$$\Phi(k+1)\begin{bmatrix} A_g(k) & E(k) \\ 0 & A_s(k) \end{bmatrix}\Phi^{-1}(k) = \begin{bmatrix} A^* & P_g(k+1)E(k)Q_s^{-1}(k) \\ 0 & A_o^* \end{bmatrix} \qquad (54)$$

Thus, since the system matrix of (49) is equivalent to the right hand side of (54), if. $P_g(k)$ and $Q_s(k)$ are the Lyapunov transformation matrices, the total closed system is stable and has a property of the separation principle.

## VI. Numerical Example

Consider the system (1), (2) with

$$A(k) = \begin{bmatrix} 2\cos(1.5k) & 0 & 0 \\ 2\sin(1.5(k-1)) & 0 & -2 \\ 2\sin(1.5k) & 2\cos(1.5k) & 0 \end{bmatrix} \qquad (55)$$

$$B(k) = \begin{bmatrix} 1 & 0 \\ 0 & 1 \\ \sin(1.5k) & 0 \end{bmatrix} \qquad (56)$$

$$C(k) = \begin{bmatrix} \frac{1}{2}\cos(1.5(k-1)) & 0 & \frac{1}{2}\cos(1.5(k-1)) \\ 0 & \frac{1}{2} & 0 \end{bmatrix} \qquad (57)$$

This system has non-lexicographically-fixed reachability indices and non-lexicographically-fixed observability indices. We design the observer based pole placement for this system. Because of the small space, we use the following symbols, i.e., $S = \sin(1.5k), S_1 = \sin(1.5(k-1)), C = \cos(1.5k), C_1 = \cos(1.5(k-1))$

The reachability indices of this system is $\mu_1 = 2$, $\mu_2 = 1$ or $\mu_1 = 1$, $\mu_2 = 2$. From this $v_1 = v_2 = 2$. The Augmented plant equation (17) becomes

$$x_g(k+1) = A_g(k)x_g(k) + B_g(k)u(k) \qquad (58)$$

$$\begin{cases} x_g(k) = \begin{bmatrix} x(k) \\ x_e(k) \end{bmatrix} \\ A_g(k) = \begin{bmatrix} A(k) & 0 \\ A_2(k) & A_1(k) \end{bmatrix}, B_g(k) = \begin{bmatrix} B(k) \\ B_e(k) \end{bmatrix} \end{cases}$$

where $x_g(k) \in R^4$ and $x_e(k) \in R^1$, and

$$B_e(k) = \begin{bmatrix} -1 & 0 \end{bmatrix} \qquad (59)$$

$$\begin{bmatrix} A_2(k) & A_1(k) \end{bmatrix} = \begin{bmatrix} 2S^2S_1^2(C_1+1) & -2S & -2C_1S^2S_1 & -2C_1^2S^2 \end{bmatrix}. \qquad (60)$$

On the other hand, the observability indices of this system is also $\nu_1 = 2$, $\nu_2 = 1$ or $\nu_1 = 1$, $\nu_2 = 2$. Then, the augmented observer becomes

$$\begin{aligned} \hat{x}(k+1) &= A(k)\hat{x}(k) + B(k)u(k) \\ &\quad -H(k)(y(k) - C(k)\hat{x}(k)) \\ &\quad -(A_4(k) + H(k)C_e(k))\epsilon(k) \qquad (61) \\ \epsilon(k+1) &= A_3(k)\epsilon(k) + H_e(k)(y(k) - C(k)\hat{x}(k)) \\ &\quad +H_e(k)C_e(k)\epsilon(k). \qquad (62) \end{aligned}$$

Here, $\epsilon(k) \in R^1$ and

$$\begin{aligned} C_e^T(k) &= \begin{bmatrix} 2 & 0 \end{bmatrix} \qquad (63) \\ \begin{bmatrix} A_4^T(k) & A_3^T(k) \end{bmatrix} &= \begin{bmatrix} 0 & 0 & 0 & 0 \end{bmatrix}. \qquad (64) \end{aligned}$$

Using the following desired stable characteristic polynomial for both of the pole placement and the observer

$$\begin{aligned} q^1(z) &= \alpha_2^1z^2 + \alpha_1^1z + \alpha_0^1 = z^2 + 0.4z - 0.05 \qquad (65) \\ q^2(z) &= \alpha_2^2z^2 + \alpha_1^2z + \alpha_0^2 = z^2 + 0.4z - 0.05 \qquad (66) \end{aligned}$$

the simulation results are shown in Fig.1 and Fig.2. Fig.1 shows the response of the augmented system, $[x(k), \hat{x}_e(k)] = [x_1(k), x_2(k), x_3(k), \hat{x}_e(k)]$, and Fig.2 shows the response of augmented state estimation error, $[e(k), \epsilon(k)] = [e_1(k), e_2(k), e_3(k), \epsilon(k)]$.

## VII. Conclutions

In this paper, the design procedure of the observer-based pole placement for linear time-varying MIMO systems is proposed. Especially, the system is supposed to have the non-lexicographically-fixed reachability indices and non-lexicographically-fixed observability indices. The total closed loop stability and the separation principle are also established.

## Appendix

Let $\tilde{c}_i^T(k)$ be the $i$-th row of $\tilde{C}(k)$. Then, we define $\tilde{c}_i^{lT}(k)$ by the following for $i = 1, \cdots, m$.

$$\begin{aligned} \tilde{c}_i^{0T}(k) &= \tilde{c}_i^T(k) \\ \tilde{c}_i^{(l+1)T}(k) &= \tilde{c}_i^{lT}(k+1)A(k) \end{aligned}$$

Using this, $F(k)$ is calculated by

$$F(k) = \begin{bmatrix} F_1^T(k) \\ \vdots \\ F_m^T(k) \end{bmatrix}$$

where

$$F_i^T(k) = [\alpha_0^i, \alpha_1^i, \cdots, \alpha_{\mu_i-1}^i, 1] \begin{bmatrix} \tilde{c}_i^{0T}(k) \\ \tilde{c}_i^{1T}(k) \\ \vdots \\ \tilde{c}_i^{\mu_i T}(k) \end{bmatrix}.$$

$\Lambda(k)$ is calculated as

$$\Lambda(k) = \begin{bmatrix} 1 & \gamma_{12}(k) & \gamma_{13}(k) & \cdots & \gamma_{1m}(k) \\ 0 & 1 & \gamma_{23}(k) & \cdots & \gamma_{2m}(k) \\ 0 & 0 & 1 & \cdots & \gamma_{3m}(k) \\ \vdots & \vdots & & \ddots & \vdots \\ 0 & 0 & \cdots & \cdots & 1 \end{bmatrix}$$

where $\gamma_{ij} = \tilde{c}_i^{(\mu_i-1)T} b^j(k) \quad (j \geq i+1)$.

# Periodic Disturbance Rejection of a Class of Nonlinear System

Xiafei Tang and Zhengtao Ding

Manchester, M13 9PL, UK
Email: zhengtao.ding@manchester.ac.uk

***Abstract*—This study presents a periodic disturbance rejection method for a class of nonlinear systems with the input weighting vector in the proportional nonlinear form. Especially, the periodic disturbance does not match with the system input. A neural network approximator is employed for the estimation of the ideal feedforward control input that tackles the influence brought by disturbances in closed-loop system. Moreover, The adaptive control techniques are applied to deal with nonlinear uncertainties and unknown parameters in the system. The proposed control design ensures the closed-loop convergence of the system, i.e. all states converge to a small set around their equilibrium points. A simulation example is included to support this control approach.**

## I. Introduction

Disturbance rejection of nonlinear systems is a widely discussed issue in the recent decade. Many existing disturbance rejection results are based on the internal model principle. An internal model is constructed to generate a desired feedforward input for the annihilation of disturbance. For the disturbance signal generated by an unknown linear exosystem, the global asymptotic stability of a disturbed nonlinear system is achieved via state feedback with a state observer and an internal model [1]. With an additional filter design, this method is extended to a nonlinear system whose nonlinear uncertainties and disturbance uncertainties are tackled concurrently [2]. Generally, not all disturbance signals are linear in practice. From this point of view, periodic disturbances suppression is investigated. An adaptive feedforward disturbance cancellation scheme is proposed for the rejection of sinusoidal disturbances [3] [4]. In particular, periodic disturbances generated by a nonlinear exosystem are considered. The asymptotic tracking is achieved for an output feedback nonlinear system via incorporating filtered transformation, high gain control and saturation for internal model design [5]. As a special case, the periodic disturbance rejection problem is examined. The nonlinear system disturbed by general periodic disturbances which are half-period alternative is asymptotically suppressed. With known wave profiles of disturbances, an estimate of the feedforward control input is constructed by bringing in new operations of a half-period integration and a delay operator [6]. This method is extended to a nonlinear system with unmatched disturbances in [7].

The aforemetioned publications focus on the reconstruction of feedforward control input via internal model design. In fact, the output of the exosystem is constrained by its structures, i.e. not all periodic disturbances can be generated by the exosystem. In terms of a general periodic disturbance without dynamic limits, new approximation methods are worth being investigated. As a hot topic, Neural Network (NN) is exploited in many control design applications. It is well-known that NN can be used to estimate any nonlinear signals in a compact set. The theory about adaptive NN approximator for the periodically disturbed nonlinear function is established. With different selections of basis functions, two types of three-layer NN approximator are included as FSE-MNN-based approximator and FSE-RBFNN-based approximator [8]. After that, A two-layer NN approximator in [9] is introduced for output feedback stochastic nonlinear stabilisation. Motivated by these NN approximator designs, the two-layer approximator is used to estimate the feedforward control input in [10].

Note that the aforementioned nonlinear system has a constant input vector. Recently, disturbance suppression is established for various types of nonlinear systems with time varying weighting vector. Robust adaptive techniques are used in output feedback control design for a disturbed nonlinear system. It is notified that the system is in output feedback form with time varying input and disturbance vectors. The terminology of flat zone in a neighbourhood of the origin is introduced such that output tracking error converges to the flat zone under that control. It is also specified that, in this case, the element in input vector is coupled with a nonlinear function of output [11]. A novel asymptotic disturbance rejection approach for unknown sinusoidal disturbances is designed for nonlinear systems in output feedback form with an input gain vector whose element is a function of the output [12].

In this paper, a new disturbance rejection method is introduced for a nonlinear system in output feedback form

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

with an input vector with elements being a production of a constant and a nonlinear function of output. This research is still based on the existence of an invariant manifold which has a zero output under an ideal feedforward control input. To extract the zero dynamics of the system, a filter based transformation is proposed as similar as in [5]. As matter of fact that an NN can be used to estimate any nonlinear signals in a prescribed compact set. Since the desired feedforward control input is regarded as an unknown function of bounded disturbance signal, an NN approximator is applied for its estimation. In addition, a new unknown parameter is introduced to compensate the closed-loop influence from nonlinear uncertainties. Adaptive techniques are then applied to estimate unknown parameters online. Finally, backstepping control design based on the estimate of filters is carried out. Lyapunov stability analysis is presented to confirm the closed-loop stability. All states converge to a small area around their equilibrium points. Compared with the existing results, the information of disturbance are not necessarily needed. Furthermore, the disturbance can be any type of periodic signals.

The structure of this paper is organised as follows. The problem description is presented in section II. Section III introduces a filtered transformation and extracts system zero dynamics. The NN approximator design is addressed in section IV. Adaptive backstepping control design procedures are presented in section V. Lyapunov stability analysis is then followed to ensure the convergence of the closed-loop system in section VI. A simulation example is included in section VII to demonstrate a standard control approach. Finally, section VIII concludes this paper.

## II. Problem Statement

Consider SISO nonlinear systems which can be transformed to the output feedback form as

$$\left\{\begin{array}{lcl} \dot{x} & = & Ax+\phi(y)+b\sigma(y)u+dw \\ y & = & C^T x \end{array}\right. \tag{1}$$

with

$$A=\begin{bmatrix} 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & 1 \\ 0 & 0 & \cdots & 0 \end{bmatrix}, b=\begin{bmatrix} 0 \\ \vdots \\ b_\rho \\ \vdots \\ b_n \end{bmatrix}, C=\begin{bmatrix} 1 \\ \vdots \\ 0 \end{bmatrix},$$

and $d=[d_1,\ldots,d_n]^T$ where state $x=[x_1,\ldots,x_n]^T$, output $y\in\mathbb{R}$, input $u\in\mathbb{R}$, smooth nonlinear function $\phi(y)=[\phi_1(y),\ldots,\phi_n(y)]^T$ with $\phi(0)=0$, smooth function $\sigma(y):\mathbb{R}\to\mathbb{R}$ with $\sigma(y)\neq 0$, $w\in\mathbb{R}$ is a bounded periodic disturbance signal, $b_i\neq 0$ for $i=\rho,\ldots,n$, i.e. this system is a relative degree $\rho$ system.

The assumption below is necessary for this control design.

***Assumption*** *2.1:* The system is minimum phase, that is, the zeros of polynomial $\mathscr{B}(s)=\sum_{i=\rho}^{n} b_i s^{n-i}$ have negative real parts.

The design objective of disturbance rejection problem is described as: Find out a finite dimensional system

$$\left\{\begin{array}{lcl} \dot{\mu} & = & \nu(\mu,y,u),\mu\in\mathbb{R} \\ u & = & \zeta(\mu,y) \end{array}\right. \tag{2}$$

The closed-loop system is then stable under this controller.

## III. Filtered State Transformation

For system (1) with relative degree $\rho$, a filter is introduced as

$$\left\{\begin{array}{lcl} \dot{\xi}_1 & = & -\lambda_1\xi_1+\xi_2 \\ & \vdots & \\ \dot{\xi}_{\rho-1} & = & -\lambda_{\rho-1}\xi_{\rho-1}+\sigma(y)u \end{array}\right. \tag{3}$$

where $\lambda_i>0$ for $i=1,\ldots,\rho-1$ are the designed parameters. The filtered transformation is implemented by introducing

$$\bar{z}=x-[\bar{f}_1,\ldots,\bar{f}_{\rho-1}]\xi \tag{4}$$

where $\xi\in\mathbb{R}^{\rho-1}$, $\bar{f}_i\in\mathbb{R}^n$ for $i=1,\ldots,\rho-1$. The value of $\bar{f}_i$ is given recursively by

$$\left\{\begin{array}{lcl} \bar{f}_1 & = & b \\ \bar{f}_i & = & [A+\lambda_{i+1}I]\bar{f}_{i+1} \quad \text{for} \quad i=2,\ldots,\rho-1 \end{array}\right. \tag{5}$$

with positive designed $\lambda_\rho$. Then, the system (1) is transformed to

$$\left\{\begin{array}{lcl} \dot{\bar{z}} & = & A\bar{z}+\phi(y)+dw+f\xi_1 \\ y & = & C^T\bar{z} \end{array}\right. \tag{6}$$

where $f=[f_1,\ldots,f_n]^T=[A+\lambda_1 I]\bar{f}_1$. It is noted that $f_1=b_\rho$. Further, it is observed

$$\mathscr{D}(s):=\sum_{i=1}^{n} f_i s^{n-i}=\mathscr{B}(s)\prod_{i=1}^{\rho+1}(s+\lambda_i) \tag{7}$$

With Assumption 2.1, it implies that all zeros of $\mathscr{D}(s)$ are located on the left half plane. $\xi_1$ is considered as the input of system (7), i.e. this system has relative degree 1. For the convenience of analysing zero dynamics, another state $\tilde{z}\in\mathbb{R}^{n-1}$ is brought in as

$$z=\bar{z}_{2:n}-\frac{f_{2:n}}{f_1}y \tag{8}$$

$(\star)_{2:n}$ stands for a new vector or matrix which is constructed by the 2nd to $n$th raw of $\star$.

The system dynamics with new coordinates is given by

$$\left\{\begin{array}{lcl} \dot{z} & = & Dz+\psi_z(y)+d_z w \\ \dot{y} & = & z_1+\psi_y(y)+d_1 w+b_\rho\xi_1 \end{array}\right. \tag{9}$$

with

$$D = \begin{bmatrix} -\frac{f_2}{f_1} & 1 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ -\frac{f_{n-1}}{f_1} & 0 & \dots & 1 \\ -\frac{f_n}{f_1} & 0 & \dots & 0 \end{bmatrix} \tag{10}$$

where $D$ is the left companion matrix of $f$ and

$$\psi_z(y) = D\frac{f_{2:n}}{f_1}y + \phi_{2:n}(y) - \frac{f_{2:n}}{f_1}\phi_1(y) \tag{11}$$

$$\psi_y(y) = \frac{f_2}{f_1}y + \phi_1(y) \tag{12}$$

$$d_w = d_{2:n} - \frac{f_{2:n}}{b_\rho}d_1 \tag{13}$$

$D$ is Hurwitz from equation (7). Thus, there exist positive matrix $P_z$ and $Q_z$ which satisfy

$$D^T P_z + P_z D = -Q_z \tag{14}$$

With the property of $\phi(y)$, It renders $\psi_z(0) = 0$ and $\psi_y(0) = 0$.

From Isidori's output regulation theory [13], the existence of a controlled invariant manifold is a necessary condition of establishing a solution to nonlinear system output regulation problem. From this point of view, the following assumption is necessary.

***Assumption** 3.1:* There exist an invariant manifold $\pi(w) : \mathbb{R} \to \mathbb{R}^{n-1}$ and a forwarding control input $\mu(w) : \mathbb{R} \to \mathbb{R}$ such that

$$\left\{ \begin{array}{rcl} \dot{\pi} & = & B\pi + d_z w \\ 0 & = & \pi_1 + d_1 w + b_\rho \mu \end{array} \right. \tag{15}$$

Let $\tilde{z}$ denotes the error between $z$ and $\pi$. The final model for control design is obtained as

$$\left\{ \begin{array}{rcl} \dot{\tilde{z}} & = & D\tilde{z} + \psi_z(y) \\ \dot{y} & = & \tilde{z}_1 + \psi_y(y) + b_\rho\left(\xi_1 - \mu\right) \\ \dot{\xi}_1 & = & -\lambda_1\xi_1 + \xi_2 \\ & \vdots & \\ \dot{\xi}_{\rho-1} & = & -\lambda_{\rho-1}\xi_{\rho-1} + \sigma(y)u \end{array} \right. \tag{16}$$

## IV. Neural Networks Disturbance Approximator

In the section, a Neural Networks approximator based on the output $y$ is introduced to approximate the desired input $\mu(\omega)$ on a compact set $\Omega$ [9].

$$\mu = W^T S(y) + \delta \tag{17}$$

where $S(y) = [s_1(y), \dots, s_l(y)]^T : \Omega \to \mathbb{R}^l$ is a known smooth vector function with neural network node number $l > 1$. The basis function is given by Gaussian function as

$$s_i(y) = \exp\left[-\frac{(y-a_i)^2}{h^2}\right], \text{for } i = 1, \dots, l \tag{18}$$

with the centre $a_i \in \Omega$ and the width $h > 0$. The desired weighting vector $W = [W_1, \dots, W_l]^T$ is defined as

$$W := \arg\min_{\hat{W}\in\mathbb{R}^l}\left\{\sup_{y\in\Omega}|\mu - \hat{W}^T S(y)|\right\}$$

$\hat{W}$ is the estimate of $W$, $\delta$ is the NN inherent approximation error satisfying $|\delta| \le \bar{\delta}$, which is the minimum upper bound of $\delta$. It can be decreased by increasing the number of $r$ and $l$. The approximation of $\mu$ can be written as

$$\hat{\mu} = \hat{W}^T S(y). \tag{19}$$

## V. Adaptive backstepping control design

In this control design, some designed parameters are introduced. They satisfy

$$\begin{array}{rcl} c_0 & > & \frac{1}{2} + \frac{b_\rho^2}{4} \\ c_1 & > & -1 \\ c_i & > & 0 \quad \text{for} \quad i = 2, \dots, \rho - 1 \\ h_i & > & 0 \end{array}$$

Define the desired value of $\xi_i$ as $\hat{\xi}_i$ for $i = 1, \dots, \rho - 2$ with error $\tilde{\xi}_i = \xi_i - \hat{\xi}_i$. Therefore, from system (9), we have

$$\dot{y} = \tilde{z}_1 + \psi_y(y) + b_\rho(\hat{\xi}_1 + \tilde{\xi}_1 - \mu) \tag{20}$$

The virtual control is designed as

$$\hat{\xi}_1 = \frac{1}{b_\rho}\left(-c_0 y - \psi_y(y)\right) + \hat{W}^T S(y) \tag{21}$$

Substituting equation (21) into (20), it gives

$$\dot{y} = -c_0 y + \tilde{z}_1 + b_\rho\tilde{\xi}_1 - b_\rho\tilde{W}^T S(y) - b_\rho\delta \tag{22}$$

with the notation $\tilde{W} = W - \hat{W}$.

The backstepping technique is employed to search other virtual controls step by step.

**Step 1**: When $i = 1$,

$$\begin{array}{rcl} \dot{\tilde{\xi}}_1 & = & \dot{\xi}_1 - \dot{\hat{\xi}}_1 \\ & = & -\lambda_1\xi_1 + \xi_2 - \frac{\partial\hat{\xi}_1}{\partial\hat{W}}\dot{\hat{W}} \\ & & -\frac{\partial\hat{\xi}_1}{\partial y}\left(\tilde{z}_1 + \psi_y(y) + b_\rho\left(\xi_1 - \mu\right)\right) \\ & = & -\lambda_1\xi_1 + \tilde{\xi}_2 + \hat{\xi}_2 - \frac{\partial\hat{\xi}_1}{\partial\hat{W}}\dot{\hat{W}} \\ & & -\frac{\partial\hat{\xi}_1}{\partial y}\left(\tilde{z}_1 + \psi_y(y) + b_\rho\left(\xi_1 - \mu\right)\right) \end{array} \tag{23}$$

Design $\hat{\xi}_2$ as

$$\begin{array}{rcl} \hat{\xi}_2 & = & \lambda_1\xi_1 - c_1\tilde{\xi}_1 - h_1\left(\frac{\partial\hat{\xi}_1}{\partial y}\right)^2\tilde{\xi}_1 + \frac{\partial\hat{\xi}_1}{\partial\hat{W}}\dot{\hat{W}} \\ & & +\frac{\partial\hat{\xi}_1}{\partial y}\left(\psi_y(y) + b_\rho\left(\xi_1 - \hat{W}^T S(y)\right)\right) \end{array} \tag{24}$$

**Step i**: Introduce $\xi_\rho$ for the convenience of notation. Similarly, virtual controls are obtained as:

$$\begin{aligned}\hat{\xi}_i \;=\;& -\tilde{\xi}_{i-2}+\lambda_{i-1}\xi_{i-1}-c_{i-1}\tilde{\xi}_{i-1}\\ &+\frac{\partial\hat{\xi}_{i-1}}{\partial y}\left(\psi_y(y)+b_\rho\left(\xi_1-\hat{W}^T S(y)\right)\right)\\ &+\sum_{i=1}^{i-2}\frac{\partial\hat{\xi}_{i-1}}{\partial\xi_i}\dot{\xi}_i-h_{i-1}\left(\frac{\partial\hat{\xi}_{i-1}}{\partial y}\right)^2\tilde{\xi}_{i-1}\\ &+\frac{\partial\hat{\xi}_{i-1}}{\partial\hat{W}}\dot{\hat{W}} \qquad \text{for}\quad i=2,\ldots,\rho \qquad (25)\end{aligned}$$

Finally, the control input $u$ is designed as

$$u=\frac{\hat{\xi}_\rho-\hat{\Theta}r(\tilde{\xi}_{\rho-1},y)}{\sigma(y)} \qquad (26)$$

where $\hat{\Theta}$ is the estimate of $\Theta\in\mathbb{R}$ that is an unknown constant, Smooth nonlinear function $r(\tilde{\xi}_{\rho-1},y)$ is given by

$$r(\tilde{\xi}_{\rho-1},y)=\frac{1}{\tilde{\xi}_{\rho-1}}\left(\|\psi_z(y)\|^2\right) \qquad (27)$$

where $\Theta$ and $r(\tilde{\xi}_{\rho-1},y)$ are introduced for the sake of compensating the closed-loop influence brought by the nonlinear function $\psi_z(y)$. The desired value of $\Theta$ is given by

$$\Theta=\beta\|P_z\|^2 \qquad (28)$$

where $\beta$ is a positive constant satisfying inequality below

$$\beta(1-\lambda_{min})+\frac{1}{2}+\sum_{i=1}^{\rho-1}\frac{1}{4h_i}<0 \qquad (29)$$

where $\lambda_{min}$ denotes the minimum eigenvalue of positive definite matrix $P_z$.

Estimates of unknown parameters $\Theta$ and $W$ are generated by following adaptive laws.

$$\begin{cases}\dot{\hat{\Theta}} \;=\; \gamma_\theta\left(\tilde{\xi}_{\rho-1}r(\tilde{\xi}_{\rho-1},y)-\sigma_\theta\hat{\Theta}\right)\\ \dot{\hat{W}} \;=\; -\Gamma_w\left(b_\rho yS(y)-\displaystyle\sum_{i=1}^{\rho-1}b_\rho\tilde{\xi}_i\frac{\partial\hat{\xi}_i}{\partial y}S(y)+\sigma_w\hat{W}\right)\end{cases} \qquad (30)$$

where $\gamma_\theta\in\mathbb{R}$ and $\Gamma_w\in\mathbb{R}^l$ are positive definite designed adaptive gain matrix, $\sigma_\theta\in\mathbb{R}$ and $\sigma_w\in\mathbb{R}$ are $\sigma$ modification gains which are selected to be small positive constants.

The dynamics of $\tilde{\xi}$ is given by

$$\begin{cases}\dot{\tilde{\xi}}_1 \;=\; \tilde{\xi}_2-c_1\tilde{\xi}_1-h_1\left(\dfrac{\partial\hat{\xi}_1}{\partial y}\right)^2\tilde{\xi}_1-\dfrac{\partial\hat{\xi}_1}{\partial y}\tilde{z}_1\\ \qquad +b_\rho\dfrac{\partial\hat{\xi}_1}{\partial y}\tilde{W}^T S(y)+b_\rho\dfrac{\partial\hat{\xi}_1}{\partial y}\delta\\ \dot{\tilde{\xi}}_i \;=\; -\tilde{\xi}_{i-1}+\tilde{\xi}_{i+1}-c_i\tilde{\xi}_i-h_i\left(\dfrac{\partial\hat{\xi}_i}{\partial y}\right)^2\tilde{\xi}_i\\ \qquad -\dfrac{\partial\hat{\xi}_i}{\partial y}\tilde{z}_1+b_\rho\dfrac{\partial\hat{\xi}_i}{\partial y}\tilde{W}^T S(y)+b_\rho\dfrac{\partial\hat{\xi}_i}{\partial y}\delta\\ \qquad \text{for}\quad i=2,\ldots,\rho-2\\ \dot{\tilde{\xi}}_{\rho-1} \;=\; -\tilde{\xi}_{\rho-2}-c_{\rho-1}\tilde{\xi}_{\rho-1}-\dfrac{\partial\hat{\xi}_{\rho-1}}{\partial y}\tilde{z}_1\\ \qquad -h_{\rho-1}\left(\dfrac{\partial\hat{\xi}_{\rho-1}}{\partial y}\right)^2\tilde{\xi}_{\rho-1}+b_\rho\dfrac{\partial\hat{\xi}_{\rho-1}}{\partial y}\delta\\ \qquad +b_\rho\dfrac{\partial\hat{\xi}_{\rho-1}}{\partial y}\tilde{W}^T S(y)-\hat{\Theta}r(\tilde{\xi}_{\rho-1},y)\end{cases} \qquad (31)$$

## VI. Stability analysis

The stability analysis is based on Lyapunov stabilising theory. The Lyapunov function candidate of this system is chosen as

$$V=V_y+\beta V_z+\sum_{i=1}^{\rho-1}V_{\xi_i}+V_w+V_\theta \qquad (32)$$

with

$$\begin{cases}V_y \;=\; \dfrac{1}{2}y^2\\ V_z \;=\; \tilde{z}^T P_z\tilde{z}\\ \displaystyle\sum_{i=1}^{\rho-1}V_{\xi_i} \;=\; \dfrac{1}{2}\sum_{i=1}^{\rho-1}\tilde{\xi}_i^2\\ V_w \;=\; \dfrac{1}{2}\tilde{W}^T\Gamma_w^{-1}\tilde{W}\\ V_\theta \;=\; \dfrac{1}{2}\gamma_\theta^{-1}\tilde{\Theta}^2\end{cases} \qquad (33)$$

with the notation $\tilde{\Theta}=\Theta-\hat{\Theta}$.

From equation (22), it shows

$$\begin{aligned}\dot{V}_y \;=&\; y\dot{y}\\ =&\; -c_0y^2+y\tilde{z}_1+b_\rho y\tilde{\xi}_1-b_\rho y\tilde{W}^T S(y)-b_\rho y\delta\\ \leq&\; -c_0y^2+\frac{1}{2}y^2+\frac{1}{2}\|\tilde{z}\|^2+\frac{b_\rho^2}{4}y^2+\tilde{\xi}_1^2\\ &\; -b_\rho y\tilde{W}^T S(y)-b_\rho y\delta\\ \leq&\; \left(-c_0+\frac{1}{2}+\frac{b_\rho^2}{4}\right)y^2+\frac{1}{2}\|\tilde{z}\|^2+\tilde{\xi}_1^2\\ &\; -b_\rho y\tilde{W}^T S(y)-b_\rho y\delta \qquad (34)\end{aligned}$$

then from equation (9), it is obtained

$$\begin{aligned}\dot{V}_z &= \dot{\tilde{z}}^T P_z \tilde{z} + \tilde{z}^T P_z \dot{\tilde{z}} \\ &= \tilde{z}^T \left(D^T P_z + P_z D\right) \tilde{z} + 2\tilde{z}^T P_z \psi_z(y) \\ &\le (1-\lambda_{min})\|\tilde{z}\|^2 + \|P_z\|^2 \|\psi_z(y)\|^2 \end{aligned} \tag{35}$$

With dynamics of $\tilde{\xi}_i$ in equation (31), it is derived that

$$\begin{aligned}\sum_{i=1}^{\rho-1} \dot{V}_{\xi_i} &= -\sum_{i=1}^{\rho-1}\left(c_i\tilde{\xi}_i^2 + h_i\left(\frac{\partial\hat{\xi}_i}{\partial y}\right)^2 \tilde{\xi}_i + \frac{\partial\hat{\xi}_i}{\partial y}\tilde{z}_1\right) \\ &\quad + \sum_{i=1}^{\rho-1} b_\rho \tilde{\xi}_i \frac{\partial\hat{\xi}_i}{\partial y}\tilde{W}^T S(y) + \sum_{i=1}^{\rho-1} b_\rho \tilde{\xi}_i \frac{\partial\hat{\xi}_i}{\partial y}\delta \\ &\quad - \tilde{\xi}_{\rho-1}\hat{\Theta} r(\tilde{\xi}_{\rho-1}, y) \\ &\le -\sum_{i=1}^{\rho-1}\left(c_i\tilde{\xi}_i^2 - \frac{1}{4h_i}\|\tilde{z}\|^2\right) + \sum_{i=1}^{\rho-1} b_\rho \tilde{\xi}_i \frac{\partial\hat{\xi}_i}{\partial y}\delta \\ &\quad + \sum_{i=1}^{\rho-1} b_\rho \tilde{\xi}_i \frac{\partial\hat{\xi}_i}{\partial y}\tilde{W}^T S(y) - \tilde{\xi}_{\rho-1}\hat{\Theta} r(\tilde{\xi}_{\rho-1}, y) \end{aligned} \tag{36}$$

Further, from equation (30), we have

$$\begin{aligned}\dot{V}_w &= -\tilde{W}^T \Gamma_w^{-1} \dot{\hat{W}} \\ &= b_\rho y \tilde{W}^T S(y) - \sum_{i=1}^{\rho-1} b_\rho \tilde{\xi}_i \frac{\partial\hat{\xi}_i}{\partial y}\tilde{W}^T S(y) + \sigma_w \tilde{W}^T \hat{W} \end{aligned} \tag{37}$$

$$\begin{aligned}\dot{V}_\theta &= -\gamma_\theta^{-1}\tilde{\Theta}\dot{\hat{\Theta}} \\ &= -\tilde{\xi}_{\rho-1}\tilde{\Theta} r(\tilde{\xi}_{\rho-1}, y) + \sigma_\theta \tilde{\Theta}\hat{\Theta} \end{aligned} \tag{38}$$

Therefore

$$\begin{aligned}\dot{V} &\le \left(-c_0 + \frac{1}{2} + \frac{b_\rho^2}{4}\right) y^2 - (c_1+1)\tilde{\xi}_1^2 - \sum_{i=2}^{\rho-1} c_i \tilde{\xi}_i^2 \\ &\quad + \left(\beta(1-\lambda_{min}) + \frac{1}{2} + \sum_{i=1}^{\rho-1}\frac{1}{4h_i}\right)\|\tilde{z}\|^2 \\ &\quad + \beta\|P_z\|^2\|\psi_z(y)\|^2 - \tilde{\xi}_{\rho-1}\Theta r(\tilde{\xi}_{\rho-1}, y) \\ &\quad + \sigma_w \tilde{W}^T \hat{W} + \sigma_\theta \tilde{\Theta}\hat{\Theta} - b_\rho y \delta + \sum_{i=1}^{\rho-1} b_\rho \tilde{\xi}_i \frac{\partial\hat{\xi}_i}{\partial y}\delta \end{aligned} \tag{39}$$

$$\begin{aligned} &\le 2\left(-c_0 + \frac{1}{2} + \frac{b_\rho^2}{4}\right) V_y - 2(c_1+1)V_{\xi_1} \\ &\quad + \left(\beta(1-\lambda_{min}) + \frac{1}{2} + \sum_{i=1}^{\rho-1}\frac{1}{4h_i}\right)\frac{V_z}{\lambda_p} \\ &\quad - \sum_{i=2}^{\rho-1} 2c_i V_{\xi_i} - \sigma_w \Gamma_w V_w - \sigma_\theta \gamma_\theta V_\theta + \frac{\sigma_w}{2}\|W\|^2 \\ &\quad + \frac{\sigma_\theta}{2}\|\Theta\|^2 - b_\rho y \delta + \sum_{i=1}^{\rho-1} b_\rho \tilde{\xi}_i \frac{\partial\hat{\xi}_i}{\partial y}\delta \end{aligned} \tag{40}$$

Note that the derivative of $V$ is in a form of $\dot{V} = -\zeta V + \eta$ where $\zeta > 0$, and $\eta$ is bounded. The system converges to a small region around its equilibrium points when time $t$ tends to infinity.

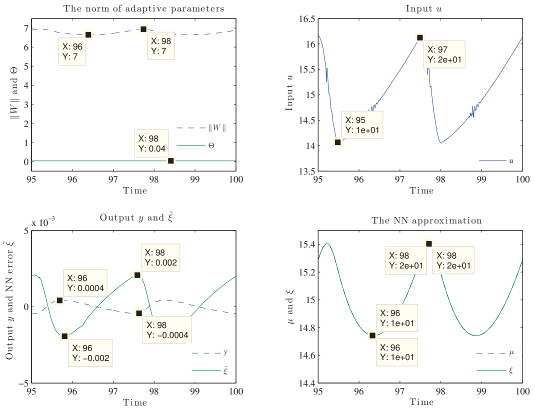

Fig. 2: An enlargement of Figure 1

## VII. Simulation study

Consider a three order disturbed nonlinear system as

$$\begin{cases}\dot{x}_1 &= x_2 + y^2 \\ \dot{x}_2 &= x_3 + y^3 + 2w + (|y| + 0.1)u \\ \dot{x}_3 &= 3w + (|y| + 0.1)u\end{cases}$$

The filter is selected as

$$\dot{\xi} = -\xi + (|y| + 0.1)u$$

with the virtual control given by

$$\hat{\xi} = -3y - 2y - y^2 + W^T S(y)$$

It is easy to find

$$D = \begin{bmatrix} -2 & 1 \\ -1 & 0 \end{bmatrix}$$

Adaptive laws are designed as

$$\begin{cases}\dot{\hat{W}} &= -\Gamma_w(yS(y) - \tilde{\xi}\dfrac{\partial\hat{\xi}}{y}S(y) + \sigma_W W) \\ \dot{\hat{\Theta}} &= \gamma_\theta\left((-3y + y^3 - 2y^2)^2 + (-2y - y^2)^2 - \sigma_\theta\Theta\right)\end{cases}$$

with adaptive gains $\Gamma_w = 100I$, $\gamma_\theta = 100$, and $\sigma$-modification gains $\sigma_W = 0.00001$, $\sigma_\theta = 0.00003$. Following our backstepping design procedure, the control input $u$ is designed as

$$\begin{aligned} u &= \frac{1}{|y|+0.1}\left(\xi - \tilde{\xi} - \left(\frac{\partial \hat{\xi}_1}{\partial y}\right)^2 \tilde{\xi} + \frac{\partial \hat{\xi}}{\partial \hat{W}}\dot{\hat{W}}\right) \\ &\quad + \frac{1}{|y|+0.1}\frac{\partial \hat{\xi}}{\partial y}(2y+y^2+\xi-\hat{W}^T S(y)) \\ &\quad - \frac{1}{|y|+0.1}\frac{\hat{\Theta}}{\tilde{\xi}}\left((-3y+y^3-2y^2)^2+(-2y-y^2)^2\right) \end{aligned}$$

where

$$\begin{aligned} \frac{\partial \hat{\xi}_1}{\partial y} &= -\frac{1}{5+2y} + W^T S'(y) \\ \frac{\partial \hat{\xi}}{\partial \hat{W}} &= S^T(y) \end{aligned}$$

The simulation result is illustrated in Fig. 1 and Fig. 2. Fig. 2 shows the steady state of systems. It can be observed that all states are going to be stable. The first subfigure illustrates the norm of adaptive parameters, the second subfigure presents the system control input which has a little transient attenuation that is caused by the small NN approximation error, the third subfigure shows the convergence of output ($|y| < 0.0001$) and NN approximation error ($|\tilde{\xi}| < 0.002$), to the end, it is also observed that the NN approximator works well from last subfigure.

## VIII. Conclusions

In this paper, disturbance rejection is achieved for a periodically disturbed nonlinear system in output feedback form with time varying input weighting vector. NN is applied to approximate the feedforward control input $\mu$. Compared with the results in [7], it is noticed the control design method is in the same way with different disturbance approximation methods. The proposed NN method estimates the feedforward control input without any pre-known information. While in [7], the wave profile of the disturbance signal is assumed to be half-period alternative. The disturbance period is known for the regeneration of the real amplitude and phase shift. Nevertheless, the method in [7] has a quick and nice time response. Generally, it is not easy to have the period of the disturbance in the real practice. The NN approximation method is a good choice when the information of disturbance signals are not enough.

***Abstract*—Alternative parameterisations have been shown to improve the feasible region for a predictive control law when the number of degrees of freedom is limited. One question yet to be resolved is: which alternative parameterisation is best for a particular problem and what choice of parameter(s) within each parameterisation will lead to an improved feasible region with good performance? This paper tackles this question and demonstrates two systematic approaches to select the best alternative parameterisations. These approaches are based on multiobjective optimisation and a pragmatic selection. Numerical examples demonstrate the efficacy of both methods.**

**Keywords: Alternative parameterisation, Feasibility, multiobjective optimisation.**

## I. Introduction

Model Based Predictive Control (MPC) or receding horizon control (RHC) or embedded optimisation or moving horizon or predictive control [2], [3], [1], is the general name for different computer control algorithms that use past information of the inputs and outputs and a mathematical model of the plant to optimise predicted future behaviour. MPC has been developed widely both in the process industry and control research community and has reached a high degree of maturity in its linear variant. Currently MPC research focuses on stochastic and nonlinear scenarios, robustness and fast optimisation or related computational aspects.

All algorithms to some extent form a trade-off between feasibility, optimality and inexpensive optimisation, but may not have systematic tools for doing this trade-off. The success of earlier industrial heuristic MPC algorithms motivated the research community to develop several algorithms with improved performance and feasibility. There are several successful theoretical approaches but few of them are exploited commercially for real-time implementation. One important issue for real-time implementation is the ability to do a systematic trade-off between feasibility, performance and computational burden when choosing from currently available algorithms. In recent years many authors have focussed on parametric solutions [5] or efficient implementations of online optimisers (e.g. for quadratic programming). However, this paper will follow a different route and consider the underlying structure of the MPC algorithm. Specifically, this paper proposes a systematic selection of an alternative parameterisation to enlarge the feasible region without too much detriment to performance (or optimality) and the computational burden.

In an MPC problem formulation, stability can be ensured using dual mode prediction by including a terminal constraint at the expense of the computational load [16]. In dual mode prediction, different formulations of the degrees of freedom (d.o.f.) or decision variables have been utilized using interpolation techniques [8] to enlarge feasible region without detriment to performance. There are different variants of interpolation, however, these methods are limited to small dimensional systems. Another approach in the literature is a concept of triple mode control [6], [7]; the triple mode strategy introduces an extra mode which may reduce t he online computational burden with good performance and feasibility. However, in this strategy, the challenge is to find a suitable linear time varying (LTV) control law which enlarge feasible region with improved performance. One pragmatic solution to finding this law is tackled in [12] which used Laguerre parameterisations. However, this paper does not pursue Triple mode approaches as the offline complexity and decision making is substantially increased as compared to dual mode approaches.

More recently, alternative parameterisation based on Laguerre [17] and Kautz functions have been proposed to simplify the trade-off without increasing computational burden within dual mode prediction paradigm [9], [10], [11]. The main idea is to form the degrees of freedom in the predictions as a combination of either Laguerre or Kautz functions. These functions have proven to be a very effective for improving the volume of the feasible region with a limited number of d.o.f. These alternative parameterisations are generalised using orthonormal basis functions with Laguerre and Kautz functions as special cases [13].

The key question left to be resolved is, what is the best prediction dynamics to assume for predicted inputs, that is the d.o.f., to allow for a large feasible region without detriment to the closed loop performance and computational burden? In [15], different ways of parameterising the d.o.f. were investigated and a mechanism based on a Monte Carlo approach to define the best parameterisation using optimal sequences for numerous search directions was considered. However, a systematic choice for the underlying dynamics remains an open question. This paper focuses on systematic approaches to identify the best parameterisation dynamics using: (i) a multiobjective optimisation and (ii) a pragmatic choice.

This paper assumes that Laguerre, Kautz and Generalised parameterisation are able to achieve large feasible regions while maintaining local optimality and a relatively low computational complexity [9], [10], [11], [12], [13], [14] and extends the earlier studies in [11], [13] in order to identify a systematic selection of the best parameterisation dynamics. Section II will give the necessary background about an optimal MPC, Laguerre MPC, generalised parameterisation for optimal MPC. Section III discusses two proposed schemes to identify the best parameterisation dynamics based on a muti-objective optimisation and a pragmatic approach. Numerical examples are presented in section IV and paper finishes with conclusions and future work in section V.

## II. Background

This section will summarise the background information related to nominal dual-mode MPC and the use of alternative parameterisations within MPC.

### A. Problem formulation for MPC

Assume a discrete time linear time invariant (LTI) state space model of the form

$$x_{k+1} = Ax_k + Bu_k \tag{1}$$

where $x_k \in R^{n_x}$ and $u_k \in R^{n_u}$ which are the state vectors and the plant input respectively. Assume that the states and inputs at all time instants should fulfill the following constraints:

$$\underline{u} \le u_k \le \overline{u}; \qquad \underline{\Delta u} \le \Delta u_k \le \overline{\Delta u}; \quad \underline{x} \le x_k \le \overline{x} \tag{2}$$

### B. Nominal MPC algorithm

In dual-mode MPC it is assumed that one has total freedom in the choice of the input signal $u_k$ up to horizon $n_c$ subject to constraints. Beyond horizon $n_c$, a terminal control law with an asymptotic stabilising optimal feedback gain $K$ is assumed. The 'predicted' control law [3], [16] takes the form

$$\begin{aligned} u_k &= -Kx_k + c_k, \qquad & k = 0, ..., n_c - 1,\\ u_k &= -Kx_k, & k \ge n_c, \end{aligned} \tag{3}$$

where only first control move is ever implemented, $c_k$ are degrees of freedom (d.o.f.) available for constrained handling. The terminal control law defines an invariant set $\chi_0$ for state vector $x_k$ [8]. This invariant set is also known as maximum admissible set (MAS) which satisfies all polytopic constraints with recursive use of the terminal control law $u_k = -Kx_k \in \chi_0$. The MAS is defined as:

$$\begin{aligned} \chi_0 = \{x_0 \in R^{n_x} : \underline{x} \le x_k \le \overline{x}, \underline{u} \le -Kx_k \le \overline{u},\\ x(k+1) = Ax(k) + Bu(k), \forall k \ge 0\} \end{aligned} \tag{4}$$

In compact form defined as $\chi_0 = \{x_k : Mx_k \le b\}$ for suitable $M$ and $b$. Performance, either predicted or actual, will be assessed by the cost

$$J = \sum_{k=0}^{\infty} x_k^T Q x_k + u_k^T R u_k \tag{5}$$

Substituting the nominal model and predicted control values (3) into (5) and ignoring terms that do not depend upon the d.o.f., one finds from [3] that the optimisation problem in (5) can be reformulated as:

$$\min_{C} \; J_c = C^T S C \; s.t. \; Mx_k + NC \le b; \tag{6}$$

where $C = [c_k^T, \dots, c_{k+n_c-1}^T]$. Details are in the literature [2], [3], [4]. The maximal control admissible set (MCAS) $\chi_c$, the feasible set for optimal control problem in (6) that satisfies all polytopic constraints, is defined as:

$$\chi_c = \{x_k : \exists C, Mx_k + NC \le b\} \tag{7}$$

The optimal MPC (OMPC) algorithm with guarantees of recursive feasibility and convergence, for the nominal case is given by solving QP optimisation (6) at every sampling instance then implementing the first component of $C$, that is $c_k$ in the control law of (3). The algorithm is formulated as:

*Algorithm 2.1:* OMPC [16], [3]

$$c_k^* = arg \min_{c_k} \; J_c \quad s.t. \quad Mx_k + Nc_k \le b;$$

Implement $u_k = -Kx_k + e_1^T c_k^*$ where $e_1^T = [I, 0, \dots, 0]$. When the initial states $x_k \in \chi_0$ then the optimising $c_k^*$ is zero so the terminal control law $u_k = -Kx_k$ is implemented.

*Remark 2.1:* There is a well understood set of potentially conflicting objectives using OMPC e.g. between the desire for good performance and large feasible regions with the equally important desire to keep the number of d.o.f. small. In order for OMPC to obtain a large feasible region and good performance, a large number of d.o.f. or $n_c$ is required.

### C. Generalised parameterisation for Optimal MPC

Alternative parameterisation techniques for the d.o.f. in the future control values have been developed to improve the feasible region in nominal case. Laguerre, Kautz and generalised parameterisations have been proposed in [9], [11], [13] as an effective alternative to the standard basis set. This section will summarise Generalised optimal MPC.

*1) Generalised functions:* The generalised parameterisation [13] is defined using a higher order network such as:

$$\begin{aligned} \mathcal{G}_i(z) = \mathcal{G}_{i-1}(z)\frac{(z^{-1} - a_1)\dots(z^{-1} - a_n)}{(1 - a_1 z^{-1})\dots(1 - a_n z^{-1})};\\ 0 \le a_k < 1, \qquad k = 1 \dots n \end{aligned} \tag{8}$$

With $\mathcal{G}_1(z) = \frac{\sqrt{(1-a_1^2)\dots(1-a_n^2)}}{(1-a_1 z^{-1})\dots(1-a_n z^{-1})}$. The generalised function with $a_k, \forall k = 1, \dots, n$ gives [13]

$$\begin{aligned} &Laguerre: \qquad &\mathcal{G}_i = \mathcal{L}_i, \quad if \;\; a_k = [a]\\ &Kautz: &\mathcal{G}_i = \mathcal{K}_i, \quad if \;\; a_k = [a, b]. \end{aligned} \tag{9}$$

The Laguerre function is a special case of a generalised function and may be computed using the following state-space dynamics model:

$$\mathcal{G}(k+1) = \underbrace{\begin{pmatrix} a & 0 & 0 & 0 & \dots \\ \beta & a & 0 & 0 & \dots \\ -a\beta & \beta & a & 0 & \dots \\ \vdots & \vdots & \vdots & \vdots & \ddots \end{pmatrix}}_{A_G} \mathcal{G}(k); \tag{10}$$

$$\mathcal{G}(0) = \sqrt{1-a^2}[1, -a, a^2, \dots]^T; \ \beta = 1 - a^2$$

*2) GOMPC: generalised functions and MPC:* The predictions using d.o.f. based on generalised functions [13] are:

$$C = \begin{pmatrix} c_k \\ \vdots \\ c_{k+n_c-1} \\ \vdots \end{pmatrix} = \begin{pmatrix} \mathcal{G}(0)^T \\ \mathcal{G}(1)^T \\ \vdots \end{pmatrix} \rho = H_G \rho \tag{11}$$

where $\rho$ is the $n_G$ dimension decision variable when one uses the first $n_G$ column of $H_G$. The only difference between Laguerre MPC and Kautz or generalised MPC is that of $H_G$ matrix. For further details readers are referred to [11] and [13].

*Algorithm 2.2:* GOMPC

$$\begin{aligned} &\rho^* = arg \ \min_{\rho} \ \rho^T [\sum_{i=0}^{\infty} A_G^i \mathcal{G}(0) S \mathcal{G}(0)^T (A_G^i)^T] \rho \\ &s.t. \ Mx_k + NH_G \ \rho \ \leq \ b \end{aligned} \tag{12}$$

Define $c_k^* = H_G \rho_k^*$ and implement $u_k = -Kx_k + e_i^T c_k^*$. where $e_i^T$ is the $i$-th standard basis vector.

*Remark 2.2:* It is straightforward to show, with conventional arguments, that all algorithms (i.e. LOMPC, KOMPC, GOMPC) using terminal constraints within MPC problem formulation provides recursive feasibility and Lyapunov stability.

## III. Best alternative parameterisation selection

In generalised parameterisation there are two clear choices within the future input predictions. First one can choose the order of the dynamics, that is the number of poles $a_i$ in $G_i(z)$, and second is the parameter selection(s), that is the actual values of $a_i$. This section discusses the systematic selection of the parameterisation dynamics by asking what impact this choice has on feasibility and performance?

### A. The best choice for order of the prediction dynamics

The prediction dynamics for the 3rd order prediction dynamics from (8) (which can easily be extended to $n^{th}$ order) can be defined as:

$$\begin{aligned} \mathcal{G}(k+1) &= \underbrace{\begin{pmatrix} b & 0 & 0 & \dots \\ b & c & 0 & \dots \\ -ab & (1-ac) & a & \dots \\ ab^2 & -b(1-ac) & (1-ac) & \dots \\ \vdots & \vdots & \vdots & \ddots \end{pmatrix}}_{A_G} \mathcal{G}(k) \\ \mathcal{G}(0) &= \gamma[1, 1, 1, -a, ab, -abc, a^2bc, \dots]^T, \\ \gamma &= \sqrt{(1-a^2)(1-b^2)(1-c^2)}, \end{aligned} \tag{13}$$

The dynamic structure of the prediction in (13) is quite generic with distinct eigenvalues. To fulfill the algebraic relations in (11), $A_G$ used in (13) must be a square matrix with a maximum number of dimensions the same as $n_c$. Moreover a key observation from the prediction matrix structure is that $dim(A_G) = n_c$ is an upper bound on dynamic dimensions. In fact, one could select $dim(A_G) \leq n_c$.

### B. Multiobjective solution to select best parameterisation

The main objective of this paper is to formulate a systematic method for handling the compromise between feasibility, performance and computational burden. This section shows how one can produce trade-off curves between feasible volume $v$, performance loss $\beta$ and computational burden (implicitly linked to $n_c$) of the parameterised MPC problem. Such trade-off curves allow us to formulate a multi-objective optimisation problem as a function of parameterisation parameters $\alpha = [a_1, \dots, a_m] \in (0, 1)^m$:

$$\begin{aligned} J(n_c, n) := \min_{\alpha} \beta, &\max_{\alpha} v \\ s.t. \ \ Mx + NH\rho &\leq b, \\ v &= \frac{vol(P_H)}{vol(P_{opt})}, \\ \beta &= \frac{1}{n} \sum \frac{J_H(x) - J_{opt}(x)}{J_{opt}(x)}, \\ \alpha = [a_1, \dots, a_m], \ 0 < a_i &< 1, \ m \leq n_c, \\ \mathcal{G}(k+1) &= A_G \mathcal{G}(k), \\ H &= \begin{pmatrix} \mathcal{G}^T(0) & \mathcal{G}^T(1) & \dots \end{pmatrix}^T, \end{aligned} \tag{14}$$

where $P_{opt} := \{(x, c) | Mx + Nc \leq b\}$ represents the MCAS with $n_c = 20$ (used as an approximate for the global maximum MCAS) for comparison, $P_H = \{(x, \rho) | Mx + NH\rho \leq b\}$ is the polytope sliced by the matrix $H$, $vol(.)$ is the volume, $J_{opt}(x) = avg. \ \{J_c(x, c) | (x, c) \in P_{opt}\}$ and $J_H(x) = avg. \ \{J_c(x, H\rho) | (x, \rho) \in P_H\}$ for convex function $J_c(x, c)$.

*1) Volume approximation:* Computing the volume of a high dimensional polytope is a complex task, and can, in the worst case be exponential in the size of the data $M$ and $N$ or $NH$. Consequently, this paper approximates the volume. First select a large number of equi-spaced (by solid angle) or random directions in the state space i.e. $x = (x_1, \dots, x_n)$ and then, for each direction, the distance from the origin to the boundary of MCAS is determined by solving a linear programming (LP) and clearly the larger the distance, hereafter denoted as radius, the better the feasibility. Finally radii are normalised against the radii obtained for $P_{opt}$. Although this might be considered somewhat arbitrary, it seems a pragmatic way of indicating relative volumes of different feasible regions compared to the best feasible shape with a large $n_c$. One might argue that a precise volume measurement would, in some sense, be an equally arbitrary comparison.

*2) Performance approximation:* Similarly in case of calculating the performance loss, it is converted from integral to sampled sum i.e.

$$\beta :\approx \frac{1}{n}\sum \frac{J_H(x)}{J_{opt}(x)} - 1 \qquad (15)$$

That is, one computes the predicted performance for all the given state directions and compares each of these to the 'global' optimum. Equation (15) normalises these so that the best achievable performance would correspond to a $\beta$ measure of unity.

By deploying explicit numeric measures of volume and performance, the multi-objective optimisation problem is able to generate trade-off curves between the d.o.f. $n_c$, average radii and average performance loss of the parameterised problem with different parameterisation settings.

### C. Pragmatic selection

In practice it is known from parameterisation insight that the optimal $\rho_k$ is highly nonlinear in terms of its dependence upon the current state $x_k$; more over the solution is to some extent unpredictable. The following gives a simple approach to identify a pragmatic selection of pole location(s) and order selection of parameterisation dynamics.

*1) Order selection:* The generalised functions with higher order orthonormal functions have more flexibility to improve feasibility while retaining good performance with a limited number of d.o.f. [13]. So $dim(A_G) = n_c$ is a sub-optimal choice to select order parameterisation dynamics.

*2) Parameter selection:* It is observed from simulation results that there is a relation between the closed loop poles and good locations of parameterisation dynamics. The pole locations of generalised functions can be selected to be equal to poles of the closed loop system using an optimal gain $K$; this may be sub-optimal but is efficient.

### D. Summary

In summary, there are two choices: (i) the order of parameterisation dynamics $(dim(A_G))$ and (ii) parameter value(s) or pole location(s) $([a_1, \ldots, a_n])$. One can use multi-objective optimisation to find $dim(A_G)$ and $[a_1, \ldots, a_n]$. Another key observation is that the maximum $dim(A_G) \leq n_c$ and closed loop eigenvalues or pole locations with an optimal gain $K$ are a pragmatic choice to tune the parameterisation dynamics.

## IV. Numerical Examples

In this section three numerical examples are presented to illustrate the efficacy of the proposed approach. The aim is to compare two aspects: (i) feasible regions; (ii) performance loss for the generalised parameterisation dynamics with different parameter(s) or pole location(s) selection by varying the d.o.f. or $n_c$. The trade-off curves are shown between average radius and performance loss as a function of the different parameterisation parameter(s) and d.o.f. or $n_c$. The parallel coordinates are also shown to represent an alternative variation of the parameter(s) and the effects on average performance loss and average feasibility gain. The multi-objective optimisation is done using the NSG-II Matlab toolbox.

### A. Examples

Three numerical examples are simulated using weightings $Q = C^TC$, $R = 2$ and are simulated by varying $n_c = [2, \ldots, 6]$ and with different parameter values. Trade-off curves between average radius and average performance loss are plotted by solving the multi-objective optimisation with varying parameter values. Similarly the effect on average performance loss and average radius are shown by varying $n_c$. Conversely, Table 1 shows the average performance loss and average radius using a pragmatic approach to parameter selection.

*1) Example 1:*

$$A = \begin{bmatrix}1.2\end{bmatrix};\ B = \begin{bmatrix}1\end{bmatrix};\ C = \begin{bmatrix}1\end{bmatrix};$$
$$-0.2 \leq u_k \leq 0.2;\ \ -0.2 \leq \Delta u_k \leq 0.2;\ \ -5 \leq Cx_k \leq 5;$$

*2) Example 2:*

$$A = \begin{bmatrix}0.6 & -0.4\\ 1 & 1.4\end{bmatrix};\ B = \begin{bmatrix}0.2\\ 0.05\end{bmatrix};\ C = \begin{bmatrix}1 & -2.2\end{bmatrix}$$
$$-0.8 \leq u_k \leq 1.5;\ \ -0.4 \leq \Delta u_k \leq 0.4;\ \ -5 \leq Cx_k \leq 5;$$

*3) Example 3:*

$$A = \begin{bmatrix}1 & 0.1 & 0.3\\ 0 & 1 & 0.1\\ 0.4 & 0 & 1\end{bmatrix};\ B = \begin{bmatrix}0\\ 1\\ 1\end{bmatrix};$$
$$C = \begin{bmatrix}1 & 0 & 0\end{bmatrix}$$
$$-2 \leq u_k \leq 2;\ \ -1 \leq \Delta u_k \leq 1;\ \ -5 \leq Cx_k \leq 5;$$

### B. Optimal selection based on multiobjective solution

The multi-objective procedure was run for different sample directions, which were chosen uniformly on the unit circle. The parameters $n_c$ representing d.o.f. were chosen in the range $\{2, \ldots, 6\}$. The results for Examples 1, 2, 3 are shown in Figures 1-2, 3-5 and 6-7 respectively. In all plots, colour circles represent the parameter values $\alpha$.

Figures 1, 3 and 6 show the parallel coordinates and trade-off between average performance loss and average radius by varying $n_c$ with different parameter values $\alpha$. Parallel coordinates are used to plot all axes representing different objectives parallel to each other. Only the Laguerre function parameterisation simulation results are shown in the figures, but there are similar results for higher order parameterisations i.e. Kautz and 3rd order functions. These trade-off curves may be used as a selection criteria to choose best function parameterisation $\alpha$.

Figures 2, 4 and 7 show the trade-off curves between average performance loss and average radius for $n_c = 4$ with different parameterisation dynamics. It is observed that $3rd$ order function parameterisation improves both the feasible region without too much detriment to performance. An average performance loss and feasible region gain for example 2 is shown in figure 5 by varying $n_c \in \{2, \ldots, 6\}$ for a Laguerre parameterisation. One can see that best parameter selection may improve the feasible region and performance with a limited number of d.o.f. $n_c$.

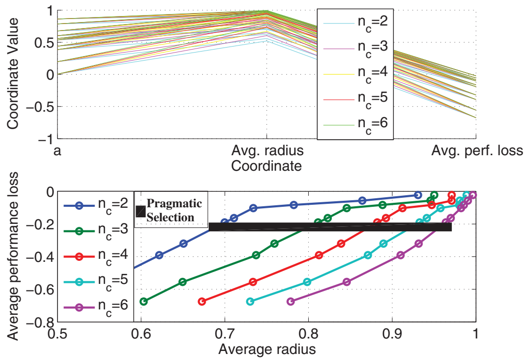

Fig. 1. Parallel coordinates and trade-off curves for Example 1

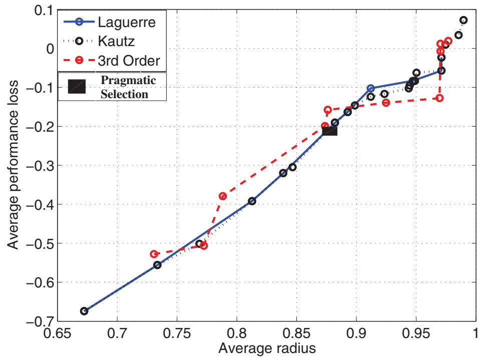

Fig. 2. Trade-off as a function of the parameter $\alpha$ : $n_c = 4$ for Example 1

### C. Sub optimal selection based on closed loop eigenvalues

Table I, II and III show the pragmatic selection of parameterisation dynamics using closed loop eigenvalues with an optimal gain $K$. It is clear from these that pragmatic choices are sub optimal. The selection of parameterisation is based on closed loop eigenvalues so parameterisation order is selected based on example dimensions.

Laguerre parameterisation is the only choice for example 1. With a sub optimal choice of $n_c = 2$ achieves 70 % of feasible set and 22 % of performance loss. Similarly in example 2, there are two parameterisation choices Laguerre and Kautz functions. The Laguerre function achieved 90 % of feasible set with 6 % performance loss. On the otherhand the Kautz function achieved 95 % of feasible set with 1 % performance loss with $n_c = 2$. In example 3, there are three parameterisation choices i.e. Laguerre, Kautz and 3rd order functions. All achieved more than 90 % global feasible set and maximum of 8 % of performance loss.

*Remark 4.1:* It is clear from figures 1-4, 6 and 7 that the pragmatic choice has solution in vicinity of an optimal pareto solution.

*Remark 4.2:* The optimisation structure of an approximate global optimal control is different to the parameterised one, so in few cases performance may even improve.

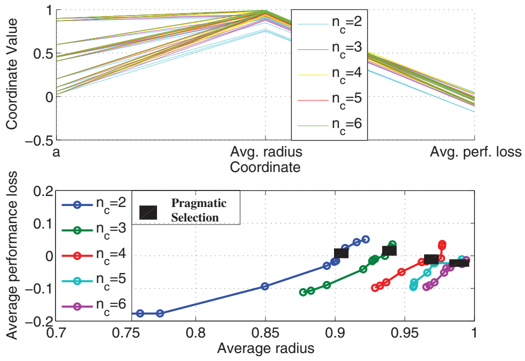

Fig. 3. Parallel coordinates and trade-off curves for Example 2

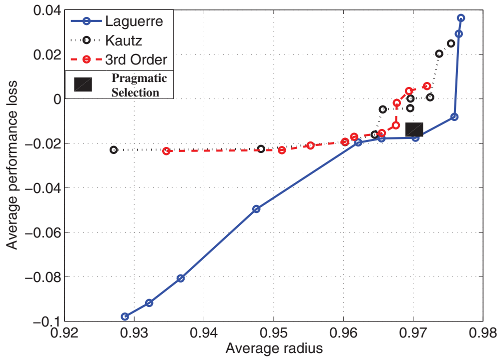

Fig. 4. Trade-off as a function of the parameter $\alpha$ : $n_c = 4$ for Example 2

## V. Conclusion

The main contribution of this paper was to present a systematic approach to selecting the best alternative parameterisation for MPC. Two techniques were discussed based on a multi-objective optimisation and a pragmatic approach using closed loop poles. Examples demonstrate that in many cases nominal closed loop poles are a good sub optimal choice to tune the parameterisation dynamics. However an optimal selection may be made using a multi-objective optimisation technique. In future work there is a need to further investigate in parallel issues such as: will these choices lead to an efficient online optimisation QP structure and/or low complexity multiparametric solution? Finally, it is an interesting future area to consider these choices within a robust scenario.

# Stability analysis and Control design of a Class of Event Based Control Systems

J. Jugo, University of Basque Country, Spain, josu.jugo@ehu.es
M. Eguiraun, ESS-Bilbao Consortium, Spain, meguiraun@essbilbao.org

***Abstract*—Event Based Control (EBC) provides a reduction of mean control rates, which is an important advantage in control systems, specially when network environment gets involved. For this reason, the study of design methodologies for EBC systems that met desired specifications regarding stability and performance issues are a valuable research field. This work presents a control design process applied to a class of EBC systems using LMIs, including stability issues on the light of Asynchronous Dynamical System theory. The application of the proposed methodology is presented by an example, showing good performance in simulation results.**

***Index Terms*—Event Based Control, Linear Matrix Inequality, Asynchronous Dynamical Systems, Control Application**

## I. INTRODUCTION

Event Based Control (EBC) has been considered complex and, in the past, the lack of a well established theory and design methods has limited its use to special cases. However, the interest in EBC control strategies is growing due to its advantages. In particular, its reduction on resource usage, which allows a reduction of the control rate [1], [2], [3], [4]. This characteristic has great importance in embedded systems, where life-time of devices is limited by batteries, or in networked environment, where the reduction on the usage of bandwidth is desirable. For instance, both requirements must be fulfilled in the case of wireless sensor networks.

Following the EBC approach, different alternatives have been developed. In [1], [2], improved system response with a reduction in the control rate is obtained using impulse control signals and observers. In [5], a piecewise control signal based scheme with level-triggered sampling is proposed. More recently in [4], the idea of sporadic control is introduced, where a minimum time difference between sampling times is proposed. A similar control scheme, which is experimentally implemented, presents an improvement of the system response in the presence of delay, jitter and noise, [6]. Moreover, PID controllers have been studied using event based sampling, [7]. The work in [8] presents a modified PID control structure that minimizes different problems related to event based sampling approach.

In addition, different schemes have been analyzed using state-space approach, showing stability properties, [9], and the existence of a lower bound for inter-events time, [10], for instance. This methodology has been extended to NCS systems in [11], including quantization effects. In [12], experimental results have been recently presented, evaluating an event based state-state approach. In [13], similar considerations are obtained for an output-based event-triggered control scheme using LMI techniques.

Therefore, different EBC schemes have been developed and evaluated. The advantages obtained applying such schemes encourage to develop new alternative approaches and specific design methodologies for such systems.

The objective of this work is to describe a design methodology useful for EBC systems, which guarantees stability and some design specifications and its validation under simulation test. The design procedure facilitates the improvement of the dynamics of the resulting EBC system, which will be experimentally implementable. The control scheme switches between different controllers following an event-triggered sampling scheme which is proposed in [6]. The stability of the closed-loop system is determined using a standard LMI methodology, [14], taking into account results derived from Asynchronous Dynamical Systems (ADS) theory. This theory is an interesting resource since it is applicable to Networked Control Systems (NCS), [15], [16].

The paper is organized as follows: first, the particular structure of the EBC scheme under study is described in Section II. In the next section, the analysis of the proposed EBC system is presented, based on the use of the ADS theory. In Section IV, the proposed approach for the design of the EBC controller is described. This process includes the LMI based stability analysis. An example of the proposed methodology is presented in Section V, where its performance is analyzed by means of simulations. Finally, conclusions end the paper.

## II. STATEMENT OF THE PROBLEM

Event Based Control is based on triggering control action only when a condition is met [2]. The main advantage of this control strategy is that the required number of control actions can be considerably reduced while maintaining the system under control.

Figure 1 presents the scheme of a basic EBC system, where a reference signal is explicitly included. The difference from a typical feedback control system is the event-based sampling technique used to perform the feedback.

Let us consider a linear, or linearized, system which can be described by the next equations:

$$\begin{aligned} \dot{x_p}(t) &= f(x,u) = Ax_p(t) + Bu(t) \\ y(t) &= g(x,u) = Cx_p(t) + Du(t) \end{aligned} \qquad (1)$$

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

Here, for the sake of simplicity, linear SISO systems with $D = 0$ are considered. Introducing a zero order hold (ZOH) in the input of the system, the control signal value $u_k$, which is generated by a digital controller, is maintained constant between consecutive control events. The closed-loop correction acts only when the event firing rule is met, e.g. when a selected signal level reaches a limit value defined during design stage. Hence, the continuous control signal, that is, the system's input signal, is

$$u(t) = h(t - t_k)u_k, \quad t \in [t_k, t_{k+1}), k = 0, \ldots, \infty \quad (2)$$

where $u_k$ is the event-triggered control signal and $h(t)$ is the Heaviside step function.

In this work, the event-based sampling of a continuous signal $z(t)$ is defined by the next expressions, with $k \geq 1$

$$\begin{array}{rcl} z_k & = & z(t_k) \\ d^{(k)}(t^*) & = & z(t_{k-1} + t^*) - z(t_{k-1}) \\ t_k & = & t_{k-1} + T_k \qquad (3) \\ T_k & = & \begin{cases} T_{min} & \text{if } \delta^{(k)}(t^*) \geq \delta_{limit} \\ & \quad \text{and } t^* \leq T_{min} \\ t^* & \text{if } \delta^{(k)}(t^*) \geq \delta_{limit} \\ & \text{and } t^* \in (T_{min}, T_{max}) \\ T_{max} & \text{if } \delta^{(k)}(t^*) < \delta_{limit} \\ & \quad \text{and } t^* = T_{max} \end{cases} \end{array}$$

where $t^*$ is the continuous time which is reset at every sampling time $t_k$, $t^* \in [0, T_k]$. The difference between the actual value of the signal and the last sampled value, $d^{(k)}(t^*)$, is a switched continuous function depending on the $k - th$ event. The parameter $\delta^{(k)}$ is the value which fires control action, continuously updated according to the following rule:

$$\delta^{(k)}(t^*) \;=\; K_p^s \left| d^{(k)}(t^*) \right| + K_i^s \int_0^{t^*} \left| d^{(k)}(t) \right| dt \quad (4)$$

This expression is reset at event time, i.e. $\delta^{(k)}(0) = 0$. Thus, the new sampling is triggered at $t_k = t_{k-1} + T_k$ time, when $\delta^{(k)}$ reaches a predefined limit $\delta_{limit}$ or when $t^*$ reaches the limit $T_{max}$. Equation 4 leads to a proportional-integral sampling scheme, where a minimum difference between sampling times $T_{min}$ (sporadic control approach [4]) and a maximum difference between sampling times $T_{max}$ are defined. Hence, $T_k \in [T_{min}, T_{max}]$.

In the same way, an integral action is added to the proportional sampling (or deadband sampling, [1]) to reduce the sticking phenomenon, [17]. Initially, when the reference varies, the proportional sampling is enough to guide the system towards the desired state. However, when it is close to the reference signal, no action will be triggered as long as $\delta^{(k)}(t^*)$ is maintained inside its deadband, so a non null error stands. In such case, the integral part of the event sampling rule will fire the control action after a time interval. This interval depends on the parameter $K_i^s$, defined in the event sampling policy. The choice of values of the parameters $\delta_{limit}$, $K_i^s$, and $K_p^s$ will have a direct impact on the performance of the system.

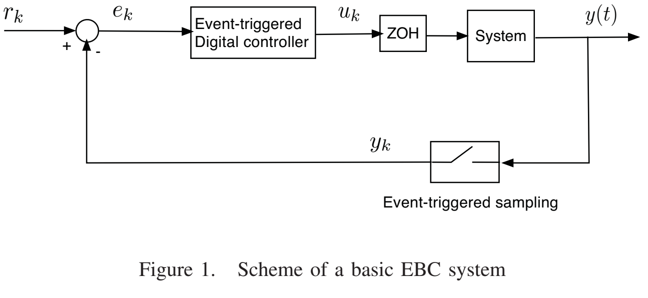

Figure 1. Scheme of a basic EBC system

**Considerations about $T_{max}$.** The existence of a maximum inter-sampling time can be considered that leads to unnecessary control actions. However, the definition of $T_{max}$ helps to minimize the sticking problem, [6]. Note that, in practice, this definition affects only in cases when the open-loop system is stable and $\delta^{(k)}$ is strictly zero, depending on the value of $\delta_{limit}$ and $K_i^s$. It is introduced to prioritize the minimization of the sticking phenomenon, with a possible penalty in the resource optimization which can be adjusted depending on the value of $T_{max}$. In addition, it facilitates the mathematical description proposed below.

For every event at $t_k$ derived from equations (3), the open-loop linear system (1) can be discretized, leading to the next representation,

$$\begin{array}{rcl} x_{k+1}^p & = & \phi_k x_k^p + \Gamma_k u_k \\ y_k & = & C x_k^p \qquad (5) \\ \phi_k & = & \phi(T_k) = e^{AT_k} \\ \Gamma_k & = & \Gamma(\;\; T_k) = \int_0^{Tk} e^{As} ds B \qquad (6) \end{array}$$

Due to the event-based sampling policy (3), $T_k$ can take any value in the interval $[T_{min}, T_{max}]$. Therefore, $\phi_k \in \mathcal{C}([T_{min}, T_{max}])$, that is, it is a continuous function with respect to variable $T_k$ in the interval $[T_{min}, T_{max}]$, that depends on matrix $A$. However, considering the nature of $t_k$, $\phi_k$ is a jump or switched function respect to the index $k$.

Let the structure of the controller be given by the next equations:

$$\begin{array}{rcl} x_{k+1}^c & = & A_k^c x_k^c + B_k^c e_k \\ u_k & = & C_k^c x_k^c + D_k^c e_k \qquad (7) \end{array}$$

where $e_k = r_k - y_k$. Defining the extended state-vector $\bar{x}_k = [x_k^{pT}, x_k^{cT}]^T$, the closed-loop system can be represented using the following equations:

$$\begin{array}{rcl} \bar{x}_{k+1} & = & \begin{bmatrix} \phi_k - \Gamma_k D_k^c C & \Gamma_k C_k^c \\ -B_k^c C & A_k^c \end{bmatrix} \bar{x}_k + \begin{bmatrix} \Gamma_k D_k^c \\ B_k^c \end{bmatrix} r_k \\ & = & \bar{A}_k \bar{x}_k + \bar{B}_k r_k \qquad (8) \end{array}$$

An EBC system following the sampling rule (3) presents the usual advantages shown in the literature for EBC systems, but with an improved behavior respect to the sticking problem, [6]. However, analysis and design techniques for this class of systems are needed, since the control structure could vary at each event.

In the next sections, there is presented an approach valid for determining the stability of the EBC systems using ADS and LMI theory and a design methodology adequate for fulfilling some specifications.

## III. Stability of EBC system under study

Some results from the ADS theory can be applied to the proposed EBC system, under several conditions. Relevant results from [15] are summarized to clarify the discussion. First, the definition of ADS systems:

**Definition 1.** An asynchronous dynamical system (ADS) with rate constraints on events is a tuple

$$\mathcal{A} = (\mathbb{R}_+, \{1, ..., N\}, \mathbb{R}^n, E, R, \mathcal{I}, F) \tag{9}$$

where $\mathbb{R}_+$ is time, $\{1, ..., N\}$ is the discrete state-space, $\mathbb{R}^n$ is the continuous state-space, $E$ is the set of events, $R = \{r_1, \dots, r_M\}$ is the set of event rates, $\mathcal{I} : 1, ..., N \to 2^E$ is the discrete state-event function, and $F$ is the set of continuous dynamical system functions. By definition, $\mathcal{I}(i) = \left\{E_{i_1}, E_{i_2}, \dots, E_{i_{M_i}}\right\}$ is the *i*th discrete state-event set, where $e_j^{(i)} \in E$ for $j = 1, ..., M_i$. An ADS has associated a discrete state $s(t)$ and a continuos state $x(t)$. $s(t) = i$ if and only if the events in $\mathcal{I}(i)$ have occurred and $\dot{x} = f_i(x)$. If the evolution of $x$ is given by a difference equation, then, the last equations is substituted by $x_{k+1} = f_i(x_k)$.

Now, the definition of the stability of such systems:

**Definition 2.** An ADS with continuous state dynamics $x(t)$ is exponentially stable if

$$\lim_{t\to\infty} e^{\alpha t} \left\|x(t)\right\| = 0,$$

for some $\alpha > 0$. If the dynamics is given by a discrete state $x_k$, the condition is

$$\lim_{k\to\infty} \alpha^k \left\|x(t)\right\| = 0$$

Focussing the discussion on the discrete case, the next theorem summarizes the main result from [15]: Consider an ADS system $\mathcal{A}$ with discrete state dynamics $x_k$ $(x_{k+1} = f_i(x_k))$, the ith discrete state-event set $\mathcal{I}(i) = \left\{E_{i_1}, E_{i_2}, \dots, E_{i_{M_i}}\right\}$ and a set of event rates $R = \{r_1, .., r_M\}$ in which $r_i$ satisfying $0 \le r_i \le 1$ is the rate of occurrence of event $E_i \in E$ over time. So, over any time period $[t, t+T]$ for large enough T, $r_iT$ is the total amount of time that $E_i$ has occurred.

In addition, suppose a Lyapunov-type function $V : \mathbb{R}^n \to \mathbb{R}_+$, which is continuously differentiable and

$$\beta_1 \left\|x\right\|^2 \le V(x) \le \beta_2 \left\|x\right\|^2 \tag{10}$$

where $\beta_{1,2} > 0$.

**Theorem 3.** *[15], if there exist scalars $\alpha_1, \alpha_2, ..., \alpha_M$ such that the system fulfills the condition*

$$\alpha_1^{r_1}\alpha_2^{r_2}\dots\alpha_M^{r_M} > \alpha > 1 \tag{11}$$

*and*

$$V(x_{k+1}) - V(x_k) \le (\alpha_{i_1}^{-2}\alpha_{i_2}^{-2}\dots\alpha_{i_{M_i}}^{-2} - 1)V(x_k) \tag{12}$$

*for i = 1,...,N, in which $i_j$ for $j = 1, ..., M_i$ correspond to the definition of $\mathcal{I}(i)$, the decay rate of the ADS is greater than $\alpha$. Then, the ADS system is exponentially stable.*

*Proof:* See, [15]. ■

In order to apply those results to the EBC scheme presented in Section II, some details have to be revised.

*Application of the ADS approach to event-based systems:* Considering the description in Section II and the Definition 1, the EBC system described by equations (8) and event-triggered mechanism (3) is similar to an ADS system. However, in this case, the events are defined by all the possible sampling instants in a continuous interval $[T_{min}, T_{max}]$. That is, $E = \{E_1, E_2, \dots, E_\infty\}$ is an infinite set. In addition, this fact difficulties the implementation of a real system using the sampling mechanism (3). To solve this problem, a finite set of possible sampling times is introduced:

$$\begin{aligned}\mathcal{T}_s \;=\; & [T_{min}, T_{min}+\Delta t_s, T_{min}+2\Delta t_s, \dots, \\ & \dots, T_{min}+n\Delta t_s = T_{max}],\ \Delta t_s = \frac{T_{max}-T_{min}}{n}\end{aligned} \tag{13}$$

with $n \in \mathbb{N}$. Now, consider the next approximation of the event-sampling approach defined in equations (3):

$$\begin{aligned}
z_k &= z(t_k) \\
e^{(k)}(t^*) &= z(t_{k-1}+t^*) - z(t_{k-1}) \\
t_k &= t_{k-1} + T_k \\
T_k^{ideal} &= \begin{cases} T_{min} & \text{if } \delta^{(k)}(t^*) \ge \delta_{limit} \\ & \quad \text{and } t^* \le T_{min} \\ t^* & \text{if } \delta^{(k)}(t^*) \ge \delta_{limit} \\ & \quad \text{and } t^* \in (T_{min}, T_{max}) \\ T_{max} & \text{if } \delta^{(k)}(t^*) < \delta_{limit} \\ & \quad \text{and } t^* = T_{max} \end{cases} \\
T_k &= \left\lfloor \frac{T_k^{ideal}}{\Delta t_s} \right\rfloor \Delta t_s
\end{aligned} \tag{14}$$

with $\delta^{(k)}$ defined by (4), $T_k \in \mathcal{T}_s$ and $T_k^{ideal}$ represents the sampling times derived from equations (3) (which is an ideal case). Note that the equations (3) are obtained from equations (14), when $n \to \infty$. The introduction of this new event-sampling approach is motivated by the implementation which is easier than in the approach given by (3), since can be based in the use of a regular periodic sampling time $\Delta t_s$. This idea is similar to the scheme proposed in [11].

Now, considering the event-sampling scheme (14), the proposed EBC system is an ADS system with discrete dynamics $\bar{x}_k$, being $E = \{E_1, E_2, \dots, E_n\}$. Note that the conclusions derived for this ADS system are valid for any $n$ and, then, the results should be valid for $n \to \infty$. Therefore, the result summarized in Corollary 4 can be concluded.

**Corollary 4.** *The stability of the EBC system described by equations* (8) *and event-triggered mechanism* (14)*, considering the definition presented in Section II, will be guarantied if:*

*- it exists a Lyapunov function $V(x_k) = x_k^T P x_k$ for some symmetric positive matrix $P > 0$ fulfilling*

$$V(x_{k+1}) - V(x_k) \leq (\alpha^{-2} - 1)V(x_k)$$

for some $\alpha > 1$ when $T_k \in [T_1, T_2] \subseteq [T_{min}, T_{max}]$.

*- the rate of event samplings in this interval is sufficiently large.*

*Proof:* By the definition of the EBC system, the finite set of events $E = \{E_1, E_2, \ldots, E_n\}$ and the related set of event rates $R = \{r_1, .., , r_n\}$ are well defined for a large period of time. Hence, there exist the scalars $\alpha_1, \alpha_2, ..., \alpha_n$ related with each n possible matrix $\bar{A}_i$ $i = 0, \ldots, n$ in equation (8). Under the conditions defined in this corollary, the system is exponentially stable for any arbitrary switch in the interval $T_k \in [T_1, T_2]$, [18]. Consider the set of $m$ events $E' \subseteq E$ related with $T_k \in [T_1, T_2]$. By Theorem 3, the set of $m$ systems $\bar{A}_j$ derived from $E'$ fulfills

$$\bar{A}_j^T P \bar{A}_j - P \leq (\alpha^{-2} - 1)P$$

for some $\alpha > 1$. In addition, if the rate of events in interval $T_k \in [T_1, T_2]$ is sufficiently large, the condition (11) in Theorem 3 will be fulfilled and the EBC system is stable. ■

A particular case derived of this Corollary is when the interval considered is $[T_{min}, T_{max}]$. In this case, the second condition is always fulfilled, but the obtaining of a controller fulfilling the first condition can be hard.

*Remark* 5. The event rate in a particular interval is directly related with the selection of $\delta_{limit}$ in each case.

*Remark* 6. The sampling mechanism can be enforced to assure the necessary rate in any interval.

The next section presents a design process valid for the proposed EBC system.

## IV. Controller design and LMI based stability analysis

Consider a continuous controller and its discretization for a sampling rate interval $T_k \in [T_1, T_2]$, under event-triggered sampling (14). This scheme leads to a discrete representation of the controller changing at every event $t_k$. If all the interval $[T_{min}, T_{max}]$ is considered, the n possible system matrices in equation 8for each $T_k \in \mathcal{T}_s$ are:

$$\bar{A}_i = \begin{bmatrix} \phi_i - \Gamma_i D_i^c C & \Gamma_i C_i^c \\ -B_i^c C & A_i^c \end{bmatrix} \quad i = 0, \ldots, n$$

where matrices $(A_i^c, B_i^c, C_i^c, D_i^c)$ are obtained by discretization, following equivalent equations to (6). Let us consider $V_k = x_k^T P x_k$ , for some $P > 0$. The system will be stable if the equations

$$\bar{A}_i^T P \bar{A}_i - P \leq -Q_i$$

are fulfilled for $i = 0, \ldots, n$ and $Q_i > 0$. However, by continuity in the discretization process, if the equations corresponding to $T_{min}$ and $T_{max}$ are fulfilled, the equivalent equation of every sampling time in interval $[T_{min}, T_{max}] \in \mathcal{T}_s$ will be fulfilled.

A more general scheme can be considered. The interval can be subdivided into $N_I$ intervals $[T_l, T_{l+1}] \subset \mathcal{T}_s$ with $l = 0, \ldots, N_I - 1$, covering the full interval $[T_{min}, T_{max}]$, being $T_0 = T_{min}$ and $T_N = T_{max}$. Then, controllers which stabilize the closed-loop for any $T_k \in [T_l, T_{l+1}]$ for each such interval $[T_l, T_{l+1}]$ are enough, if the conditions of Corollary 4 are fulfilled. Therefore, $N$ design problems must be solved, one for each time interval $[T_l, T_{l+1}]$ , which can be expressed as the next LMIs

$$\begin{aligned} \bar{A}_l^T P_l \bar{A}_l - P_l &\leq -Q_l \\ \bar{A}_{l+1}^T P_l \bar{A}_{l+1} - P_l &\leq -Q'_l \quad l = 0, \ldots, N_I - 1 \end{aligned} \tag{15}$$

with $P_l > 0$, $Q_l > 0$ and $Q'_l > 0$. The simplest way to fulfill Corollary 4 is to force a unique $P$ matrix, i.e. $P_l = P > 0$ $l = 0, \ldots, N_I - 1$,. This design problem can be expressed by mean of a set of LMIs to fulfill some specification.

However, the feasibility of the LMI problem considering an unique $P$ matrix can be difficult to satisfy in general. A more open problem is to relax this condition allowing multiple $P_l$ matrices. In such case, in order to achieve the second condition in Corollary 4, a supervisor assuring a minimum rate in each interval $[T_l, T_{l+1}]$, a dwell time, [18], is required. Note that several politics can be followed by this supervisor.

## V. Example of application

In this section, an example of application of the tools described in the previous section is presented. The procedure applied in this example is summarized as follows:

- Considering the plant to control and the basic specifications, the parameters for the event sampling approach (14) are selected: interval $[T_{min}, T_{max}]$, $n$, $\delta_{limit}$, $K_p^s$ and $K_i^s$.
- Selection of the $N_I$ intervals $[T_l, T_{l+1}] \subset \mathcal{T}_s$ covering the full interval $[T_{min}, T_{max}]$.
- Perform a controller design in the continuous domain applicable for each interval. A reasonable design constrain is that the bandwidth of the closed-loop system in each interval is directly related to the sampling times involved, that is, for higher sampling rates, larger bandwidth.
- Solve the LMI feasibility problem derived from equations (15). Note that those problems are solved in the discrete domain and the controller must be conveniently discretized, using a kind of emulation technique.

Resolving satisfactorily the last point, the EBC system can be implemented and performance tests done. Now, details about the example are presented.

### A. Controller Design

The plant used in current analysis consist of a DC motor connected to a rotational-to-translational motion converter. The continuous plant dynamics relating the input voltage and the position has been modeled approximately by the following transfer function:

$$G(s) = \frac{1}{s}\frac{K}{(\tau_m s + 1)} \tag{16}$$

where, $K = 6536\,mm\,vol^{-1}$ and $\tau_m = 1/4.3$. So, a state-space representation is given by the following equations:

$$A_p = \begin{pmatrix} 0 & 1 \\ 0 & -1/\tau_m \end{pmatrix} \; B_p = \begin{pmatrix} 0 \\ K/\tau_m \end{pmatrix} \tag{17}$$

$$C_p = \begin{pmatrix} 1 & 0 \end{pmatrix} \tag{18}$$

A standard PID controller can be enough for controlling this second order system. After design, the standard version must be rewritten as the equivalent representation in the state-space.

For a first example of application, the sampling interval defined by the event-based sampling scheme (14) is split in three zones, $N_I = 3$:

$$\overbrace{[T_{min}, T_1]}^{controller\,1} \bigcup \overbrace{[T_1, T_2]}^{controller\,2} \bigcup \overbrace{[T_2, T_{max}]}^{controller\,3} \tag{19}$$

being $T_{min} = 0.5msec.$ , $T_1 = 1msec.$, $T_2 = 3msec.$, $T_{max} = 50msec.$. In addition, the other parameters needed in (14) are $K_p^s = 0.1$, $\delta_{limit} = 0.01$ and $K_i^s = 100$. The last one has been selected as reference, since an analysis of the effect of this parameter in the behavior of the EBC system has been done. This is presented below.

The EBC sampling scheme leads to a changing variable time between consecutive control actions, depending on the speed of the changes on the error signal. Therefore, three different controllers are proposed for different sampling times, corresponding to the three intervals in (19). For high sampling rates, faster controller is preferred, with a higher bandwidth. On the contrary, for low sampling rates, a control system with a lower bandwidth is enough for leading the system to the desired state.

The overall methodology for the full controller design procedure is presented in Figure (2), starting from the model of the system to be controlled. After obtaining a valid controller for each different region, the LMI feasibility problem is analyzed. The implementation consist on the use of event sampling strategy (14), followed by a decision algorithm which chooses the correct controller for each interval. Depending on the different sampling times $T_k$, appropriate discrete controller is used when applying the event sampling policy.

For each region, the next controller parameters are obtained, requiring in the design process different closed-loop bandwidths:

$$\begin{array}{lll} K_p^{(1)} = 0.0016737 & K_i^{(1)} = 0.0002193 & K_d^{(1)} = 0.0010633 \\ K_p^{(2)} = 0.0072328 & K_i^{(2)} = 0.0011645 & K_d^{(2)} = 0.0095654 \\ K_p^{(3)} = 0.0163627 & K_i^{(3)} = 0.0020823 & K_d^{(3)} = 0.0325810 \end{array} \tag{20}$$

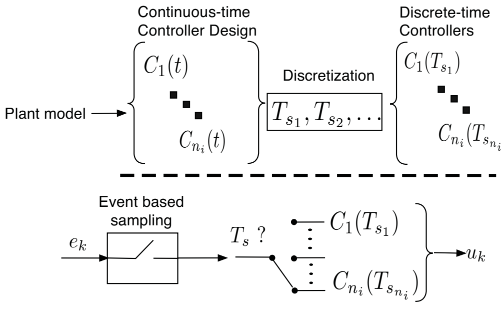

Figure 2. Proposed controller design methodology for the presented Event Based control.

Since the presented event based methodology implies the use of discrete domain controllers, the PID is approximated using the backward approximation of the derivate as

$$G_{pid}(z) = K_p + K_d \frac{(1 - z^{-1})}{T_k(1 - \alpha z^{-1})} + K_i \frac{T_k}{(1 - z^{-1})}$$

which can be represented in the state-space

$$\begin{aligned} A_c &= \begin{pmatrix} 1+\alpha & -\alpha \\ 1 & 0 \end{pmatrix} \quad B_c = \begin{pmatrix} 1 \\ 0 \end{pmatrix} \\ C_c &= \begin{pmatrix} K_1^c & K_2^c \end{pmatrix} \quad D_c = K_p + \frac{Kd}{T_k}(1-\alpha) + K_i T_k \\ K_1^c &= -\left( (1+\alpha)K_p + 2(1-\alpha)\frac{Kd}{T_k} + \alpha K_i T_k \right) \\ K_2^c &= \alpha K_p + (1-\alpha) K_i T_k \end{aligned}$$

The parameter $\alpha$ is introduced to solve possible numerical issues. Now, three LMI feasibility problems following (15) can be proposed. Those equations admits some variations.

Indeed, the overall control design can be proposed as a LMI, [19]. In fact, the control representation in the state-space has been selected to facilitate this possibility. In any case, the controllers 20 fulfill the first condition of Corollary 4.

The switching between the different controllers is facilitated for the use of the same structure in all the cases. When an event is received, $T_k$ is known and the appropriated controller gains can be applied. A supervisor acts in parallel in order to prevent continuous switching between different control intervals (second condition in Corollary 4). A minimum dwell time can be established if necessary.

For a first implementation of the proposed control approach, the choice of designing just three different regions is considered enough for comparison purposes. In addition, obtained results show better performance comparing to a single controller solution. The values of parameters $T_{min}$, $T_{max}$ and $T_i$ $(i = 1, 2)$ comes from the fact that the obtained discrete controllers must be stable, but also the performance of the system must be maintained inside reasonable limits.

### B. Simulations results

In order to perform a correct study under a simulation test, the hybrid nature of the overall system must be adequately described. In this case, the tool used is Ptolemy II, a Java based software system valid for the use of heterogeneous mixtures of models of computation, [20]. This software allows the definition of components for the event based scheme proposed in this paper, including switching between different controllers, in addition to the continuous plant.

Using this simulation framework, the performance of the system when using a multiple EBC controller scheme has been compared to a single EBC controller solution. Both solutions use the same parameter values when applying (14).

The results of the simulations show the evolution of the *Mean Sampling Time*, the *Mean Error*, defined as $\langle |r-y| \rangle$, and the *Event Ratio* (Event ratio is defined as the mean number of produced control events for a given time interval). As long as event occurrences increases, this value will also increase.

While most parameters are maintained constant, the integral part of the event triggering level has been varied in the range $K_i^s \in [50, 200]$ (Figures 3, 4 and 5).

As can be expected, increasing $K_i^s$, which rises the effect of the integral part of the event sampling, the number of event occurrences increases. Thus, more control actions are generated, reducing the system error.

The multi-controller case presents higher mean sampling time and lower error and event ratio. In addition, as Figures 6 and 7 show, the multi-controller scheme presents an improved system behavior, for same event sampling parameters ($K_p^s = 0.1$, $\delta_{limit} = 0.01$ and $K_i^s = 100$). The oscillations are reduced by switching to a more suitable controller for higher sampling times. Therefore, the use of multiple controllers allows a better definition of the closed-loop dynamics, adding more degree of freedom.

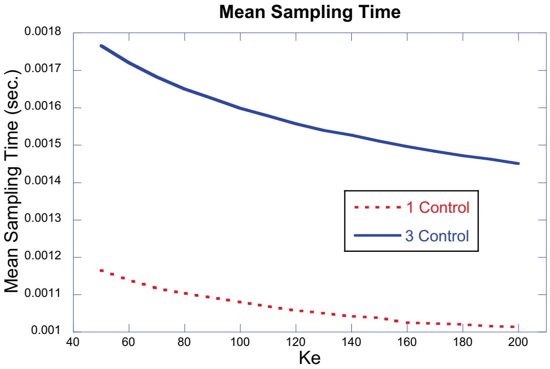

Figure 3. Mean Sampling Time vs parameter $K_i^s$, for both control schemes

A remarkable fact is that, in both cases, those results are qualitatively similar to the ones presented in previous works (e.g. [4]). They show a reduction in the needed resources, specially mean sampling time, without a notorious system performance reduction comparing to a pure periodic case.

Increasing the number of controllers, i. e., increasing the number of ranges in (19), the performance of the system is improved, but it also requires a more complex implementation. For the system under control, presented results are considered good enough and the addition of extra regions does not give significant advantages.

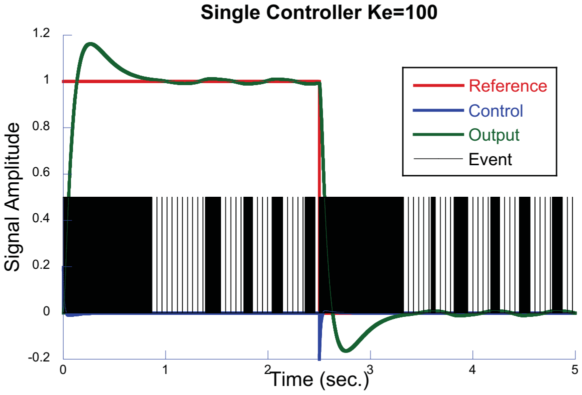

Figure 6. System output and event occurrences for single controller

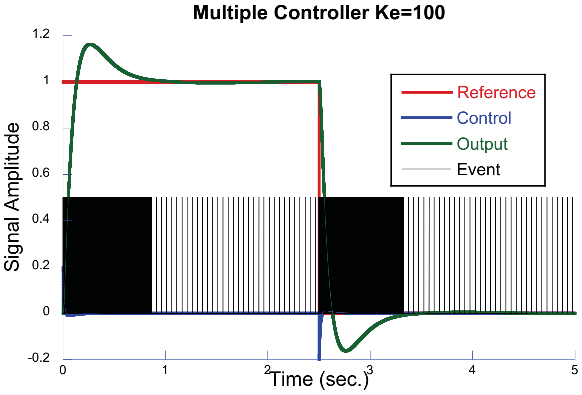

Figure 7. System output and event occurrences for multiple controller

## VI. CONCLUSIONS

In this work, a design methodology for a class of event based controllers has been presented. The stability of the closed-loop system is guaranteed by applying ADS theory and solving several LMI problems Moreover, the proposed scheme allows the use of different controllers depending on the event rate, leading to a better closed-loop dynamics definition. So, desired dynamics specifications can be met more efficiently.

The principal advantage of the resulting closed-loop system is that the EBC control structure lets a reduced control rate. This characteristic makes the proposed scheme very adequate for networked environments, for saving energy and for reducing actuators' stress. In fact, this methodology has been chosen since LMI and ADS theory have been successfully applied to NCS systems in the literature. Therefore, the extension of the approach for EBC systems in a networked environment will follow a natural way.

In addition, the simulations in the example show that an improved system performance can be obtained by designing different controllers for several sampling time intervals, as opposed to use a single controller independent of the sampling period of each control action. The reduction of the number of control actions, comparing with a periodic sampling scheme, is still guaranteed. However, the improvement of the dynamics obtained with multiple EBC controllers requires, in general, an increased event rate, comparing with the single EBC controller case.

Future work will consist in the extension of the presented control strategy to a networked environment.

## ACKNOWLEDGEMENTS

The authors are very grateful to the Basque Government for the financial support to our research group and to ESS Bilbao Consortium for supporting this work.

***Abstract*—This paper describes a systematic sensitivity analysis of optimal operation conducted on an activated sludge process model based on the test-bed Benchmark Simulation Model No. 1 (BSM1). The objective is to search for an operational structure that leads to optimal economic operation, while promptly rejecting disturbances at lower layers in the control hierarchy avoiding thus violation of the more important regulation constraints on effluent discharge. We start by optimizing a steady-state nonlinear model of the process. The resulting active constraints must be chosen as economic controlled variables. These are the effluent ammonia from the bioreactors and the final effluent total suspended solids at their respective upper limits, as well as the internal recycle flow rate at its lower bound. The remaining degrees of freedom need to be fulfilled, and we use several local (linear) sensitivity methods to find a set of unconstrained controlled variables that minimizes the loss between actual and optimal operation; particularly we choose to control linear combinations of readily available measurements so to minimize the effect of disturbances and implementation errors.**

## I. INTRODUCTION

Much to the authors' surprise, optimization of wastewater treatment plants has not received much attention in the WWTP research community given the small number of contributions found in the literature. Only few articles discuss the subject from a heuristic economic point of view[1], [2], [3] to formal optimization using an explicit mathematical model of the process[4], [5], [6] for optimal design and operation. However, none of the publications define an optimal operation policy from a systematic prism. Araujo *et al.*[7] applied a systematic procedure for control structure design of an activated sludge process in which optimization for various operational conditions were carried out on a mathematical model of the process.

In this communication a systematic sensitivity analysis of optimal operation of an activated sludge process model based on the Benchmark Simulation Model No. 1 (BSM1) [8] is conducted. It must be clear that all analysis, and hence all conclusions, from this work are based on the underlying mathematical model of the process, and should not be considered as definite guidelines for actual plant operation since the mathematical model may not be able to reproduce many operational situations. However, the results can be used in practice as general rules-of-thumb to be tested in actual wastewater treatment plants of the kind discussed here.

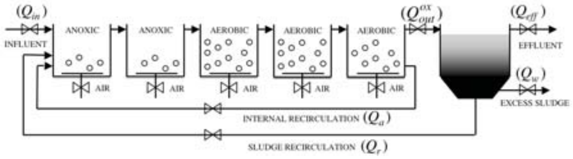

Fig. 1. Schematic representation of the BSM1 activated sludge process.

## II. PROCESS DESCRIPTION

The BSM1 [8] represents a fully defined protocol that characterizes the process including the plant layout, influent loads, modeling and test procedures as well as evaluation criteria. Figure 1 shows a schematic of the process consisting of a bioreaction section divided into five compartments, which can be anoxic or aerobic, and a secondary settling device. In order to maintain the microbiological population, sludge from the settler is re-circulated into the reaction section (returned activated sludge, $Q_r$). Also, part of the mixed liquor leaving the last reactor can be recycled to the inlet of the bioreactor (internal recycle, $Q_a$) to enhance nitrogen removal. Moreover, excess sludge at a rate $Q_w$ is continuously withdrawn from the settler underflow.

From a modeling point of view, the original BSM1 is based on two widespread accepted process models: the celebrated Activated Sludge Model No.1 (ASM1) [9] used to model the biological process, and a non-reactive Takacs one dimensional layer model for the settling process [10], [11]. The full model equations as well as kinetic and stoichiometric parameters are given within the benchmark description [8]. In addition, influent data are provided in terms of flow rates and ASM1 state variables over a period of 14 days with 15 minutes sampling time.

Each reactor is modeled as a perfectly-mixed, constant-volume tank within which complex biological reactions give

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

rise to component mass balance equations, generating a system of (coupled) ordinary differential equations. The ASM1 is a well establish and reliable model widely used among WWT modelers, and further discussion on its known capabilities of reproducing with fidelity the behavior of the reaction section of an activated sludge process can be found in the vast wastewater literature.

However, the same cannot be said about the settler model, though, for the reason that these units display very complex mechanisms that are not still fully understood [12]. Nevertheless, much progress has been made towards building a physically sound model for the secondary clarifier based on the theory of partial differential equation applied to conservation law with discontinuous fluxes [13], [14], [15], [16]. While these more meaningfully grounded mathematical models satisfying fundamental physical properties [17] still have not found widespread application in the WWT field, it is a commonplace to resort to approximate models of the settler, and the one due to Takacs [10], [11] is the most widely used representation of the secondary settler in published studies and commercial software environments. Some authors [18], [19], [20], however, pointed out many setbacks related to this model, among which is the fact that the number of discretization layers is not in agreement with numerical convergence and without distinguishing model formulation and numerical solution, but instead it is used solely as a model parameter in order to match experimental observations [21]. Numerical simulations have showed [17] the failure of Takacs' model to represent the complex behavior of secondary settlers under certain conditions, and this has led researchers to switch to more reliable physically meaningful sedimentation models. One such development is described by Diehl [13] who formulated and analyzed dynamically the settler model based on the one-dimensional scalar mass conservation law (1)

$$\frac{\partial X(z,t)}{\partial t} + \frac{\partial}{\partial z}(F(X(z,t),z)) = s(t)\delta(z) \tag{1}$$

where $X$ is the flocculated solids concentration, $\delta$ is the Dirac measure, $s$ is a source, and $F$ is a flux function, which is discontinuous at three points in the space coordinate $z$, namely at the inlet and the two outlets. Details are fully given in the cited references. We here are interested in the sensitivity of the static optimum of the settler coupled with the biological reaction section, and the steady-state solutions of the above equation provide the basis for our analysis.

A simple analysis of the model described in [15], shows that the steady-state model of the settler that must hold for optimization purposes is given by (2)

$$\begin{aligned} X_e &= \frac{s - f(X_M)}{q_e} \\ X_u &= \frac{f(X_M)}{q_u} \\ X_M &= M(q_u) \\ X_f &\in (X_m, X_M) \end{aligned} \tag{2}$$

where $X_e$ and $X_u$ are the solids concentration in the effluent and in the wastage streams, respectively; $s$ is the feed flux given by $s = q_f X_f$, where $q_f$ is the feed flux and $X_f$ is the solids concentration in the feed; $f(X)$ is a flux function given by $f(X) = Xv_s(X) + q_u X$, where $v_s(X)$ is the settling velocity law given by the double exponential equation [10]; $X_M$ is a minimizer of $f(X)$; $X_m$ is a value strictly less than $X_M$ satisfying $f(X_m) = f(X_M)$; $q_e$ and $q_u$ are the effluent and wastage fluxes, respectively; $M$ is a function that computes the local minimizer of $f(X_M)$. In addition, we can also calculate the steady-state concentration of suspended solids in the clarification ($X_{cl}$) and thickening zones ($X_{th}$) as in (3) [15]

$$\begin{aligned} g(X_{cl}) + s &= f(X_M) \\ X_{th} &= X_M \end{aligned} \tag{3}$$

where $g(X_{cl}) = X_{cl}v_s(X_{cl}) - q_e X_{cl}$.

Note that, although in this communication a nonreactive settler is considered, we here follow [14] and treat the dissolved oxygen in the settler in a special way. We assume that the oxygen is consumed within the settler and, consequently, the oxygen concentration at the settler's outlets is set to zero, which is indeed a realist assumption. This results in a more conservative computation of the oxygen demand in the reaction section.

## III. Systematic sensitivity analysis methodology

The methodology is mainly based on the first 4 steps, known as "top-down analysis", of the more general procedure described in [22], where economic variable selection is the key issue. The analysis conducted is of local nature, i.e., we use linearized models of the process to develop the methodology.

In this communication we use optimal measurement combinations [23] for unconstrained variable selection, i.e. the ones left after choosing the active constraints as "primary" economic variables. The basic idea is to select combinations $c$ of the measurements $y$ such that $c = Hy$, where $H$ is a (static) selection matrix. To determine $H$, two approaches are developed based on a linearized model of the process and a second-order Taylor series expansion of the cost function used for optimization; two sources of uncertainty are assumed which are represented by (1) external disturbances ($d$) and (2) implementation (measurement) errors ($n$). The first of two approaches combines these uncertainties in one single scaled vector to minimize the worst case economic loss ($L$), defined as the difference between actual operation (with a given control structure in place) and operation under optimal control. The second approach is to first minimize the loss with respect to external disturbances, and then, if there are still available measurements, minimize the loss with respect to implementation (measurement) errors.

The steps to be followed are:

**1. Define operational objectives**: We first quantify the operational objectives in terms of a scalar cost function (here denoted $J$) as given in (4) that should be minimized

$$J = \textit{cost of feed + cost of utilities (energy)} \\ -\textit{revenue from valuable products} \tag{4}$$

Constraints can then be added to the process as inequality equations of the form $g \leq 0$.

**2. Determine the steady-state optimal operation**: Using a steady-state model of the process, identify degrees of freedom and expected disturbances, and perform optimizations to assess sensitivity for the expected disturbances.

Usually, the economics of the plant are primarily determined by the (pseudo) steady-state behavior [24], so the steady-state degrees of freedom ($u_0$) are usually the same as the economic degrees of freedom. Which variables to include in the set $u_0$ is immaterial, as long as they make up an independent set. The important disturbances ($d$) and their expected range for future operation must then be identified. These are generally related to feed rate and feed composition, as well as external variables such as temperature and pressure of the surroundings. We should also include as disturbances possible changes in specifications and active constraints (such as product specifications or capacity constraints) and changes in parameters (such as equilibrium constants, rate constants and efficiencies). Finally, we need to include as disturbances the expected changes in prices of products, feeds and energy.

In order to achieve near optimal operation without the need to re-optimize the process when disturbances occur, one needs to minimize the loss in (5)

$$L = J_0(c, d) - J_0(c^{opt}(d), d) \geq 0 \tag{5}$$

where $J_0(c, d)$ is the value of the cost for a chosen set of constant setpoint variables $c$ that fulfill all remaining degrees of freedom and $J_0(c^{opt}(d), d)$ is the value of the cost after re-optimization. Clearly, the loss in (5) depends on the objective function as well as on the measurements through $c$, since $c$ is a function of the available $y$. We then need to learn about the sensitivity to disturbances not only of the cost function, but also of the measurements.

At last, the steady-state optimization problem can be formulated as in (6)

$$\begin{aligned} &\min_{u_0} J_0(x, u_0, d) \\ &\text{subject to} \\ &\text{Model equations: } f(x, u_0, d) = 0 \\ &\text{Operational constraints: } g(x, u_0, d) \leq 0 \end{aligned} \tag{6}$$

where $x$ are internal variables (states). In $f(x, u_0, d) = 0$ possible operational equality constraints (like a given feed flow) is also included. The main objective is to determine the optimal nominal operating condition to be used in the variable selection step.

**3. Select "economic" (primary) controlled variables**: In this step, the issue is the implementation of the optimal operation point found in the previous step in a robust and, most importantly, simple manner. We need to identify as many economic controlled variables ($c$) as there are economic degrees of freedom ($u_0$). For economic optimal operation, active constraints must be selected [25], which in turn consumes part of the degrees of freedom ($u'$). For the remaining degrees of freedom $u$ (with $n_u = n_{u_0} - n_{u'}$), we select variables for which close-to-optimal operation is achieved with constant nominal setpoints, even when there are disturbances [26]. Because our considerations in this communication are of local nature, we assume that the set of active constraints does not change with changing disturbances, and we consider the problem in reduced space in terms of the remaining unconstrained degrees of freedom $u$, which can be expressed as in (7) [27]

$$\begin{aligned} &\min_{u} J_0(x, u, d) \\ &\text{subject to} \\ &\text{Model equations: } f(x, u, d) = 0 \\ &\text{Active constraints: } g_{active}(x, u, d) = 0 \end{aligned} \tag{7}$$

where we consider as active constraints a subset $g_{active}(x, u, d)$ of $g(x, u_0, d)$ for which optimal values are always at bounds for all disturbances. By eliminating the states using the equality constraints in (7), the unconstrained optimization problem can be expressed simply as in (8)

$$\min_{u} J(u, d) \tag{8}$$

Ensuring active constraint operation consumes part of the degrees of freedom for optimization. The remaining degrees of freedom need to be fulfilled, and we select variables such that when kept at optimal setpoints leads to near optimal economic operation despite of disturbances, i.e., the deviation (loss $L$ in (5)) from re-optimization as a function of disturbances should be small. The optimal setpoints of $c$ are then determined from the optimization at the nominal operating point. This is the celebrated "self-optimizing" control technology [26]. It can be shown that the loss in (5) can be expressed in its worst case form ($L_{wc}$) as in (9) [23]

$$L_{wc} = \max_{\left\| \begin{bmatrix} d' \\ n^{y\prime} \end{bmatrix} \right\|_2 \leq 1} L = \frac{1}{2}\bar{\sigma}^2(M) \tag{9}$$

where $d'$ and $n^{y\prime}$ are the scaled disturbance and measurement error variables related by $d = W_d d'$ and $n^y = W_{n^y} n^{y\prime}$ ($W_d$ and $W_{n^y}$ are scaling matrices), and $M = -M_n H \tilde{F}$, where $\tilde{F} = [F W_d W_{n^y}]$ being $F = \frac{\partial y^{opt}}{\partial d}$ the optimal measurement ($y^{opt}$) sensitivity with respect to the disturbances and $M_n$ any nonsingular $n_u \times n_u$ matrix. In other words, we need to find $H$ that minimizes $\bar{\sigma}(M)$, i.e., $H = arg \min_H \bar{\sigma}(M)$.There are basically two approaches to solve for this minimization problem. The first one solves the minimization at once by combining disturbances and measurement errors, and an explicit formula for $H$ is given by (10) [23]

$$H^T = (\tilde{F}\tilde{F}^T)^{-1}G^y(G^{yT}(\tilde{F}\tilde{F}^T)^{-1}G^y)^{-1}J_{uu}^{1/2} \quad (10)$$

where $G^y$ is the static model of the process from the unconstrained inputs $u$ to the measurements and $J_{uu} = \left(\frac{\partial^2 J}{\partial u^2}\right)_{u^{opt}}$ is the Hessian of $J$ with respect to $u$ evaluated at $u^{opt}$ ($u^{opt}$ is the optimal value of the manipulated variables).

The second approach, called the extended nullspace method [23], solves the problem by first minimizing the loss with respect to disturbances, and then, if there are still enough measurements left, minimize the loss with respect to measurement errors. It can be shown that the explicit expression for $H$ in this case is given in (11)

$$H = M_n^{-1}\tilde{J}(W_{n^y}^{-1}\tilde{G^y})^{\dagger}W_{n^y}^{-1} \quad (11)$$

where $\tilde{J} = [J_{uu}^{1/2} \quad J_{uu}^{1/2}J_{uu}^{-1}J_{ud}]$ ($J_{ud} = \frac{\partial^2 J}{\partial u \partial d}$) and $\tilde{G^y} = [G^y \quad G_d^y]$ ($G_d^y$ is the static model from disturbances $d$ to $y$).

There are four cases where (11) can be applied:

3a. "Just-enough" measurements, i.e., $n_y = n_u + n_d$. Here, the expression for $H$ becomes (12)

$$H = M_n^{-1}\tilde{J}(\tilde{G^y})^{-1} \quad (12)$$

which is the same as having $H$ in the left null space of $F$, i.e., $H \in N(F^T)$.

3b. Extra measurements (select just enough measurements), i.e., $n_y > n_u + n_d$, and we want to select a subset of the measurements $y$ such that $n_y = n_u + n_d$. The solution is to find such a subset that maximizes $\underline{\sigma}(\tilde{G^y})$ using, e.g. existing efficient branch-and-bound algorithms [28]. The resulting $\tilde{G^y}$ is then used to compute $H$ in (12).

3c. Extra measurements (use all available measurements), i.e., $n_y > n_u + n_d$. $H$ is calculated using (11), where † denotes the left inverse, calculated as $A^{\dagger} = (A^TA)^{-1}A^T$ for any given matrix $A$.

3d. "Too few" measurements, i.e., $n_y < n_u + n_d$. In this case, the optimal $H$ in (11) is not affected by the noise weight and therefore becomes

$$H = M_n^{-1}\tilde{J}(\tilde{G^y})^{\dagger} \quad (13)$$

where † denotes the right inverse, calculated as $A^{\dagger} = A^T(AA^T)^{-1}$.

The above procedure boils down to selecting suitable candidate measurements, i.e. identify $n_y$ vis-a-vis $n_u + n_d$, and find that linear combination (matrix $H$) of all, or a given subset, which results in the smallest loss among all possible solutions. One big hurdle to be surmounted is the numerical calculation of $J_{uu}$ and $J_{ud}$. For some ill-posed problems, it may become an intractable task, and one solution is to compute $F$ numerically instead, since $F = \frac{dy^{opt}}{dd}$. Particularly, the extended nullspace general formula (11) can, after some matrix algebra, be reformulated as in (14)

$$H = M_s(G^y)^{\dagger}[G^y \quad (G_d^y - F)](W_{n^y}^{-1}\tilde{G^y})^{\dagger}W_{n^y}^{-1} \quad (14)$$

where $M_s = (J_{uu}^{-1/2}M_n)$ can be any non-singular $n_u \times n_u$ matrix. In this case, we could select $M_n = J_{uu}^{1/2}$ so that (10) and (11) are independent of Hessian information.

## IV. Sensitivity analysis results

### A. Step 1. Operational objectives

The operational costs in a wastewater treatment plant depend on the wastewater system itself and can be divided into manpower, energy, maintenance, chemicals usage, chemical sludge treatment, and disposal costs. However, in this work, the objective is to reduce the cost of energy and sludge disposal as much as possible. Therefore, the following costs are considered:

- Required pumping energy ($E_P$ expressed in $kWh/d$);
- Required aeration energy ($E_A$ expressed in $kWh/d$);
- Required mixing energy when the aeration is too low ($E_M$ expressed in $kWh/d$);
- Sludge disposal ($C_D$ expressed in \$ $/d$).

The mathematical expressions for all these quantities can be found in [8], and by assuming a constant energy price of $k_E = 0.09$ \$ $/kWh$ and a sludge disposal price of $k_D = 80$ \$ $/ton$, the total cost in \$$/d$ can be calculated as:

$$Cost = k_E(E_P + E_A + E_M) + k_D C_D \quad [\$/d] \quad (15)$$

The overall cost function in (15) is then minimized subject to environment regulations for the effluent and some constraints related to process operability, as listed in Table I.

TABLE I
CONSTRAINTS TO THE PROCESS.

| Constraint | Unit | Status |
|---|---|---|
| $COD^{(eff)} \leq 100$ | $gCOD/m^3$ | Regulation constraint |
| $TSS^{(eff)} \leq 30$ | $gSS/m^3$ | Regulation constraint |
| $TN^{(eff)} \leq 18$ | $gN/m^3$ | Regulation constraint |
| $BOD_5^{(eff)} \leq 10$ | $gBOD/m^3$ | Regulation constraint |
| $S_{NH}^{(eff)} \leq 4$ | $gN/m^3$ | Regulation constraint |
| $Q_w \leq 1845$ | $m^3/d$ | Manipulation constraint |
| $Q_r \leq 36892$ | $m^3/d$ | Manipulation constraint |
| $Q_a \leq 92230$ | $m^3/d$ | Manipulation constraint |
| $K_La^{(1-5)} \leq 360$ | $d^{-1}$ | Manipulation constraint |

### B. Step 2. Steady-state optimal operation

There are 8 manipulated variables (last four entries in Table I), which correspond to 8 steady-state degrees of freedom ($u$). The liquid levels in the reactor tanks are assumed constant at maximum capacity due to the overflow layout considered for the plant.

Compared to other process industries, a wastewater treatment plant is subject to very distinct operation modes because of daily, weekly and seasonal variation in the incoming wastewater. In this paper we consider the influent load data as given by the IWA Task Group in the benchmark website. The data are presented in terms of ASM1 state variables and influent flow rates. In general, these data reflect expected diurnal trend variations in weekdays which are typical for normal load behavior at a municipality treatment facility. Table II summarizes the given disturbances in terms of influent flow rate and load. The average composition and flow rate and the average values for the process inputs are taken from the various weather data.

TABLE II
WEATHER PROFILES EVENTS.

| | $Q_0$ | $COD^{(in)}$ | $TSS^{(in)}$ | $TN^{(in)}$ | $T$ |
|---|---|---|---|---|---|
| | $[m^3/d]$ | $[gCOD/m^3]$ | $[gSS/m^3]$ | $[gN/m^3]$ | $[^oC]$ |
| $e_0$ | 18446 | 381 | 211 | 54 | 15 |
| $e_1$ | 21320 | 333 | 183 | 48 | 15 |
| $e_2$ | 40817 | 204 | 116 | 28 | 15 |
| $e_3$ | 19746 | 353 | 195 | 50 | 15 |
| $e_4$ | 34286 | 281 | 101 | 37 | 15 |
| $e_5$ | 20850 | 347 | 199 | 41 | 15 |
| $e_{5,min}$ | 20850 | 347 | 199 | 41 | 9 |
| $e_{5,max}$ | 20850 | 347 | 199 | 41 | 21 |

### C. Step 3. Variable selection

The results of the optimization shows that three constraints are active, namely, $TSS^{(eff)}$ (upper limit), $S_{NH}^{(eff)}$ (upper limit), and $Q_a$ (lower limit). As expected, $TSS^{(eff)}$ is at its maximum to make $Q_w$ small. In general, the reason why free ammonia ($S_{NH}^{(eff)}$) is active at its upper bound is that, as nitrification is an oxygen demanding process and because the transfer efficiency of oxygen from gas to liquid is relatively low so that only a small amount of oxygen supplied is used by the microorganisms, the aeration demand ($E_A$), which is the major cost contributor in a wastewater treatment plant, is high. One interesting fact is that the process is optimally operated aerobically, that is to say, with no anaerobic zone. The possible reason is due to the attempt to minimize the high aeration costs and to the fact that the effluent total nitrogen and ammonia constraints are quite easily reached for the given influent loads.

As those 3 active constraints must be implemented to ensure optimal operation [25], we are left with 5 degrees of freedom, and we use the local methods described in step 3 of the procedure to decide for the best (optimal) set of unconstrained self-optimizing control variables to fulfill the available degrees of freedom. We consider $n_y = 28$ measurements (the list is not shown here for the sake of compactness), $n_u = 5$ manipulated variables, and $n_d = 5$ disturbances, and clearly with $n_y > n_u + n_d$ one can expect to substantially reduce the loss for disturbances and measurement errors. As there are as many measurements as there are manipulations and disturbances, one can compute various $H$ matrices and their respective local losses. The methods considered in this communication are

1. The combined disturbances and measurements errors using all available measurements, where $H$ is computed by (10). In this case, $H_1$ is a $5 \times 28$ combination matrix.
2. The extended nullspace using all measurements, with $H$ computed by (14). In this case, $H_2$ is also a $5 \times 28$ combination matrix.
3. The extended nullspace using just enough measurements, where $\tilde{G^y}$ in (14) is found by a branch and bound algorithm [28]. In this case, $H_3$ is a $5 \times 10$ combination matrix.

For the sake of compactness only the resulting local losses calculated using (9) are reported, and they are $L_{wc}^{H_1} = 0.1184$, $L_{wc}^{H_2} = 0.1291$, and $L_{wc}^{H_3} = 0.0761$, and one should expect to have actual (nonlinear) losses of the same magnitude for any of the calculated $H$ matrices. In the last case, where the loss is expected to be the smallest, the variables chosen by the branch and bound algorithm that maximized the minimum singular value of $\tilde{G^y}$ were $S_O^{(3)}$, $S_O^{(4)}$, $S_{NO}^{(4)}$, $MLSS$, $K_La^{(1)}$, $K_La^{(2)}$, $K_La^{(3)}$, $K_La^{(4)}$, $COD^{(in)}$ and $T^{(in)}$.

## V. Discussion

The nominal optimization results showed that it is economically optimal to keep effluent suspended solids and ammonia concentrations at their respective upper bounds, and that no internal recirculation of sludge should be used, at least under the steady-state assumption. This fact is surprising but quite realistic. Indeed, the main purpose of the internal recirculation is to provide enough nitrate to enhance denitrification in the bioreactor anoxic zones and from an economical point of view this can be efficiently achieved by the return sludge (Qr) only which brings back sufficient nitrate for denitrification reducing the pumping costs due to $Q_a$. However, when operating the process dynamically, one may consider using $Q_a$ to control some internal variable so as to improve the disturbance rejection capability of the process.

If these variables are controlled at their respective optimal setpoints (active constraint control), a choice had to be made on the selection of the remaining 5 degrees of freedom, and we use the sensitivity analysis based on a plantwide procedure to decide on which 5 variables to fix/control at their respective nominal optimum values. The exact local (linear) method and the extended nullspace method based on the concept of self-optimizing control were used to systematically select those variables such that the cumbersome combinatorial curse of choosing and testing 5 out of 28 possible variable combinations is avoided. The resulting combination matrices $H$ were easily computed using elementary matrix algebra, as described by the formulas (10), (11), and (12). The only burden with those calculations lies on the computation of the optimal matrices $J_{uu}$, $J_{ud}$, and $F$. Since accuracy of second order information found numerically is known to be difficult to guarantee, in addition to assuring positive definiteness of $J_{uu}$, calculation of $F$ might become more attractive, and a replacement formula for (11) was derived as in (14). $M_n$ in this equation can be freely selected, as long as it is a non-singular matrix, and we chose $M_n = J_{uu}^{1/2}$ so to avoid the need to compute $J_{uu}$. Moreover, since the solution for $H$ in (10) is not unique [23], we can also find a non-singular $n_u \times n_u$ $D$ matrix such that $H_{new} = DH$ is another yet solution, and we can select $D$ as a function of $J_{uu}^{1/2}$; in this paper we assumed $D = J_{uu}^{-1/2}$.

The above derivations are local since we assume a linear process and a second-order objective function in the inputs and the disturbances. Thus, the proposed controlled variables are only globally optimal for the case with a linear model and a quadratic objective. In this article, for a final validation, the actual losses are checked using the nonlinear model of the process. Table III shows that the losses are about the same order of magnitude for a given disturbance. Note also that feasibility is not always guaranteed for all alternatives, and indeed only the alternative where $H$ was computed using the extended nullspace method with "just-enough" measurements is feasible for all disturbance spectrum.

TABLE III
NONLINEAR LOSS CALCULATION FOR VARIOUS DISTURBANCES.

| | $e_1$ | $e_2$ | $e_3$ | $e_4$ | $e_5$ | $e_{5,min}$ | $e_{5,max}$ |
|---|---|---|---|---|---|---|---|
| $J^{opt}$ | 426.78 | 490.09 | 420.56 | 599.36 | 419.83 | 491.28 | 357.96 |
| $J^{H_1}$ | 427.08 | 507.18 | 420.62 | 602.53 | 420.36 | 494.37 | Inf |

| $J^{H_2}$ | 426.97 | 495.86 | 420.59 | 608.95 | 420.37 | 492.82 | 358.71 |
| $\%L^{H_2}$ | 0.04 | 1.18 | 0.01 | 1.60 | 0.13 | 0.31 | 0.21 |
| $J^{H_3}$ | 427.07 | Inf | 420.60 | Inf | 419.94 | 507.74 | 359.40 |
| $\%L^{H_3}$ | 0.07 | Inf | 0.01 | Inf | 0.03 | 3.35 | 0.40 |

## VI. CONCLUSION

This paper discussed the application of a sensitivity procedure for optimal operation of a wastewater treatment plant. For the given modified mathematical model of the process, where the settler is modeled based upon the static one-dimension scalar mass conservation law with discontinues fluxes theory, keeping the active constraints ($S_{NH}^{(eff)}$, $TSS^{(eff)}$, and $Q_a$) at their optimal values and using linear combinations of the measurements as the five remaining unconstrained degrees of freedom can guarantee near-optimal operation with minimum loss when operating at the nominal optimal mode despite the severe disturbances that affect the process.

***Abstract*—In order to meet tight product quality specifications for batch/fed-batch processes, it is vital to monitor and control batch product quality throughout the batch duration. The ideal strategy is to control batch product quality through trajectory tracking of a desirable batch product quality evolution during the batch run. However, due to the lack of in-situ sensors for continuous measurements of batch product quality, the measurement of batch product quality is usually implemented by laboratory assay of samples and thus these measurements are generally intermittent. Therefore direct trajectory tracking of batch product quality is not feasible for such scenarios with intermittent measurements. This paper proposes an approach to use intermittent measurements to realize trajectory tracking control of batch product quality through moving window estimation. The first step of the approach is to identify a partial least squares (PLS) model using intermittent measurements to relate process variable trajectories and batch product quality. Then the identified PLS model is further applied to predict product quality trajectory during the batch run so as to realize trajectory tracking of a desirable product quality evolution. An example from fed-batch fermentation for penicillin production is used to illustrate the principle and the effectiveness of the proposed approach.**

## I. Introduction

Batch processes are widely used in industry for manufacturing low-volume and high-value added products such as specialty chemicals, polymers and pharmaceuticals [1]. The popularity of batch operation in industry has two main reasons [2]: one is that batch processes are easier to set up and operate with the possibility of continuous improvements from earlier batch runs; the other is that batch operation is more efficient than continuous operation for frequent product changes and the production of small quantities with little or no hardware modification at all, which is especially attractive for starting commercial productions of novel materials to recover research and development costs before competing products affect prices.

The ultimate task for batch processes is to ensure consistent and desirable batch end-product quality for each batch run. This is not easy to fulfil in practice as batch processes are usually complex physical-chemical processes with time-varying and nonlinear dynamics. Furthermore, there still lack reliable in-situ sensors to monitor batch product quality during the batch run. Batch-to-batch variations resulting from changes to raw material properties and operating conditions also render robust control of batch end-product quality even more challenging. Many process monitoring and control schemes have been proposed in the literature to confront the issues encountered in batch operations [3], [4], [5], [6], [7]. Initial studies for the control of batch processes were based on mechanistic process models and traditional control methods [8], [9], [10], [11], [12], [13]. However, the identification of an accurate mechanistic model for a batch process is often difficult and time-consuming. Therefore multivariate statistical process control methods, which are based on process history data to develop empirical models, become a popular technique for modern process monitoring and control [14], [1], [15], [4], [16], [7], [17]. Among them, multi-way principal components analysis (PCA) and multi-way projection to latent structures (PLS), which are the extensions of PCA and PLS, enabling them handle three-dimensional matrices, are most widely used [18], [19], [20], [21], [7].

Using latent variable models such as multi-way PCA and PLS, currently there are two control approaches for batch processes: batch end-product quality control and trajectory tracking. The typical batch end-product quality control approach is addressed in [19], [22], where a PLS model relates process variable trajectories to batch end-product quality. Manipulated variable trajectories (MVTs) are determined such that they minimize the difference between the predicted and the target batch end-product quality. Since there is no measurement of batch product quality during the batch running period, the effectiveness of the approach relies heavily on the accuracy of the identified PLS model. The typical trajectory tracking approach is addressed in [21], [7], where a PCA model is identified to model the process dynamics of all process variable trajectories and MVTs are deduced from feeding future process variable trajectories with the target trajectories. Due to the difficulty of on-line measurements of batch product quality during the batch run, the target trajectories are usually some key process variable trajectories such as temperature set-points rather than the target batch product quality trajectories and thus the assumption is that the batch end-product quality can be guaranteed if these key process variable trajectories follow their pre-determined set-points. However, such an assumption is not always true as the batch end-product quality

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

can deteriorate in the case of disturbances even if the predetermined process variable trajectories are perfectly tracked.

Although batch product quality cannot typically be measured continuously along with other process variables due to the lack of in-situ sensors for quality measurement, it can often be measured intermittently through laboratory assay of samples taken during the batch run. Making use of the intermittent measurement data, a PLS model can be identified according to the method proposed in [5], where a series of created pseudo batches are synchronized to their batch endpoints and a PLS model is identified upon the synchronized pseudo batch data. The identified PLS model can further be applied to predict future batch product quality trajectories using moving window estimation. Thus it is possible to realize trajectory tracking of a pre-determined product quality trajectory directly rather than trajectory tracking of other process variable trajectories for a new batch run.

This paper proposes a practical approach to realize trajectory tracking control of batch product quality using intermittent measurements and moving window estimation. The paper is organized as follows: Section 2 details the methodology of the proposed trajectory tracking control of batch product quality; a case study of penicillin fermentation is described in Section 3; some conclusions and remarks are provided in Section 4.

## II. Trajectory Tracking Control of Batch Product Quality

In order to realize trajectory tracking control of batch product quality using intermittent measurements and moving window estimation, three steps are to be fulfilled: the first step is to identify a PLS model using intermittent quality measurements and a PCA model without any data from intermittent quality measurements; the second step is to predict future quality trajectories using the identified PCA&PLS models and the strategy of moving window estimation; and the third step is to compute the MVTs and implement them in a receding horizon manner. These three steps are to be described in detail in the following subsections.

### A. Model identification

For PLS, process variables are divided into two groups: the predictor values such as measured process variable trajectories and manipulated variable trajectories; the response values such as measured batch product quality variables. The method for identifying the PLS model using intermittent measurements is similar to the approach proposed in [5], where pseudo batches are created at those measurement points and they are further aligned toward their end-points for identifying the PLS model based on a selected modeling window.

Taking two batches shown in Figure 1 as an example, each batch has three intermittent measurements for product quality during the batch run. Therefore a total of six pseudo batches are created and they are aligned toward their end-points as shown in Figure 1. Then a modeling window is selected to identify the PLS model with the intermittent measurements as the response values and all other process variable measurements including the manipulated variables as the predictor values. The predictor and response values are generally three-dimensional matrices of size $I \times J \times K$, where $I$ is the number of pseudo batches for which data are available, $J$ is the number of variables that are measured and $K$ is the number of samples collected during the time period of the modeling window. These three dimensional matrices of data can be unfolded in a batch-wise way to model differences among batches [7]. The batch-wisely unfolded data are further mean-centered and scaled to be unit variance and performing PLS on the obtained data results in a latent variable model of the form:

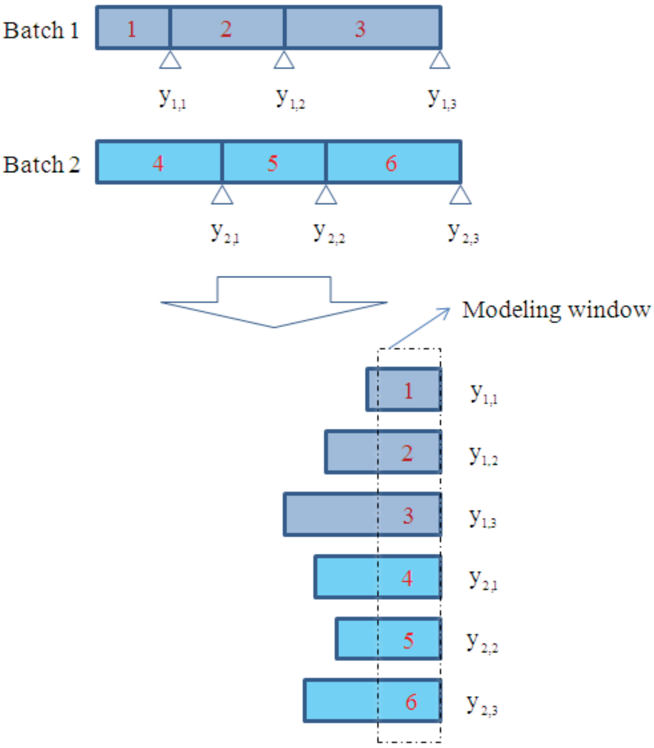

Fig. 1. Model building using intermittent measurements

$$\mathbf{X} = \mathbf{T}\mathbf{P}^T + \mathbf{E}, \tag{1}$$
$$\mathbf{Y} = \mathbf{U}\mathbf{Q}^T + \mathbf{F}, \tag{2}$$

where $\mathbf{X}$ is a matrix of $I \times J_x K_x$ for the predictor variables, $\mathbf{Y}$ is a matrix of $I \times J_y K_y$ for the response variables, $\mathbf{P}$ of $J_x K_x \times A$ and $\mathbf{Q}$ of $J_y K_y \times A$ are the loading matrices, respectively. Here $A$ is the number of latent variables. The scores $\mathbf{T}$ and $\mathbf{U}$ are related by a diagonal matrix $\mathbf{B}$ of proper dimensions with $\mathbf{U} = \mathbf{TB}$. $\mathbf{T} = \mathbf{XW}(\mathbf{P}^T\mathbf{W})^{-1}$, where $\mathbf{W}$ is the weight matrix. Finally, $\mathbf{E}$ and $\mathbf{F}$ are residual matrices. In practice, the PLS model is often expressed as a predictive model relating the predictor variables and the response variables directly [23]:

$$\mathbf{Y} = \mathbf{XW}(\mathbf{P}^T\mathbf{W})^{-1}\mathbf{B}\mathbf{Q}^T + \mathbf{F}^*, \tag{3}$$

where $\mathbf{F}^*$ is a residual matrix.

Without considering the intermittent measurements for product quality variables, multi-way PCA can be identified instead to model the correlation structure for all predictor variables:

$$\mathbf{X} = \mathbf{T}_c\mathbf{P}_c^T + \mathbf{E}_c. \tag{4}$$

### B. Moving window estimation

Once the PCA and PLS models have been identified from past batch data, they can be further used to predict future batch product quality for a new batch run through the strategy of moving window estimation. The principle of moving window estimation can be described in Figure 2, where the length of the modeling window for the identified PCA&PLS models is assumed to be $l$ and the current time instant is $\theta_i$. The first step for moving window estimation is to place the modeling window to cover the measured $l-1$ samples of predictor variables, which are $\mathbf{u}_{\theta_i-l+1\to\theta_i-1}$ for the manipulated variable $\mathbf{x}_{\theta_i-l+2\to\theta_i}$ and for all other measured process variables. Assume that the future manipulated variable trajectory is known in advance, then the future process variables $\mathbf{x}_{\theta_i+1}$ can be estimated using the identified PCA model and missing data algorithms. Several missing data imputation methods have been proposed in the literature [24], [25]. The common idea of them is to make use of the underlying data pattern to deduce the missing part from the known part. Taking the missing data algorithm called Projection to the Plane as an example, the predictor variables $\mathbf{x}$ are grouped into two parts $\mathbf{x}^T = [\mathbf{x}^{*^T}\mathbf{x}^{\sharp^T}]$, where $\mathbf{x}^{*^T} = [\mathbf{x}^T_{\theta_i-l+2\to\theta_i}\ \ \mathbf{u}^T_{\theta_i-l+1\to\theta_i}]$ contains the known data and $\mathbf{x}^\sharp = \mathbf{x}_{\theta_i+1}$ contains the missing data. The loading matrix $\mathbf{P}$ from the identified PCA model can also be grouped into two corresponding parts $\mathbf{P}_c^*$ and $\mathbf{P}_c^\sharp$. Then the missing data can be deduced from the optimal score vector $\hat{\tau}$, which is obtained from minimizing the following objective function [21]:

$$J = \frac{1}{2}(\mathbf{x}^* - \mathbf{P}_c^*\tau)^T(\mathbf{x}^* - \mathbf{P}_c^*\tau). \tag{5}$$

The optimal solution for Eq. (5) is $\hat{\tau} = (\mathbf{P}_c^{*^T}\mathbf{P}_c^*)^{-1}\mathbf{P}_c^{*^T}\mathbf{x}^*$ and thus the missing data $\mathbf{x}^\sharp$ can be deduced from it straightforwardly:

$$\mathbf{x}^\sharp = \mathbf{P}_c^\sharp\hat{\tau}. \tag{6}$$

Therefore the estimation of the future process variable $\mathbf{x}_{\theta_i+1}$, denoted as $\hat{\mathbf{x}}_{\theta_i+1}$, can be expressed as a function of the measured process variable trajectories $\mathbf{x}_{\theta_i-l+2\to\theta_i}$ and the manipulated variable trajectories $\mathbf{u}_{\theta_i-l+1\to\theta_i}$:

$$\hat{\mathbf{x}}_{\theta_i+1} = \mathbf{P}_c^\sharp(\mathbf{P}_c^{*^T}\mathbf{P}_c^*)^{-1}\mathbf{P}_c^{*^T}[\mathbf{x}^T_{\theta_i-l+2\to\theta_i}\ \ \mathbf{u}^T_{\theta_i-l+1\to\theta_i}]^T. \tag{7}$$

Using the estimated $\hat{\mathbf{x}}_{\theta_i+1}$ and the identified PLS model, the product quality at the time instant $\theta_i+1$, denoted as $\hat{\mathbf{y}}_{\theta_i+1}$, can be predicted as follows according to Eq. (3):

$$\hat{\mathbf{y}}_{\theta_i+1} = [\mathbf{x}^T_{\theta_i-l+2\to\theta_i}\ \ \hat{\mathbf{x}}^T_{\theta_i+1}\ \ \mathbf{u}^T_{\theta_i-l+1\to\theta_i}]\mathbf{W}(\mathbf{P}^T\mathbf{W})^{-1}\mathbf{B}\mathbf{Q}^T. \tag{8}$$

After the process variable values and the product quality value at the time instant $\theta_i+1$ have been estimated using the identified PCA&PLS models, the modeling window is to be moved forward as shown in Figure 2. Then the process variable values and the product quality value at the time instant $\theta_i+2$ can be deduced in a similar way, where the value of $\mathbf{x}_{\theta_i+1}$ is assumed to be known in advance as the formerly estimated value $\hat{\mathbf{x}}_{\theta_i+1}$. The whole estimation process is repeated sequentially up to the end of the control horizon $\theta_c$. So the estimated process variable trajectories $\hat{\mathbf{x}}_{\theta_i+1\to\theta_c}$ and the estimated product quality trajectories $\hat{\mathbf{y}}_{\theta_i+1\to\theta_c}$ can both be expressed as a function of the future manipulated variable trajectories $\mathbf{u}^T_{\theta_i\to\theta_c-1}$.

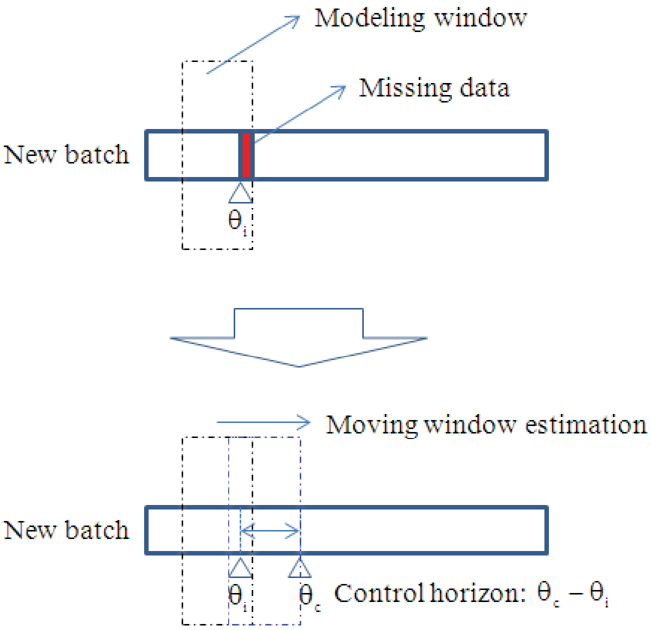

Fig. 2. Moving window estimation

### C. Trajectory tracking control

The proposed trajectory tracking control is performed in a typical receding horizon manner: the future manipulated variable trajectories with the horizon of $c$ are optimized to minimize the difference between the predicted future quality trajectory and the target future quality trajectory at each control decision point; the optimized future manipulated variable trajectories are implemented into the process up to the next control decision point and the whole process is repeated until the operation ends. Assume that the control decision point is at the current time instant $\theta_i$ and the target future quality trajectory is $\bar{\mathbf{y}}_{\theta_i+1\to\theta_i+c}$, the predicted future quality trajectory $\hat{\mathbf{y}}_{\theta_i+1\to\theta_i+c}$ can be obtained using moving window estimation. According to the moving window estimation procedure described in Eqs. (7-8), the predicted future quality trajectory $\hat{\mathbf{y}}_{\theta_i+1\to\theta_i+c}$ can be illustrated as a function of the future manipulated variable trajectory $\mathbf{u}_{\theta_i\to\theta_i+c-1}$, i.e.,

$$\hat{\mathbf{y}}_{\theta_i+1\to\theta_i+c} = \mathbf{f}(\mathbf{x}_{\theta_i-l+c+1\to\theta_i}, \mathbf{u}_{\theta_i\to\theta_i+c-1}). \tag{9}$$

The corresponding optimization for the optimal future manipulated variable trajectory $\tilde{\mathbf{u}}_{\theta_i \to \theta_i + c - 1}$ can then be formulated as follows:

$$\begin{aligned} \min_{\mathbf{u}_{\theta_i \to \theta_i + c - 1}} \quad & (\hat{\mathbf{y}}_{\theta_i + 1 \to \theta_i + c} - \bar{\mathbf{y}}_{\theta_i + 1 \to \theta_i + c})^T \mathbf{Q}_1 \\ & (\hat{\mathbf{y}}_{\theta_i + 1 \to \theta_i + c} - \bar{\mathbf{y}}_{\theta_i + 1 \to \theta_i + c}) + \\ & \Delta \mathbf{u}^T_{\theta_i \to \theta_i + c - 1} \mathbf{Q}_2 \Delta \mathbf{u}_{\theta_i \to \theta_i + c - 1}, \\ s.t. \quad & \mathbf{U}_{lb} \leq \mathbf{u}_{\theta_i \to \theta_i + c - 1} \leq \mathbf{U}_{ub} \end{aligned} \tag{10}$$

where $\mathbf{Q}_1$ and $\mathbf{Q}_2$ are the weight matrices for trajectory errors and control rates, respectively; $\mathbf{U}_{lb}$ and $\mathbf{U}_{ub}$ are the lower and upper bound for $\mathbf{u}_{\theta_i \to \theta_i + c - 1}$, respectively.

## III. CASE STUDY

In order to assess and validate the proposed approach for trajectory tracking control of product quality, a benchmark simulation for fed-batch fermentation of penicillin is used. The simulator, called Pensim, is based upon a series of detailed mechanistic models that describe the fermentation process [26]. The following process variables are collected hourly during the fermentation process: aeration rate, agitator power, substrate feed temperature, substrate concentration, dissolved oxygen concentration, culture volume, carbon dioxide concentration, pH, fermenter temperature, generated heat and substrate feed rate. The substrate feed rate is the manipulated process variable and the batch product quality is the biomass concentration that is measurable intermittently through laboratory assay during the batch run. Ten batch data are collected for model building and each batch has a duration time of 200 hours. It is further assumed that the biomass concentration is measured four times at a time interval of 50 hours during the batch running for each batch and therefore a total of 40 pseudo batches are created according to Figure 1. The validation of the proposed approach is performed in two steps: the first step is focused on building the PCA&PLS models and validating their accuracy for the strategy of moving window estimation; the second step is focused on realizing trajectory tracking control of batch product quality using the identified PCA&PLS models and the strategy of moving window estimation. These two steps are detailed in the following two subsections.

### *A. Building the PCA&PLS models and validating their accuracy using moving window estimation*

The PCA&PLS models are identified using the created 40 pseudo bath data, where the length for the modeling window is selected to be 50 hours and the number of latent variables for the identified PCA&PLS models is selected to be 12 through cross-validation [27]. Taking a new batch run for an example, the control decision point is set at 50th hour and the future substrate feed rate is also assumed to be known. Then the future process variables such as the future carbon dioxide concentration can be estimated recursively using the identified PCA model according to Eq. (7). The estimated future carbon dioxide concentration from 50th hour to 90th hour is shown in Figure 3, where the estimated values are compared with their actual values. It can be seen that the estimated values are close to their actual values and thus the identified PCA model can be used to estimate the future process variable trajectories using the strategy of moving window estimation.

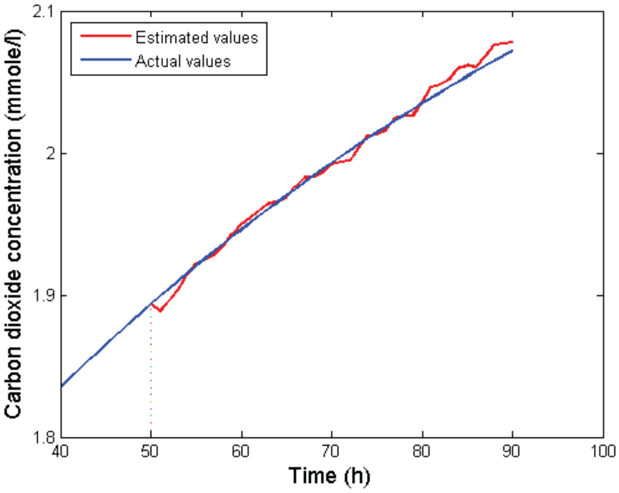

Fig. 3. Moving window estimation of the future carbon dioxide concentration

Using the same known future substrate feed rate and the estimated future process variable trajectories, the future biomass concentration can also be predicted using the identified PLS model and the strategy of moving window estimation according to Eq. (8). The predicted future biomass concentration from 50th hour to 90th hour is shown in Figure 4, where the predicted values are compared with their actual values. It can be seen that the identified PLS model can also successfully apply to predict the future product quality trajectory. These results shown in Figures 3 and 4 have demonstrated the accuracy of the identified PCA&PLS models as well as the effectiveness of moving window estimation and therefore they can be used for the following trajectory tracking control of batch product quality.

### *B. Trajectory tracking control using the identified PCA&PLS models and moving window estimation*

For the same new batch run, the task of the proposed controller is to track a pre-determined product quality trajectory during the batch run. Taking a pre-determined biomass concentration trajectory under nominal conditions as an example, the control result of tracking the predetermined trajectory is shown in Figure 5, where the control horizon is selected to be 10 hours and the controller is switched on at 50th hours. It can be seen that the target product quality trajectory has been tracked approximately. However, there are some oscillations for the controlled quality trajectory. This is due to the oscillatory trajectory of the computed substrate feed rates, as shown in Figure 6. Additional measures such as adding extra constraints on control input sequences are to be taken to reduce such oscillatory behavior for a smoother trajectory tracking in the

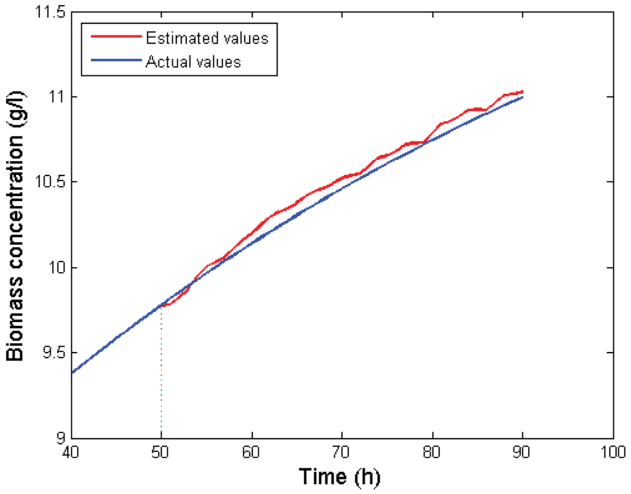

Fig. 4. Moving window prediction of the future biomass concentration

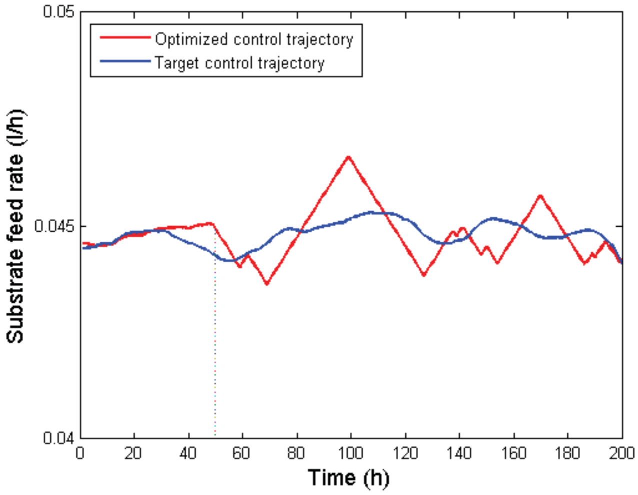

Fig. 6. The computed manipulated variable trajectory from the controller

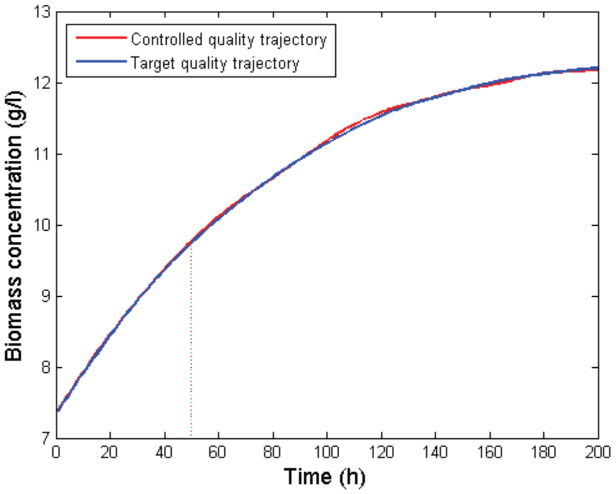

Fig. 5. Tracking an ideal product quality trajectory using the controller

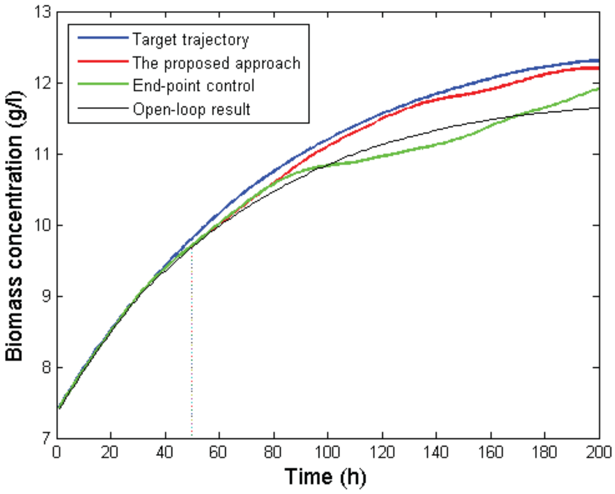

Fig. 7. Tracking product quality trajectory subject to un-modeled disturbances

future work [22].

The proposed control approach for trajectory tracking of batch product quality is further compared to the traditional end-point control approach of batch product quality [19]. In order to demonstrate the benefits of considering intermediate product quality trajectory rather than just the batch end-product quality, the fed-batch process is assumed to be subject to un-modeled disturbances. The added disturbance is chosen to be a step change in the concentration of the substrate feed from its nominal value of 600 $g/l$ to 570 $g/l$ occurring at the 30th hour. As shown in Figure 7, the traditional batch end-product quality control approach lacks the capability to detect the occurred disturbance and thus generates a much lower batch end-product quality than the proposed control approach. The proposed control approach manages to track the target product quality trajectory approximately despite the occurrence of the added disturbance and thus it can generate a much better batch end-product quality as well.

## IV. Conclusions

Due to the lack of in-situ sensors for continuous measurements of batch product quality, it is hard to realize trajectory tracking control of product quality directly. Making use of intermittent measurements for batch product quality, this paper proposes a practical approach for tracking a desirable quality trajectory during the batch runs. The proposed approach is based on the strategy of moving window estimation for online prediction of future product quality trajectory. The benchmark simulation results have demonstrated the accuracy of the identified PCA&PLS models using intermittent measurements and

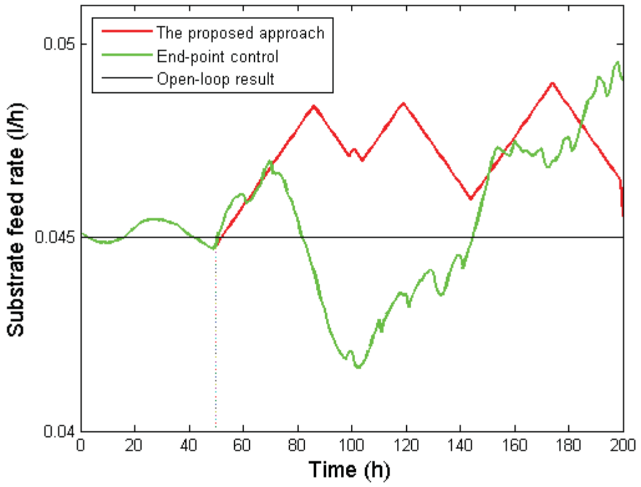

Fig. 8. The computed manipulated variable trajectories subject to un-modeled disturbances

the effectiveness of the proposed trajectory tracking scheme for batch product quality control, especially in the case of un-modeled disturbances. The obtained manipulated variable trajectory tends to be oscillatory and measures are to be taken to reduce such oscillatory behavior in the future work.

*Abstract*— **This paper presents batch-to-batch iterative learning control (ILC) of a fed-batch fermentation process using batch-wise linearised models identified from process operation data. The newly obtained process operation data after each batch is added to the historical data base and an updated linearised model is adaptively identified. In an effort to adapt to the current process environment, the updated model is identified from a moving window of the most recent historical batches. The new model is used to compute control policy for the next batch. The control policy at different batch stages are generally correlated as the overall control policy is obtained to maximize the amount of product at the end of a batch. To address the colinearity issue, partial least square (PLS) is used in estimating the linearised model parameters. The proposed strategy is applied to a simulated fed-batch fermentation process and the performance is evaluated. The effect of window sizes was studied. Simulation results show that the proposed approach improves the batch-to-batch ILC performance.**

## I. INTRODUCTION

Fed-batch fermentation is vital in manufacturing high value added pharmaceutical and biochemical products. Fed-batch process is an evolution from batch reactor. The only difference between batch and fed-batch reactor is the feeding technique. In a batch reactor the substrate is only fed at the beginning of the process while in a fed-batch reactor it is fed over a few intervals with varying feed rates if necessary depending on the cell growth curve. The objective of using fed-batch in a fermentation process is to feed the substrate at the same rate that the organism utilizes it. That way, fed-batch fermentation increases input-yield ratio compared to the batch fermentation.

A core issue in fed-batch fermentation is the inability to sustain end-product quality specification due to the presence of model plant mismatches and unknown disturbances. Although every single batch repeats with exactly the same nominal initial parameters, somehow the end-product concentration varies due to unknown process variations. At present, the optimal control policy (feed rate) to obtain desired product quality in fed-batch fermentation is calculated off-line. The off-line calculated control policy may not be optimal when implemented to the real process due to model-plant mismatches and presence of unknown disturbances.

The repetitive nature of batch processes allows information from previous batches being used in modifying the control policy of the next batch in the framework of iterative learning control (ILC). ILC exploits every possibility to incorporate past control information into construction of present control action through memory based learning. The basic idea of ILC is to update the control trajectory for a new batch run using information from previous batch runs so that the output trajectory converges asymptotically to the desired reference trajectory [1],[2],[3]. The concept of ILC was first developed in the robotics industry to render a high precision in performing repetitive action of a given task [4], [5], [6]. In the recent years, ILC have been actively studied for application in injection moulding, batch reactor, chemical batch process, extrusion and batch distillation [7], [8], [9].

In a batch reactor, final product quality is usually controlled through controlling measurable variables such as pH, temperature and feed rate. The optimal trajectory of the measured variable is set and every batch run for the same process follows the same fixed trajectory [10]. This strategy fails when process disturbance in non-measured variables such as feedback condition, raw material properties, impurities and catalyst activities is present and affects the product quality [1]. This means a consistent input trajectory will not ensure product quality especially when unknown disturbances are present. This setback brings about the idea to update and re-optimize the input trajectory after every run to achieve desired product quality iteratively [10]. In a recent development, batch to batch ILC based on linearized perturbation model identified using multiple linear regressions (MLR) is reported [10]. In that work [10], the perturbation model is obtained using deviations of process input and output from their nominal trajectories and is updated after every batch by using the immediate previous batch as the nominal batch. This way, the unexpected process and parametric disturbances is expected to be captured and removed to render a more precise model prediction.

This paper presents an ILC strategy for a fed-batch fermentation process using linearised models identified from process operational data. The control policy updating is calculated using a model linearised around a reference batch. In order to cope with process variations and disturbances, the

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

reference batch can be taken as the immediate previous batch. In such a way, the model is a batch wise linearised model and is updated after each batch. The newly obtained process operation data after each batch is added to the historical data base and an updated linearised model is re-identified. In order to overcome the colinearity among the predictor variables, this paper proposes that the linearised model can be identified using partial least square regression (PLS) [11].

In order for the updated model to capture the process behavior in the face of process variations, a new technique using a moving window of the historical batches to update batch-wise linearised models is developed in this paper. The historical batches were updated after every batch run but using only the *M* recent number of batches. In other words, after every run the "oldest" batch is forgotten and the new batch is included into the sliding "window" of historical batches.

The proposed strategy is applied to a simulated fed-batch fermentation process. The results show that enhanced control performance is obtained under the proposed approach. Model updating using PLS leads to better control performance than model updating using MLR. Different window sizes were studied and the performances were evaluated.

The paper is organized as follows. Section II presents batch-to-batch ILC with updated linearised model. Application to a simulated fed-batch fermentation process is presented in Section III. Section IV concludes this paper.

## II. Batch-to-batch Iterative Learning Control with Updated Linearised Model

### *A. Linearised Models for Batch Processes*

Consider batch processes where the batch run length ($t_f$) is fixed and consists of *N* control intervals. For simplicity in implementation, the manipulated variable, $u \in R^m$ ($m$=1 in this work), is kept constant within each control interval and, thus, the control policy for a batch is a vector with *N* elements. Product quality variables (outputs), $y \in R^n$ ($n \geq 1$), can be obtained off-line by analysing the samples taken during the batch run. The product quality and control trajectories are defined, respectively, as

$$\mathbf{Y}_k=[y_k^{\mathrm{T}}(1), y_k^{\mathrm{T}}(2),\ldots, y_k^{\mathrm{T}}(N)]^{\mathrm{T}} \tag{1}$$

$$\mathbf{U}_k=[u_k(0), u_k(1),\ldots,u_k(N\text{-}1)]^{\mathrm{T}} \tag{2}$$

where the subscript *k* denotes the batch index. The desired reference trajectories of product quality are defined as

$$\mathbf{Y}_d=[y_d^{T}(1), y_d^{T}(2),\ldots, y_d^{T}(N)]^{T} \tag{3}$$

A batch process is typically modelled with a dynamic model, but it would be convenient to consider a static function relating the control sequence to the product quality sequences over the whole batch duration [10].

$$\mathbf{Y}_k = \mathbf{F}(\mathbf{U}_k) + \mathbf{v}_k \tag{4}$$

where $\mathbf{F}(\cdot)$ represents the non-linear static functions between $\mathbf{U}_k(t)$ and $y_k(t)$ at different sampling times and $\mathbf{v}_k=[v_k^T(0),v_k^T(1),\ldots, v_k^T(N\text{-}1)]^T$ is a vector of measurement noises. Linearising the non-linear batch process model described by Eq(4) with respect to $\mathbf{U}_s$ around the nominal trajectories ($\mathbf{U}_s$, $\mathbf{Y}_s$), the following can be obtained.

$$\mathbf{Y}_k = \mathbf{Y}_s + \left.\frac{\partial \mathbf{F}(\mathbf{U}_k)}{\partial \mathbf{U}_k}\right|_{\mathbf{U}_s} (\mathbf{U}_k - \mathbf{U}_s) + \mathbf{w}_k + \mathbf{v}_k \tag{5}$$

where $\mathbf{w}_k=[w_k^T(1), w_k^T(2), \ldots, w_k^T(N)]^T$ is a sequence of model errors due to the linearization (i.e., due to neglecting the higher order terms) and $\mathbf{v}_k$ represents the effects of noise and unmeasured disturbances. Define the linearised model $\mathbf{G}_s$ as

$$\mathbf{G}_s = \left.\frac{\partial \mathbf{F}(\mathbf{U}_k)}{\partial \mathbf{U}_k}\right|_{\mathbf{U}_s} \tag{6}$$

The structure of $\mathbf{G}_s$ is restricted to the following lower-block-triangular form due to the causality.

$$\mathbf{G}_s = \begin{bmatrix} g_{10} & 0 & \cdots & 0 \\ g_{20} & g_{21} & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ g_{N0} & g_{N1} & \cdots & g_{NN-1} \end{bmatrix} \tag{7}$$

The linearised model can be identified from historical process operation data using MLR [10]. Let **X** and **Y** be the deviations from the reference trajectories of historical data in the manipulated variables and product quality variables respectively, then $\mathbf{Y} = \mathbf{G}_s\mathbf{X}$ and the linearised model $\mathbf{G}_s$ can be obtained through MLR as

$$\mathbf{G}_s = (\mathbf{X}^{\mathrm{T}}\mathbf{X})^{-1}\mathbf{X}^{\mathrm{T}}\mathbf{Y} \tag{8}$$

To cope with process drift, the linearised model can be re-identified after each batch run with data from the most recent batch added to the historical process data. Furthermore, the control trajectory and quality variable trajectory from the most recent batch can be used as the reference trajectories.

### *B. Partial Least Squares*

PLS projects the **X** and **Y** matrices to a subset of latent variables, **t** and **u**, respectively.

$$\mathbf{X} = \sum_{j=1}^{k} \mathbf{t}_j \mathbf{p}_j^T + \mathbf{E} \tag{9}$$

$$\mathbf{Y} = \sum_{j=1}^{k} \mathbf{u}_j \mathbf{q}_j^T + \mathbf{F} \tag{10}$$

In the above equations, **E** and **F** are residual matrices of unfitted variations in the **X** and **Y** data respectively. If sufficient numbers of latent variables (sufficiently large *k*) are used, then both **E** and **F** can be made zero or close to zero if the modeled relationship is linear. The objective is to fit a linear relationship between **X** and **Y** by performing least square regression between each pair of corresponding **t** and **u** latent vectors while making $\|\boldsymbol{F}\|$ as small as possible.

$$\hat{\mathbf{u}}_j = \mathbf{t}_j \mathbf{b}_j \qquad j=1,2,\ldots k \tag{11}$$

where $\mathbf{b}_j$ is the coefficient from the inner linear regression between the j^th^ latent variables $\mathbf{u}_j$ and $\mathbf{t}_j$ which is

$$\mathbf{b}_j = (\mathbf{t}_j^T \mathbf{t}_j)^{-1} \mathbf{t}_j^T \mathbf{u}_j \tag{12}$$

PLS provides a bilinear decomposition of the **X** and **Y** matrices into a number of rank-one matrices. The decomposition can be defined as the product between each pair of input scores vector, **t**, and predicted output scores vector, $\hat{\mathbf{u}}_j$, and a set of corresponding input and output loading vectors **p** and **q**.

The number of latent variables, *k*, to be retained in the model for PLS is usually determined through cross-validation [12]. The data set for building a model is partitioned into a training data set and a testing data set. PLS models with different number of principal components are developed on the training data and then tested on the testing data. The model with the smallest testing errors is then selected.

### C. Model Updating Using a Sliding Window of Historical Batches

Let *M* be the size of a sliding window of the past batches and use the immediate previous batch, the (k-1)th batch, as the nominal batch, then the deviations of the process input and output trajectories from their nominal trajectories in the sliding window can be represented as:

$$\Delta \mathbf{X}_{k=1} = \begin{bmatrix} \mathbf{U}_{k-M} - \mathbf{U}_{k=1} \\ \mathbf{U}_{k-M+1} - \mathbf{U}_{k=1} \\ \cdots \\ \mathbf{U}_{k-1} - \mathbf{U}_{k=1} \end{bmatrix} \tag{13}$$

$$\Delta \mathbf{Y}_{k=1} = \begin{bmatrix} \mathbf{Y}_{k-M} - \mathbf{Y}_{k=1} \\ \mathbf{Y}_{k-M+1} - \mathbf{Y}_{k=1} \\ \cdots \\ \mathbf{Y}_{k-1} - \mathbf{Y}_{k=1} \end{bmatrix} \tag{14}$$

The updated model parameters can be obtained using MLR or PLS. If correlations exist among the control actions at different stages of a batch, then PLS will give robust and reliable estimation of the model parameters.

### D. Iterative Learning Control

The batch to batch iterative learning control strategy was developed in [10] and is briefly introduced here.

The prediction of perturbation model is defined as

$$\hat{\overline{\mathbf{Y}}}_k = \hat{\mathbf{G}}_s \overline{\mathbf{U}}_k \tag{15}$$

and the absolute model prediction is defined as

$$\hat{\mathbf{Y}}_k = \mathbf{Y}_s + \hat{\overline{\mathbf{Y}}}_k = \mathbf{Y}_s + \hat{\mathbf{G}}_s \overline{\mathbf{U}}_k \tag{16}$$

After completion of the *k*^th^ batch run, prediction errors between off-line measured or analysed product qualities and their model predictions can be calculated as

$$\varepsilon_k = \mathbf{Y}_k - \hat{\mathbf{Y}}_k = \overline{\mathbf{Y}}_k - \hat{\overline{\mathbf{Y}}}_k \tag{17}$$

Based on the prediction errors of the *k*^th^ batch run, the modified prediction of perturbation model in the (*k*+1)^th^ batch run is obtained as

$$\tilde{\overline{\mathbf{Y}}}_{k+1} = \hat{\overline{\mathbf{Y}}}_{k+1} + \varepsilon_k \tag{18}$$

The absolute modified model prediction is defined as

$$\tilde{\mathbf{Y}}_{k+1} = \hat{\mathbf{Y}}_{k+1} + \varepsilon_k = \mathbf{Y}_s + \hat{\overline{\mathbf{Y}}}_{k+1} + \varepsilon_k \tag{19}$$

The modified prediction error is defined as

$$\tilde{\varepsilon}_{k+1} = \mathbf{Y}_{k+1} - \tilde{\mathbf{Y}}_{k+1} = \overline{\mathbf{Y}}_{k+1} - \tilde{\overline{\mathbf{Y}}}_{k+1} \tag{20}$$

From the definitions in Eq(17) and Eq(18), we have

$$\tilde{\varepsilon}_{k+1} = \varepsilon_{k+1} - \varepsilon_k \tag{21}$$

We assume that the prediction error of the perturbation model is bounded by a certain small positive constant $B_m$ such that

$$|\varepsilon_k| < B_m \tag{22}$$

The prediction error bound $B_m$ is a measure to represent the deviation of $\hat{\overline{\mathbf{Y}}}_k$ from $\overline{\mathbf{Y}}_k$ or $\hat{\mathbf{Y}}_k$ from $\mathbf{Y}_k$. The higher the value of $B_m$ is, the poorer the identified model is. The modified prediction error is bounded by $2B_m$ as follows

$$|\tilde{\varepsilon}_k| < |\varepsilon_k| + |\varepsilon_{k-1}| < 2B_m \tag{23}$$

The tracking errors of process and perturbation model are respectively defined as

$$\mathbf{e}_k = \mathbf{Y}_d - \mathbf{Y}_k = \overline{\mathbf{Y}}_d - \overline{\mathbf{Y}}_k \tag{24}$$

$$\hat{\mathbf{e}}_k = \mathbf{Y}_d - \hat{\mathbf{Y}}_k = \overline{\mathbf{Y}}_d - \hat{\overline{\mathbf{Y}}}_k \tag{25}$$

where $\overline{\mathbf{Y}}_d$ is the deviated desired trajectory and defined as

$$\overline{\mathbf{Y}}_d = \mathbf{Y}_d\text{-}\mathbf{Y}_s \tag{26}$$

The tracking errors of modified prediction of perturbation model is defined as

$$\tilde{\mathbf{e}}_k = \mathbf{Y}_d - \tilde{\mathbf{Y}}_k = \overline{\mathbf{Y}}_d - \tilde{\overline{\mathbf{Y}}}_k \tag{27}$$

From the definitions in Eq(17), Eq(24) and Eq(27), the following relationship among these three tracking errors can be obtained

$$\varepsilon_k = \hat{\mathbf{e}}_k - \mathbf{e}_k \tag{28}$$

$$\tilde{\mathbf{e}}_k = \hat{\mathbf{e}}_k - \boldsymbol{\varepsilon}_{k-1} \tag{29}$$

From Eq(25) and Eq(15), an iterative relationship for $\hat{\mathbf{e}}_k$ along the batch index $k$ can be obtained as

$$\hat{\mathbf{e}}_{k+1} = \hat{\mathbf{e}}_k - \hat{\mathbf{G}}_s \Delta\overline{\mathbf{U}}_{k+1} \tag{30}$$

where $\Delta\overline{\mathbf{U}}_{k+1}$ is defined as

$$\Delta\overline{\mathbf{U}}_{k+1} = \overline{\mathbf{U}}_{k+1} - \overline{\mathbf{U}}_k \tag{31}$$

From the definition of perturbation variables, we can have

$$\Delta\overline{\mathbf{U}}_{k+1} = \overline{\mathbf{U}}_{k+1} - \overline{\mathbf{U}}_k = \mathbf{U}_{k+1} - \mathbf{U}_k \tag{32}$$

Substitute Eq(28) and Eq(30) to Eq(29), we have

$$\tilde{\mathbf{e}}_{k+1} = \hat{\mathbf{e}}_{k+1} - (\hat{\mathbf{e}}_k - \mathbf{e}_k) = \mathbf{e}_k - \hat{\mathbf{G}}_s \Delta\overline{\mathbf{U}}_{k+1} \tag{33}$$

On the other hand, Eq(28) can be rewritten as

$$\mathbf{e}_k = \hat{\mathbf{e}}_k - \varepsilon_k \tag{34}$$

From Eq(34) and Eq(30), an iterative relationship for $\mathbf{e}_k$ along the batch index $k$ can also be obtained as

$$\mathbf{e}_{k+1} = \mathbf{e}_k - \hat{\mathbf{G}}_s \Delta\overline{\mathbf{U}}_{k+1} - \tilde{\varepsilon}_{k+1} \tag{35}$$

Given the error transition model in the form of Eq(33) and Eq(35), the objective of ILC is to design a learning algorithm to manipulate the control policy so that the product qualities follow the specific desired reference trajectories. The following quadratic objective function based on the modified prediction errors upon the completion of the $k^{\text{th}}$ batch run is minimised to update the input trajectory for the $(k+1)^{\text{th}}$ batch run

$$J_{k+1} = \min_{\Delta\overline{\mathbf{U}}_{k+1}} \frac{1}{2}[\tilde{\mathbf{e}}_{k+1}^T \mathbf{Q} \tilde{\mathbf{e}}_{k+1} + \Delta\overline{\mathbf{U}}_{k+1}^T \mathbf{R} \Delta\overline{\mathbf{U}}_{k+1}] \tag{36}$$

where **Q** and **R** are positive definitive matrices. Note that the objective function, Eq(36), has a penalty term on the input change $\Delta\overline{\mathbf{U}}_{k+1}$ between two adjacent batch runs, the algorithm has an integral action with respect to the batch index $k$ [10]. The weighting matrices **Q** and **R** should be selected carefully. A larger weight on the input change will lead to more conservative adjustments and slower convergence. There are also other variants of the objective function. For example, the weighting matrices **Q** and **R** may be set as **Q** = diag{$Q(1)$, $Q(2)$, …, $Q(N)$}, **R** = diag{$R(0)$, $R(1)$, …, $R(N\text{-}1)$}, where $Q(i)$ and $R(j)$ increase with respect to the time intervals $t$ in proportion to its effect of the final product quality. For the sake of simplicity, **Q** and **R** are selected in this study as $\mathbf{Q}=\lambda_q\cdot\mathbf{I}_N$ and $\mathbf{R}=\lambda_r\cdot\mathbf{I}_N$.

By finding the partial derivative of the quadratic objective function Eq(36) with respect to the input change $\Delta\overline{\mathbf{U}}_{k+1}$ and through straightforward manipulation, the following ILC law can be obtained

$$\Delta\overline{\mathbf{U}}_{k+1} = \hat{\mathbf{K}}\mathbf{e}_k \tag{37}$$

where $\hat{\mathbf{K}}$ is defined as the learning rate

$$\hat{\mathbf{K}} = [\hat{\mathbf{G}}_s^T \mathbf{Q} \hat{\mathbf{G}}_s + \mathbf{R}]^{-1} \hat{\mathbf{G}}_s^T \mathbf{Q} \tag{38}$$

From Eq(32) and Eq(37), the ILC law can be written as

$$\mathbf{U}_{k+1} = \mathbf{U}_k + \hat{\mathbf{K}}\mathbf{e}_k \tag{39}$$

## III. Application to a Fed-batch Fermentation Process

### A. A fed-batch Fermentation Process

The process considered in this paper is a fed-batch yeast fermentation process taken from [14], where a detailed kinetic and dynamic model is presented. The kinetic model of yeast metabolism is based on the bottleneck hypothesis by [15] and a dynamic model is developed based on mass balance equations for glucose, ethanol, oxygen and biomass concentrations. In this study, a simulation programme is developed in MATLAB using the kinetic and dynamic model and is verified with the results presented in [14]. The operation objective is to produce maximum amount of biomass by adjusting the glucose feed rate subject to operation constraints.

In this case study, each batch had a finite run time of 16.5hrs. The batch duration was divided into 10 equal stages and the feed rate remains constant within each stage. An initial feed rate profile was obtained from [14]. Then, 20 historical batches were generated by adding random variations to the initial feed rate profile. The end-batch biomass concentration of the historical batches ranged between 45-60g/L. Then, MLR and PLS regression methods were used in estimating the linearised model parameters from these historical process data. Batch –to-batch iterative learning control with updated historical batches was applied to the simulation. The **Q** and **R** values were fixed at 1**I** and 0.0001**I** respectively. The **R** and **Q** weighting were decided using a trial and error method.

### *B. Results for Batch to Batch ILC with Updated Models*

A batch-to-batch control study using linearised models from updated historical batches was conducted. The number of historical bathes used to develop a current batch process model keeps building up after every batch run. In other words, after every batch trial, the data is added into the pile of historical batches. Then all previous batches are used to identify a new process model which is used to generate a new control policy for the current batch. The cycle repeats and the process model is developed using both old and new batch data.

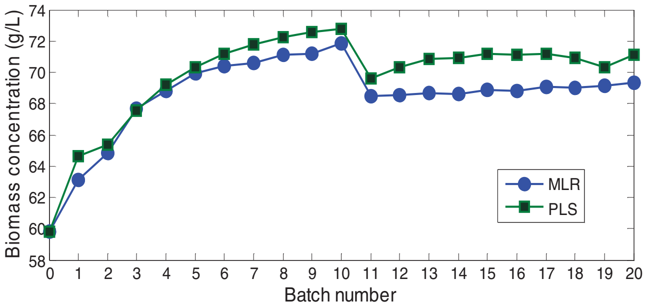

Figure 1. End of batch biomass concentration under ILC with batch-wise updated models

Figure 1 shows the performance of batch to batch ILC using updated MLR and PLS models identified from growing number of historical batches. The desired final biomass concentration was set at 74g/L. Batch 0 represents the last historical batch before implementing ILC. It is used as reference point to show process improvements due to the implementation of ILC. Batches 1 to 10 were used to test the ability of tracking desired trajectory without the presence of disturbances. From batch 11, a disturbance was introduced in that the initial substrate concentration was changed to 305g/l from its nominal value of 325g/l. Note that the initial substrate concentration is not measured and, hence, this is an unmeasured disturbance. Overall, MLR and PLS model revealed improving process operation with slight instability for both with and without disturbances. Comparing MLR and PLS models, it is evident that ILC based on the PLS model delivered higher biomass concentration for almost all the batches. This is due to the ability of PLS model to alleviate co-linearity issue. Although PLS model resulted in higher biomass concentration in the presence of disturbance, the convergence rate and stability was quite unsatisfactory. MLR model exhibited steadier performance from batch 11 to batch 20 because larger number of historical batches is favourable to obtain a better MLR model, thus better performance. The PLS model based ILC gives higher biomass but it does not always improve from batch to batch.

### *C. Results for Batch to Batch ILC with Updated Models and Moving window Historical Batches*

Further improvement was done for PLS model using a sliding window of historical batches to develop process models. After each batch run, the new batch data is added into the window of historical batches. The oldest batch in the window is removed. The idea is to use latest information to update the model and calculate the control policy for the current batch. Three sliding window sizes of 10, 15 and 20 historical batches were studied.

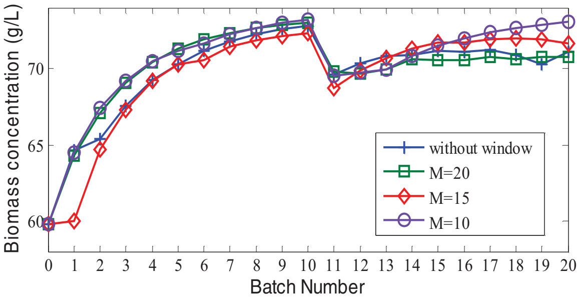

Figure 2. End of batch biomass concentration under ILC with batch-wise updated models using a sliding window of historical batches

Figure 2 shows that all three windows sizes exhibit improving results with varying stability before and after the disturbance was introduced. Performances of different window sizes (N) were compared with the one without using sliding window. For window size of 20, the convergence rate and stability were better and satisfactory when there is no disturbance. In the presence of disturbance, the results fluctuated and were not any better compared to ILC without using a sliding window. As for window size of 15, the biomass concentrations were lesser for most of the batches with no disturbances but in the presence of disturbance, the convergence rate were improving steadily from batch 11 to batch 15. From batch 16 to batch 20 slight fluctuations were noticed though the biomass concentrations were higher than the plot with no window. For window size of 10, the performance with no disturbance is as good as window size of 20. For batch 12 and 13 the biomass yield was lesser than that under ILC without using sliding window, but in the following 7 batches the performance improved steadily. The convergence rate was very satisfactory. The PLS model was able to attain final output almost as good as without disturbance within 10 batches. Amongst the three window sizes, window size of 10 gave the most stable and fastest converging performance. It is shown in the results that PLS method does not need a growing number of historical batches to develop a reliable model. An updated historical batch data with window size equal to the number of control policies used in the fed-batch fermentation process is able to generate optimal process model by using the PLS method.

## IV. Conclusions

An ILC technique with model adaptation using a sliding window of historical batches is developed in this paper. PLS is used to estimate model parameter in order to address the colinearity issues. The proposed method is applied to a simulated fed-batch fermentation process. Application results show that ILC based on batch-wise updated model using a sliding window of recent historical batches improves the control performance with and without disturbance. The effect of window sizes is studied. It is shown that model updating using PLS does not need large window size in providing enhanced control performance.

*Abstract*—**Industrial processes can be divided into two main areas: upstream processing; involving the manufacture of product and downstream processing; product separation and purification. Although both of these operations are necessary to obtain the final product; optimisation and improvement efforts are generally biased towards upstream processing. The importance of downstream processing can often be neglected to concentrate on the "more important"aspect of upstream processing. However, if the purification and separation steps aren't controlled effectively it can result in a significant reduction in the overall process yield. This investigation focuses on the control of a two stage counter current liquid-liquid extraction unit downstream of a batch process. A reduced separation capacity of this process is observed due to a flow oscillation in the solvent stream. The cause of this oscillation is investigated by analysing process variable behaviour, paying particular attention to the interplay between the control strategy and disturbances of the process. The effect on separation efficiency is shown through high frequency analysis of product concentrate in the output stream.**

**The aim of this work is to highlight the importance of the process control strategy. Reviewing the linkages between the process controls, product yield and quality are essential as part of a continuous improvement strategy. Such reviews can highlight opportunities for significant increases in yield that are often masked out through infrequent sampling procedures.**

## I. Introduction

Downstream processing is an integral and essential aspect of many industrial processes. Its application can be varied from industry to industry but the goal remains the same: to separate and purify a product. The downstream processing operation of concern here is liquid-liquid extraction. This is used across a large range of industries; including the biotechnology sector to separate out enzymes [1] and antibotics [2], removal of toxic metals from waste water systems [3], and in the reprocessing of nuclear fuel waste [4]. Generally liquid-liquid extraction processes involve the extraction of a product from an aqueous phase into a solvent phase. This is achieved through the physical contact between the two liquids. There are many different types of liquid-liquid extraction equipment; but the centrifuge extractor will be the focus here. This work will look at the current control strategy implemented on a liquid-liquid extraction process on a large scale manufacturing plant, depicted in Fig. 1. The unit operation is a batchwise continuous process with each batch lasting approximately 15 hours. The aqueous stream flows in the direction of Pod-A to Pod-B and the solvent phase flows counter currently in the direction of Pod-B to Pod-A. The product from the aqueous phase is extracted through physical contact with the solvent phase. Separation of the product is promoted by a chemical adjustment in the aqueous phase. Pod-A is the primary extractor; removing approximately 85% of the product and Pod-B is the secondary extractor; removing approximately 13%. Improving the separation capacity of Pod-A is the primary goal of this work.

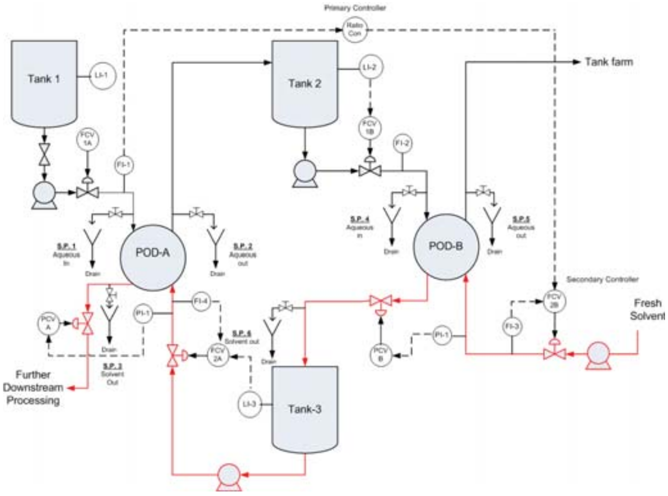

Fig. 1. Schematic of liquid-liquid extraction unit operation

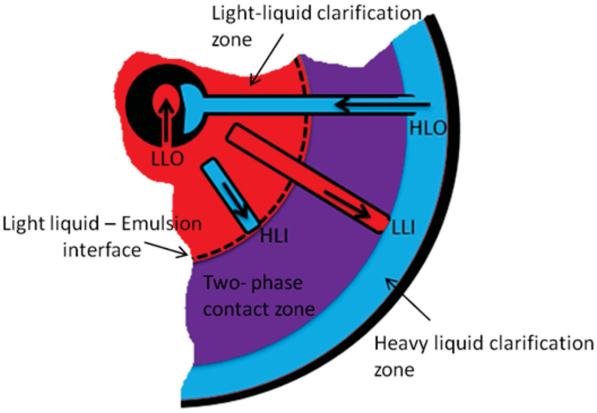
Before the process trends are considered, it is important to understand the fundamentals of liquid-liquid extraction. One of the most important variables to control during operation is the back pressure on the solvent phase. This back pressure is controlled by manipulating the two pressure control valves PCV-A for Pod-A and PCV-B for Pod-B. Fig. 2 illustrates the steady state operation of one of the centrifuges/pods during normal operation. The heavy liquid in (HLI: aqueous phase) enters near the shaft, the light liquid in (LLI: solvent) enters near the rim. Due to the centrifugal forces and the differences in specific gravity of the two phases, the heavy liquid is forced towards the rim and the light liquid is forced towards the centre. This results in the formation of three phases:



Light-liquid clarification zone
HLO
LLO
Light liquid – Emulsion interface
HLI
LLI
Two- phase contact zone
Heavy liquid clarification zone

Fig. 2. Schematic of Pod internals

1) Heavy liquid phase towards the rim.
2) An emulsion of both heavy and light liquids mixed together (contact zone).
3) Light liquid phase towards the shaft.

The position of the interface between the emulsion phase and the light liquid out (LLO) is primarily controlled by imposing a back pressure on the LLO. The position of the interface is also affected by the ratios of the two phases entering the pod. Controlling this interface is key and it is important to ensure adequate separation of the two liquids. If the back pressure is too low, heavy liquid can become entrained in the light liquid out; known as shaft flooding. And if the back pressure is too high, light liquid can't leave the shaft and can become entrained in the heavy liquid out; known as rim flooding. As shown on Fig. 1, the back-pressure of the solvent exiting the pods is controlled using a pressure control valve which is manipulated using the output from the pressure indicator on the solvent flow in. The outlet pressure is adjusted to ensure the ratio of the pressure in to pressure out is kept at 65%.

## II. Discussion

The overall ratio of the streams entering the unit is controlled through feed forward ratio control. The aqueous flow entering Pod-A produces the set point for the primary controller; the output of this is used by the secondary controller to manipulate the valve position of FCV-2B to ensure the aqueous to solvent ratio of 6.75:1 is kept as constant as possible. Fig. 3 shows a typical representation of the trends associated with this cascade control loop. The flow of aqueous entering Pod-A is shown to be relatively constant at 12,000 L/hr, changing by a maximum of 2.3%. The solvent flow entering Pod B is controlled by the secondary flow controller FCV-2B. The valve position of this secondary loop oscillates from 75% to 67% every 2-3 minutes. These small changes in the valve position result in the solvent stream fluctuating repeatedly from 1600 L/hr to 2000 L/hr; a 22.5% change . Although the output of controller FCV-2B only tries to make small adjustments to the flow, the indicator FI-3 shows that the resulting changes in the flow are significant. The difference between the flow set-point and the actual flow may be the result of numerous reasons including a high back pressure on solvent entering the process, poor tuning of the control loop or a result of a faulty or oversized valve.

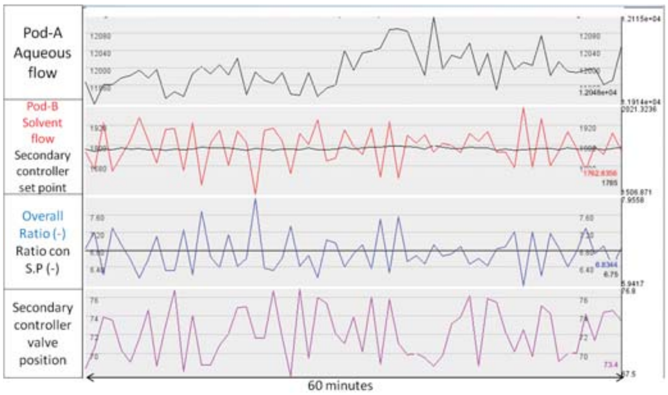


Fig. 3. Trends for overall flow ratio control

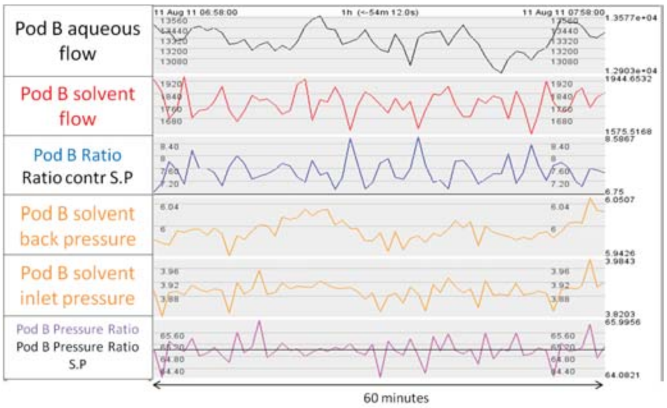

Fig. 4. Trends of flow ratio and pressures across Pod B

Fig. 4, looks at the actual ratio of the two streams entering Pod B. As the process is a continuous one, the above mentioned trends would be expected to be similar as long as the levels of the tanks 2 and 3 are kept constant. However after comparing figures 3 and 4, the flow ratio of the streams entering Pod-B is shown to be consistently higher than its set-point of 6.75:1. The pressures of the solvent entering and exiting the pods are shown to fluctuate around their set point of 65%. Some of the larger fluctuations are shown to correlate with the peaks shown by the flow ratio of Pod-B, however since both signals are quite noisy it is difficult to show a direct relationship.

Fig. 5, shows the process trends for Pod-A; a large fluctuation is seen by indicator FI-4 on the solvent stream. The ratio of the aqueous to solvent phase entering the pod is shown to periodically oscillate around its set point of 6.75, ranging from 5.45 to 7.54. This oscillation is shown to repeat throughout each batch and has a complete cycle of approximately 22

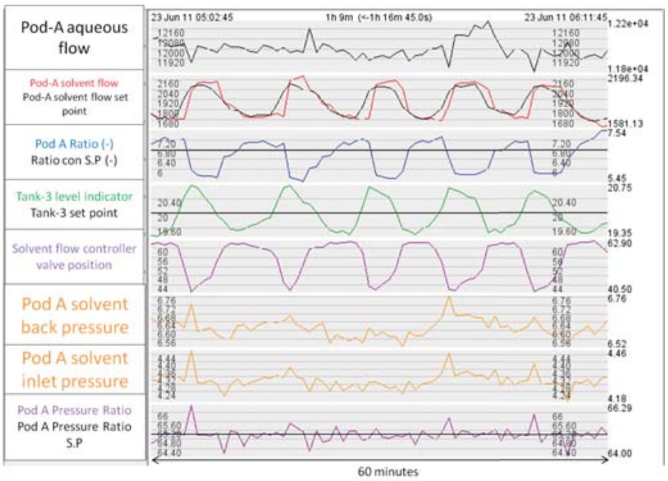

Fig. 5. Trends of flow ratio, pressures and levels associated for Pod A

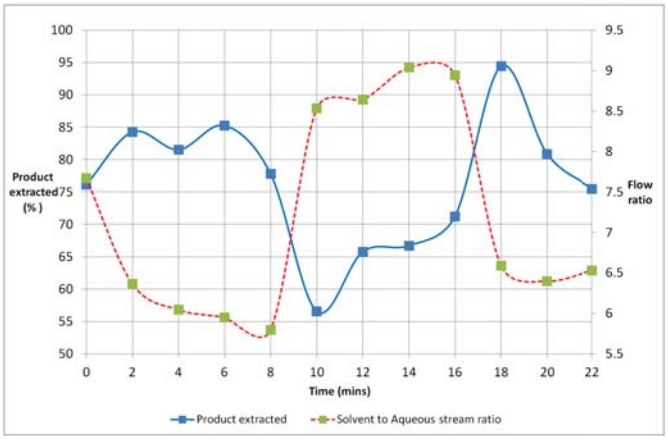

Fig. 6. High frequency sampling campaign modelling the pod efficiency during normal operation

minutes. In order to examine the root cause of this fluctuation the level controller of Tank-3 (LI-3) is examined.

The flow of solvent entering Pod-A is manipulated based on the level in Tank-3. The level in this tank is shown to oscillate around its set point of 20% , peaking at a high of 21.07% and a low of 19.23%. Although this deviation from set point is very minor, it causes the output of the valve FCV-2A to change significantly. The valve position of FCV-2A is shown to change by 20% in direct response to the small changes in the level of Tank-3. This consistent opening and closing of the valve results in the solvent stream entering Pod-A to oscillate from 1600 to 2300 L/hr with the same frequency as the level controller.The actual solvent flow to Pod-A matches the cycling set point closely showing that the root cause of the cycle to be the level controller output of Tank-3. Although the pressure ratio of the two pods are shown to be reasonably well controlled to their set points, some spikes on the flow ratio are shown to align up with the valve positions of FCV-2A. This implies that the solvent flow ratio is also having an effect on the position of the light liquid-emulsion interface which is of primary importance to the separation efficiency of the pods.

Although the above mentioned flow oscillation has been an inherent problem on this plant for many years, its effect on the separation capacity of the pods had never been quantified. The current sampling procedure is too infrequent to capture the effect of this flow oscillation on the separating efficiency of the process. The current sampling procedure takes three process samples from the sampling points 1, 3 and 5 outlined in Fig. 1 every two hours. These sample points allow one to calculate the overall efficiency of the process by performing a simple mass balance but it is too infrequent to capture the effect of the solvent flow fluctuation.

In order to quantify the effect of the solvent flow oscillation on the process, a high frequency sampling campaign was undertaken. This campaign concentrated on Pod-A, as this pod accounts for approximately 85% of the product separation. It was carried out through two separate sampling campaigns. The first campaign involved sampling the process over a 24 minute period during normal operating conditions, with the aim to model the effect of the solvent flow oscillation. The second involved fixing the ratio of the two streams entering the pod with the aim to model the pod's behaviour when the ratio of the two streams entering the pod is held constant.

The high frequency sampling campaign involved taking process sample every two minutes from the sample points 1, 2, 3 and 4 shown in Fig. 1. Once the process samples were collected, the product concentration was measured in these samples using off line analysis techniques. Fig. 6 shows the effect of the oscillating flow ratio on the separating efficiency of Pod-A, based on the product concentrations measured during the high frequency sampling campaign. The percentage of product extracted is calculated using the mass flow rate of product extracted into the solvent phase in Pod-A divided by the total mass flow rate of product entering the process.

The second high frequency sampling campaign is shown by Fig. 7, it shows the separation capacity of Pod-A when the flow ratios entering the unit are kept constant. This shows that by controlling the ratio of the two fluids to set point, the separation capacity of the pod also remains constant.

Comparing the results shown in Fig. 6 with the process trends shown in Fig. 5, an approximate average concentration for the entire batch can be calculated to be just above 75%. This can be compared against the average separation efficiency of 85% approximated by Fig. 7 when the ratio of the flows entering the pods is held constant. This highlights the significant effect of the flow fluctuation on the separation capacity of Pod-A, and is summarised by Fig. 8.

Fig. 8 highlights the opportunity to increase the overall efficiency of Pod-A by approximately 10%. This is a significant improvement to the overall efficiency of the process as the product quality extracted by Pod-A is of higher quality than that extracted from Pod-B.

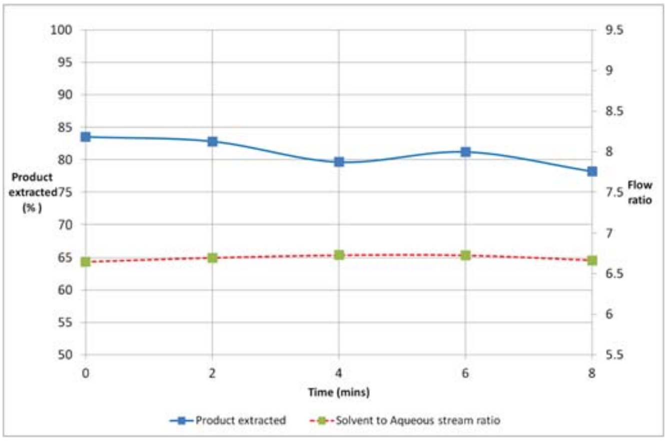

Fig. 7. High frequency sampling campaign modelling the pod efficiency during normal operation

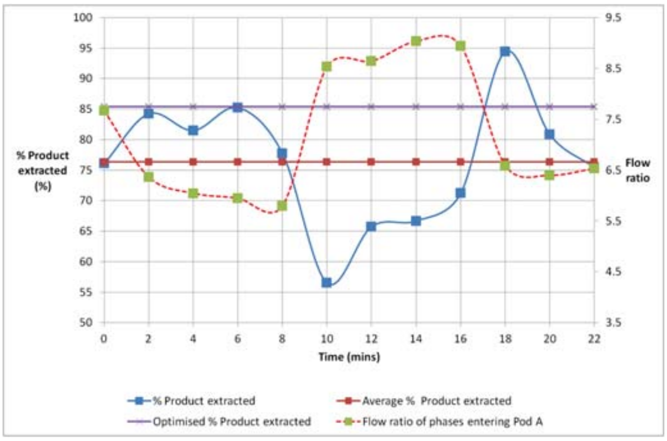

Fig. 8. Approximated average and optimised % product extracted

## III. Future work

Investigate some of the possible ways to improve the flow ratio across the two pods. One possible solution is seen by analyzing the ranks of the individual control loops. The overall ratio of flows entering the unit operation and the levels of the tanks, are shown to take precedence over the actual ratio of flows entering the pods. This ranking of the control loops does not reflect the key process parameters of the operation. This could be overcome by installing individual cascade control loops across the two pods; FCV-2A cascaded against FI-1 for Pod A and FCV-2B cascaded against FI-2 for Pod B. Although the levels in the tanks 2 and 3 will fluctuate this control strategy will ensure that the stability of the flow ratios across the pods will take priority. Once the solvent flow fluctuation have been fixed, a design of experiment will be conducted on the process with the aim of finding the optimum flow ratio set point and back pressure for the individual pods.

## IV. Conclusion

This work highlights the importance of regularly reviewing the process control strategy. These reviews must consider the interplay between the different control loops; failure to do so may result in an undesired interaction and may lead to unwanted disturbances. The disturbance highlighted here between the level controller and the flow controller was shown to have a significant effect on the separating capacity of this liquid-liquid extraction process. The work also highlights the importance of considering the key performance parameters of the process when designing the control strategy. These should take preference in the control strategy allowing the variability to be absorbed by the less important parameters such as tank levels.

***Abstract*— Glass container forming processes have attracted more attention over the past years due to the problem of lacking process information and correlation for key variables within the processes. In this paper an approach to develop process modeling and intelligent software sensing is presented for application based on multivariate statistical process control methods. The intelligent software sensors are able to provide real time estimation of key variables, and Partial Least Squares (PLS) techniques have allowed for forward prediction of final product quality variables. An application of software sensors used for container forming blank temperature is presented along with PLS being applied to predict the wall and base dimensions of glass container products. Initial results show that these methods are very promising in providing a significant improvement within this area which is usually unmonitored and is susceptible to long time delays between forming and quality inspection.**

***Keywords- Glass Container Forming; Batch Control, Software Sensors; Condition Monitoring; MSPC, PLS, PCA***

## I. Introduction

The Glass container manufacturing industry is a huge global sector of package manufacturing which produces products for various industrial sectors such as cosmetics, pharmaceutical and the food and beverage industry. Glass containers are produced by the melting of raw materials mainly sand, soda ash and limestone in a gas or electric fired furnace at temperatures above 1200 °C. The glass once molten is then distributed away from the furnace along channels known as fore-hearths which are at set controlled temperatures to the relevant glass forming machines, where upon arrival the molten glass is allowed to drain through an orifice. The molten glass is then cut as it leaves the orifice at a precise set rate to allow for enough molten material for the particular product being formed. This ‘cut’ molten glass is then delivered to the glass forming machine, typically in double or triple cavities.

At this stage high capacity, high volume production machinery is used to mould the molten glass into the various batches of containers that one manufacturing facility may produce. It is this part of the Glass Container Forming Processes which have been a difficult challenge to engineers. Difficulties with the harsh nature of the environment and obtaining accurate information relating to its process make it extremely challenging. The lack of on-line sensing for process variables has been a serious obstruction and has left the process to somewhat a ‘black art’ over the years. Now with higher expectations and demands from customers this process has never been as important to monitor and refine. At present almost all control methods and policies applied are based on off line information for the process operators and supervision, this compromises quality as the delays between product formation and inspection is so large that abnormalities can go undetected for a while. It is also relatively unknown at this stage as to the actual limits and constraints that exist on the variables within this part of the process or as to the actual combined contribution that each of these variables actually has upon the final product being made.

Multivariate Statistical process control methods based upon linear projection have attracted interest and have been are proven method for producing empirical models for Industrial processes. Principle Component Analysis (PCA) and Partial Least Squares (PLS) techniques have been applied to many practical regression problems to estimate quality related variables. Zhang and Lennox [1] applied these techniques to batch fed fermentation processes with the focus on the adoption and application of PLS and PCA techniques for sensor failure detection and prediction. Other promising results were achieved within batch fermentation processes with various publications made [2][3][4][5], applications have also been deployed within the steel industries and used for advanced monitoring of plant functions to determine the relationship between process variables and production quality [6].

The applications of the above-mentioned PLS and PCA techniques have proved successful in providing soft-sensing techniques and linear regression model prediction for process variables.

This paper aims to develop software sensors and also linear regression model prediction of glass container forming quality related variables using PLS techniques. Also the paper will demonstrate the ability of PCA to provide abnormal condition detection and isolation within glass container forming processes.

## II. Statistical Modelling and Soft-sensing using Multivariate Statistical Process Control Techniques

### A. *Principle Component Analysis*

Principle Component analysis (PCA) is a multivariate statistical method for identifying patterns within data sets by highlighting similarities and differences within the data presented. PCA attempts to find combinations of factors or variables that describe trends within the data, after data assembly PCA mathematically it is a method of writing a matrix of X variables of rank R as the sum of R matrices of rank 1 initially assuming the data are mean cantered [7].

$$X = M1 + M2 + ... + M3 + ... + Mr \tag{1}$$

Each matrix with *m* rows and *n* columns, and each variable being a column and each sample a row

PCA decomposes the matrix X as the sum of *r* $t_i$ and $p_i$ pairs where *r* is the rank of the matrix X

$$X = t_1pT_1 + t_2pT_2 + ... + t_kpT_k + ... + t_rpT_r \tag{2}$$

The $t_i$, $p_i$ pairs are ordered by the amount of variance captured. The $t_i$ vectors are known as scores and contain information on how the samples relate to each other. The $p_i$ vectors are known as loadings and contain information on how the variables relate to each other. Mathematically, PCA relies upon an eigenvector decomposition of the covariance or correlation matrix of the process variables. For a given data matrix X with m rows and n columns, the covariance matrix of X is

$$\mathrm{cov(X)} = \frac{X^T X}{m-1} \tag{3}$$

provided that the columns of X have been “mean-cantered" by subtracting off the original mean of each column.

In the PCA decomposition, the $p_i$ vectors are eigenvectors of the covariance matrix;

$$\mathrm{cov(X)}p_i = \lambda_i p_i \tag{4}$$

where $\lambda_i$ is the eigenvalue associated with the eigenvector $p_i$. The score vector $t_i$ is the linear combination of the original X variables defined by $p_i$.

Another way to look at this is that the $t_i$ are the projections of X onto the pi. The $t_i$, $p_i$ pairs are arranged in descending order according to the associated $\lambda_i$. The $\lambda_i$ are a measure of the amount of variance described by the $t_i$, $p_i$ pair. The first pair captures the largest amount of information in the decomposition and each subsequent pair captures the greatest possible amount of variance remaining after subtracting $t_ip_i$ from X.

### B. *Partial Least Squares*

PLS is a system identification tool that is capable of identifying the relationships between input (X) and output (Y) variables. The advantage that this approach offers over more traditional identification techniques, such as ordinary least squares, is that it is able to extract robust models even in applications involving large numbers of highly correlated and noisy process variable measurements.

The approach works by selecting factors of cause variables in a sequence that successively maximizes the explained covariance between the cause and effect variables. Given a matrix of cause data, **X**, and effect data, **Y**, a factor of the cause data, $\mathbf{t}_k$, and effect data, $\mathbf{u}_k$, is evaluated, such that:

$$X = \sum_{k=1}^{np<nx} t_k p_k^{\ T} + E \tag{5}$$

and

$$Y = \sum_{k=1}^{np<nx} u_k q_k^{\ T} + F \tag{6}$$

where **E** and **F** are residual matrices, *np* is the number of inner components that are used in the model and *nx* is the number of causal variables. $\mathbf{p}_k$ and $\mathbf{q}_k$ are referred to as loading vectors.

These equations are referred to as the *outer relationships*. The vectors $\mathbf{t}_k$ are mutually orthogonal. These vectors and $\mathbf{u}_k$ are selected so as to maximise the covariance between each pair, ($\mathbf{t}_k$, $\mathbf{u}_k$). Linear regression is performed between the $\mathbf{t}_k$ and the $\mathbf{u}_k$ vectors to produce the inner relationship, such that:

$$u_k = b_k t_k + \varepsilon_k \tag{7}$$

where $b_k$ is a regression coefficient, and $\varepsilon_k$ refers to the prediction error. The PLS method provides the potential for a regularised model through selecting an appropriate number of latent variables, $\mathbf{u}_k$ in the model (*np*). The number of latent variables is typically generated through the use of cross validation.

## III. Advanced Monitoring Techniques using PCA

### A. *PCA Arrangement*

PCA does not attempt to resolve any relationship between input and output data but it identifies patterns within data, as the glass container forming process is constant, by analysing the data present at one condition would give a suitable set of data to train a PCA model for identification of process changes. The data was constructed into a Matrix (X), where each column was a variable and each row a sample of the variables at a specific point in time.

$$X = \begin{bmatrix} & & \\ x_{11} & x_{21}\cdots & x_{n1} \\ x_{12} & x_{22}\cdots\cdot & x_{n2} \\ \cdots\cdots & \cdots\cdots & \cdots\cdots \\ \cdots\cdots & \cdots\cdots & \cdots\cdots \\ x_{1(86)} & x_{2(86)}\cdots & x_{n(86)} \end{bmatrix}$$

### B. *Implementation Of Advanced Monitoring Using PCA*

A PCA Model was generated which consisted of 4 principle components which described 95% of the entire variation within the data sets , this model was then used to test against known faulty conditions which occurred within the glass container forming process.

Figure 1 shows the impact of the erroneous data upon the first two principle components. It depicts the new loaded data to exist well outside that of known good limits, this breach alone could be used to detect process abnormality. There are other components of further interest when performing Principle Component Analysis these are that of the Q residuals and Hoitelling T2 charts. The Q residuals give an indication of the measure of difference 'or residual' between a sample of data and its projection onto the components retained in the original model and the Hoi telling T2 contributions describe how much variation is within each sample to that retained within the  model. Figure 2 shows this information.

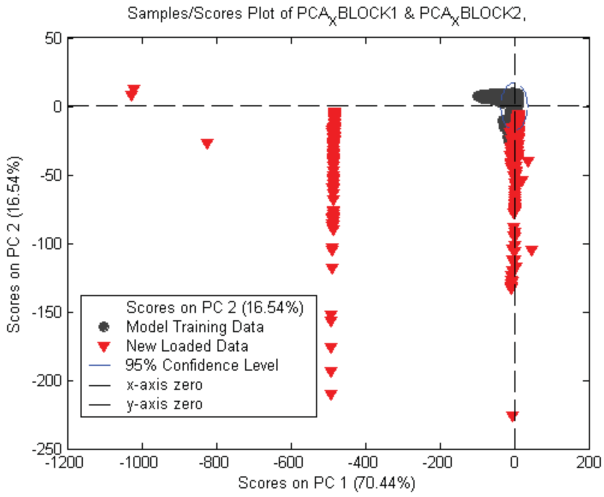

Figure 1 First two PC's loaded against Model Data

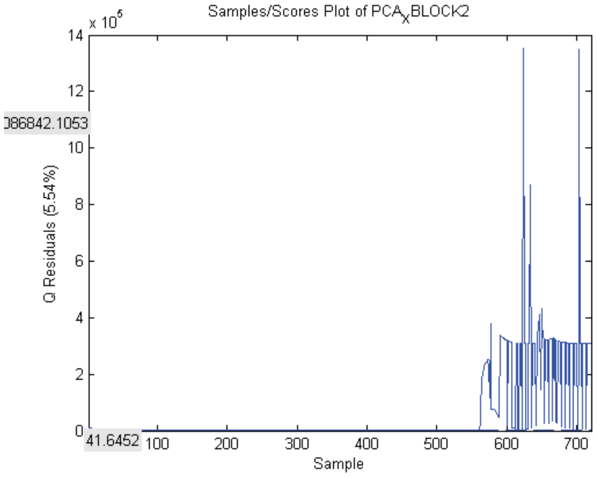

Figure 2 Q residual chart of new loaded PCA data

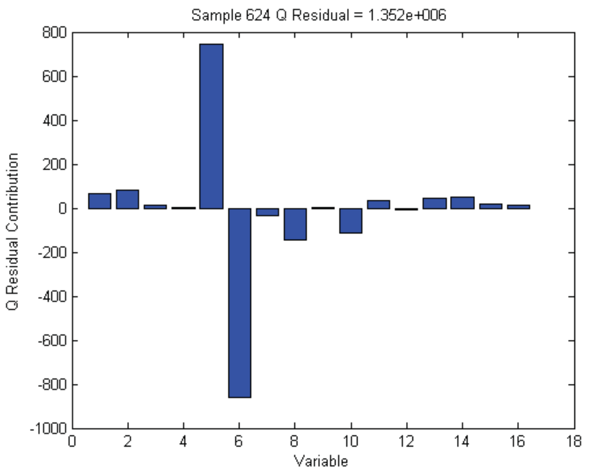

Figure 3 Q Residual Contributions at point of detection

From Figure 2, it can be seen that at around sample 570 a difference between the data in the model and the data now loaded is detected, this difference becomes even worse, at around sample 624 where the Q residual value goes extremely large. What we are actually experiencing here is an indication that something is wrong, to what we deem normal operating conditions for blank temperatures. Further investigation into the data at sample 624 shows that variables 5 and 6 are the main cause of this anomaly.

Looking at the data at this point indicates a sensor failure on IS station 3, variables 5 and 6. The above shows promising results that PCA techniques can be used for identifying process abnormalities.

## IV. Construction of Intelligent Software Sensors

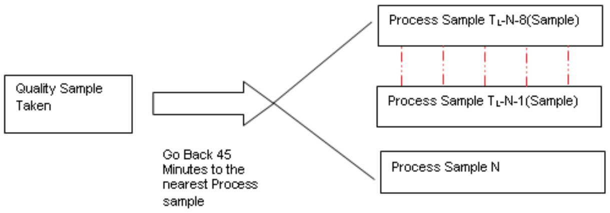
### A. *PLS Model Development*

The first stage in the development of a suitable PLS Model is to obtain relevant training and model testing data. In this application Data was collected from two main process areas, the actual process variables themselves and the final product quality data measured and recorded by the operatives themselves.

There was also a further problem introduced within this process as there is huge transport lag between the process data recorded and the quality data obtained from the operatives, here an empirical approach was undertaken in order to calculate the desired transport lag and construct the data matrix for analysis to begin.

Finally a PLS Model was generated which contained 3 latent variables was developed using this data.

In this model the following measurements were used as input variables (X) 50 Psi  I-S Station operating Air , 35 Psi I-S Station Operating Air , Plunger Cooling I-S Station Air and IS Station Blank Temperatures , with Output Variables (Y) of container wall thickness measurements and container base thickness Measurements.



Quality Sample Taken
Go Back 45 Minutes to the nearest Process sample
Process Sample T$_L$-N-8(Sample)
Process Sample T$_L$-N-1(Sample)
Process Sample N

Figure 4 PLS Model Data Construction

The input Variables were constructed into the input variable matrix X and the output variables into the column vectors.

$$X=\begin{bmatrix} x_{11} & x_{21}\cdots & x_{n1} \\ x_{12} & x_{22}\cdots & x_{n2} \\ \cdots\cdots & \cdots\cdots & \cdots\cdots \\ \cdots\cdots & \cdots\cdots & \cdots\cdots \\ x_{1(86)} & x_{2(86)}\cdots & x_{n(86)} \end{bmatrix}, \quad Y_1=\begin{bmatrix} y_1 \\ y_{12} \\ \cdots\cdots \\ \cdots\cdots \\ .y_{1(86)} \end{bmatrix} Y_2=\begin{bmatrix} y_2 \\ y_{22} \\ \cdots\cdots \\ \cdots\cdots \\ .y_{2(86)} \end{bmatrix}$$

These data matrices were then split into two, half utilised for model training data and the remaining half utilised for model verification.

### B. *Implementation of Software Sensors*

Based on the PLS model generated, a software sensing approach was investigated as due to the harsh nature of the environment it was common to experience sensor failures, so with the ability to predict these variables we would be at an advantage if required to adopt such soft sensing techniques for further applied control loops around this process. A 'software sensor' was developed to estimate a container forming IS station Blank temperature. The accuracy of this software sensor is illustrated in Figure 5, although there is some modelling error present this model development is a big step forward and as a basis to providing feasibility towards such applications. The figure gives good evidence that PLS based model prediction is feasible for 'soft sensing' applications on glass container forming processes.

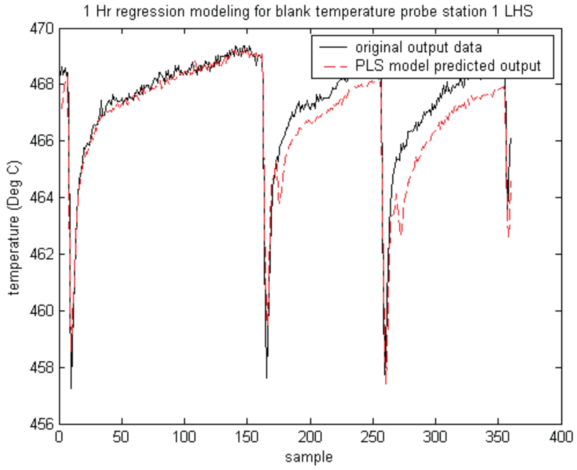


Figure 5 PLS Blank Temperature Prediction

## V. Model Prediction of Glass Container Wall and Base Thickness

### A. *PLS Model Development*

Using the data Matrices X, Y1 and Y2 previously constructed it is also possible to utilise the obtained process data to predict product quality variables.

### B. *Implementation of Linear regression Modellling using PLS fitting*

In the previous section it was demonstrated that PLS techniques can be used for software sensing techniques within glass container forming processes, in this section it will be shown that the same techniques are able to be applied to predict two important glass container quality variables - container wall thickness and base thickness. Based upon the PLS model generated, real data measured for container base thickness and wall thickness are compared with what are predicted using the container forming process input variables, this is of great benefit as the ability to predict such variables would remove the transport times involved before any feedback is generated on glass container variables.

The PLS Model generated is found to be very good in this application and has the ability to predict the container wall thickness, the model generated actually does so to within 0.5mm. Further tests gave similar promising results with the ability to predict container base thickness as shown in Figures 6 and 7. Comparing with the real data collected from production (solid green line), PLS Model is found to predict these product quality variables and shows promising evidence that these techniques and methods are applicable to glass container forming processes.

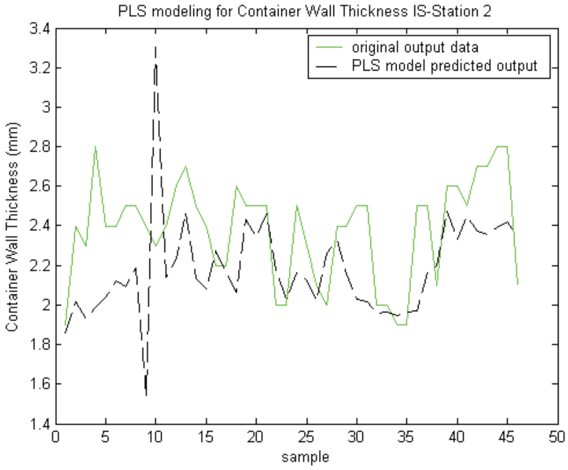

Figure 6 PLS Model Wall Thickness Prediction

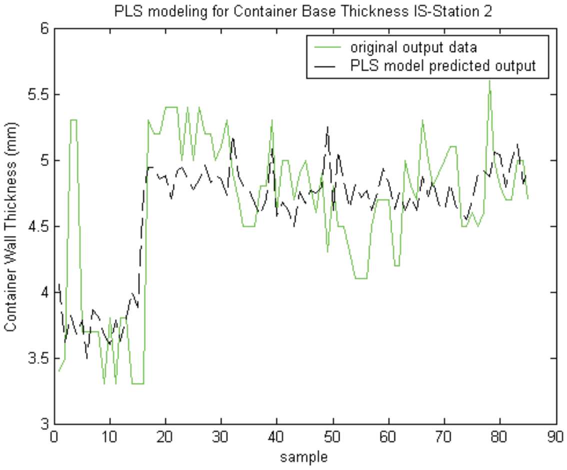

Figure 7 PLS Model Base Thickness Prediction

## VI. Conclusions

In this paper, statistical models of a glass manufacturing IS machine processes have been produced. Comparisons between the real-world data and that produced from the developed models were produced and gave promising results towards the application of such techniques. Intelligent software sensors were also developed and discussed. All the initial results show that these methods are very promising in providing a significant improvement within this area which is usually unmonitored and is susceptible to long time delays between forming and quality inspection.

## Acknowledgment

The authors of this paper would like to thank Ardagh Group for the support and the funding required for the hardware and software tools that were vital for this project.

***Abstract*—With advances in UAS technologies the quadrotor was given a special interest for its manoeuvrability and payload capacity. These assets are amplified when more of them are deployed simultaneously in order to improve the situational awareness over areas of interest. As the number of agents operating in the same environment grows, a common intelligence is needed to optimize their cooperation and ensure their safety throughout the completion of the missions. This paper presents the results of experiments conducted to demonstrate a set of algorithms on a surveillance system employing a swarm of quadrotor UAVs to track detected targets. It was initially assumed that the UAV paths are generated at constant altitude to replace the complicated quadrotor dynamics by ones of a point mass entity. The system is then extended to the third dimension to allow for a more complex guidance and navigation scheme. Several simulations were performed under various circumstances to validate the accuracy and robustness of the system.**

**Keywords:** Autonomous, swarm, UAV, quadrotor, control.

## I. Introduction

Recent events have highlighted the ever-changing face of modern warfare and the need for strategically urban battle techniques to be developed and improved upon. The increase in asymmetric warfare shows that the current forces have particular weaknesses exploited by the enemy, due to an increased knowledge of the urban battlespace, putting lives in greater danger. With advances in UAV and UGV technologies together with the improvements in sensor capabilities there is a definite domain that allied forces can use to their advantage. Covert operations, disposable resources and getting closer to the enemy are all assets that these technologies carry on. Using multiple platforms to detect and inspect targets in regions of interest could provide precious information of the surrounding urban area, paving safer corridors, increasing the situational awareness. A thorough analysis of the data gathered by the swarm would help mapping safer and more effective missions. Ultimately, an on-board processing of these information would enable the system to function in real time applications to execute such recognition missions.

The state of the art in swarm behaviour has changed in the past few years and an increasing number of teams focus their research on formation flying and multi-agent control [1][2]. However, most of their work is based on off-the-shelf platforms modified to grab certain objects, land on a given surface or fly alongside its pears in an ideal environment. Resource optimisation, conflict resolution and failure diagnostic are still challenging fields of study to draw the need of human interaction further back.

## II. Two dimensional simulation

### A. The simplified model

Initially, the 3D environment is reduced to a two dimensional space and the 6 Degrees of Freedom (DoF) quadrotor is replaced by a 3 DoF entity. The simplified kinematics enables the testing of the following algorithms in real time and in more complex scenarios involving more units and several types of targets. In order to match the behaviour of its flying counterpart, the two dimensional model must be non-holonomic. For bench testing purposes, the point mass replacement was based on differential drive vehicle for which the user can easily control the rotation speeds $\omega_L$ and $\omega_R$ of the left and right wheels to direct the unit. This gives the unit's kinematics the advantage of being linear:

$$\begin{aligned} V_L &= R_{wheel}\,\omega_L \\ V_R &= R_{wheel}\,\omega_R \end{aligned} \tag{1}$$

$$\begin{aligned} V &= \tfrac{V_R+V_L}{2} \\ \omega &= \tfrac{V_R-V_L}{d} \end{aligned} \tag{2}$$

Thanks to this linearity, $\omega_L$ and $\omega_R$ can be monitored by a simple PI controller, easy to implement and computationally quick. The emphasis will be put on individual guidance and swarm cooperation.

### B. Guidance and navigation

In mobile robotics, it is important that the environment in which the vehicles will be driving is eciently converted to a road map that the system can use to optimize the units movements. Even if the map is only partially known or uncertain, the conversion to a C-space representation needs to be simple enough to run in real-time, but still precise enough to guarantee the optimality of the calculated path. Looking forward a little bit, the main application of the system developed in this research would be a permanent surveillance setup in a dense urban environment. In this context, a cell decomposition coupled with an A* algorithm

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

would guarantee a quick and easy way to find the shortest path between two points separated by several obstacles. Its computational lightness also makes it the most fitting solution to be implemented on the on-board processor. The A* algorithm is based on a step-by-step effort to minimize the path [3]. The idea is very intuitive: at each step of the way, it favours the solutions directly closer to the targets and leaves the other cells on the side. Those unfit solutions can be temporarily ignored but not deleted because there is no way to be sure that a path is going to be the right one. They are stored in a list of unexplored possibilities that the algorithm can search later on if the previously chosen path leads to a dead end. The path can then be cut down in the middle and restarted from a point previously left aside.

Developing an algorithm capable of finding the optimal path to a given point is essential to make the system intelligent. To make it autonomous, the quadrotor would then have to reach the goal point on its own by following the path allocated to it. Once again we want to implement on-board the algorithm in charge of guiding the quadrotor along its path. The pure pursuit (or carrot following) method answers the simplicity requirement and presents three additional assets.

- The guidance algorithm itself does not need to consider the dynamics of the vehicle.
- The method generates a virtual point, called carrot, on the path in front of the vehicle it wants to move which then has to determine the sequence of commands in speed and heading to stay at a look-ahead distance away from the virtual point while permanently aiming towards it (Fig.1). Since the point has no reality it can be created, deleted or moved with ease and the quadrotor will always follow. An appropriate control of the carrots behaviour could prove to be very beneficial for the upcoming conflict detection and resolution in 3D.

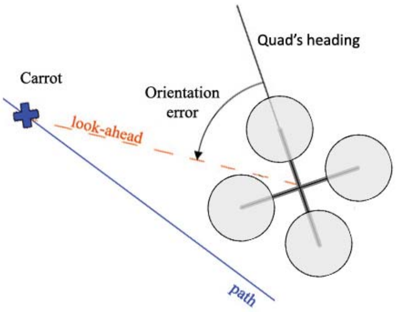

Fig. 1. Pure pursuit principle

- Though the A* generated path is made of straight segments, tracking the carrot leads the vehicle to cut the corner resulting in a much smoother trajectory and an even shorter trajectory. To avoid bumping into one of the obstacles while cutting a corner, the map of the environment is pre-processed to widen every obstacle. The path generated by the A* will therefore have a bigger clearance distance with the obstacles in the environment to ensure the safety of the quadrotor throughout the mission.

It is assumed that the vehicles have a relatively accurate knowledge of their environment. The number of unexpected obstacles should therefore be limited and a brute-force A* replaner is sufficient to guarantee an optimized avoidance. Once the system is aware of the threat, it adds the obstacle on the map and runs the A* once again. The next commands sent to the quadrotor will take the presence of the new obstacle into account and avoid it.

### *C. Cooperation*

To match the competences of their manned competitors, automated vehicles need to be developed for numerous applications which require a larger range of action and long-term possibilities. By increasing the number of units deployed, one can also increase the systems capabilities. In the scope of this work, the augmented number of agents widens the surveillance area and enables the system to reach more targets in less time [4]. Cooperative protocols are then implemented for versatility, so that the system could guarantee an optimized assignment of the quadrotors regardless of the number and types of the detected targets.

*1) Single fixed target:* When a target is spotted in the environment, the system attempts to send an agent to the targets location as fast as possible. If only one vehicle is deployed, it is automatically sent to any target that might appear in the area. The path is planned using the A* algorithm in order to reach the target with the shortest path possible. Although if several agents are used simultaneously, the system calculates the path of all the units to the target and only the closest one is assigned to the target. The others can ignore the assignment and focus on something else as shown in Fig.2.

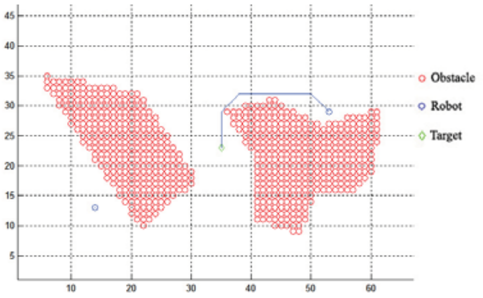

Fig. 2. Single assignment

This assignment method assumes that a target can be covered by a single unit. It would however be easy to imagine scenarios where several agents need to rendezvous at the target's location (Fig.3). For that purpose, the pure pursuit algorithm was modified to create a carrot for unit $i$ of variable speed $V_{C_i}$. Hence if we need all the vehicles to reach the target at the exact same time, each $V_{C_i}$ can be set to travel the path of unit $i$ in a given time $\tau$. The travel time $\tau$ is fixed by the central intelligence based on the kinematic limitations of the slowest unit. It could also be possible to establish a hierarchy within the vehicles forcing them to reach the target in a certain order. $V_{C_i}$ would then vary depending on the priority level of unit $i$ as well as its distance to the target.

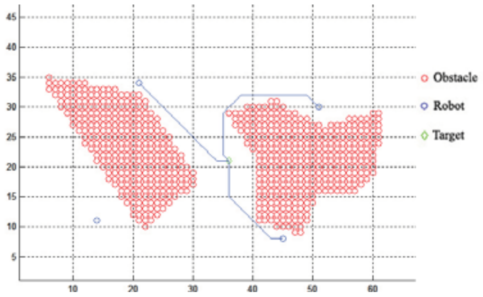

Fig. 3. Multiple assignment

*2) Multiple fixed targets:* To complete the target tracking protocols it is important to take into account a multi-target assignment. If the number of targets is smaller than the number of quarotors, the objective is to minimize the overall travelled distance. Rather than treating each target individually as they appear, the system tries to optimize the movements of the entire swarm. Every time a new target is detected, it is added to a list of previously detected targets and the allocation process is reiterated. This way each assignment is coherent with the rest of the system. To do so, the user has to deal with all the possible combinations unit/target and when the numbers increase, the optimal allocation quickly stops to be evident. An auction algorithm is therefore implemented to deal with this type of situations.

The Auction algorithm is a method used to solve classical assignment problems and is very well suited for parallel computation [5]. In the basic auction problem, there are n people and n objects (quadrotors and targets respectively) that have to be paired. Each combination person i - object j is associated to a benefit $a_{ij}$ so that the user will try and maximize the total benefit. Mathematically, the aim is to construct n pairs person-object $\{(1,j_1),(2,j_2),...,(n,j_n)\}$, where all the objects $j_1$,...,$j_n$ are distinct, that maximizes the total benefit $\Sigma_{i=1}^{n} a_{ij_i}$. The basic algorithm is modified to account for a higher number of vehicles than targets. The aim of the algorithm remains the same but in order to optimize the assignment it is capable of leaving agents out of it.

On the other hand if the number of targets becomes greater than the number of quadrotors, these targets are no longer seen as individual missions but rather as checkpoints (Fig 4). The units have to find the optimal path going through all the targets as quickly as possible. Since the number of quadrotors/targets is not limited, the solution for that problem needs to be versatile enough to answer any type of configuration. To meet this requirement, it was decided to use a genetic algorithm to handle the allocation of the targets.

Even though the method is largely based on the resolution of the multiple Travelling Salesman Problem (mTSP), parts of the method were modified to fit the overall system. In the original Traveling Salesman Problem, the salesman is supposed to come back to the initial location after visiting all the cities thereby creating a looped path. It is also common for a mTSP to fix a single point of origin for all the salesmen and a single end point. This final point can sometimes even be the same as the initial location. For the target-tracking application, each unit has a different initial position and is not required to terminate its path on the exact same node. Once again the priority is given to a minimum time constraint.

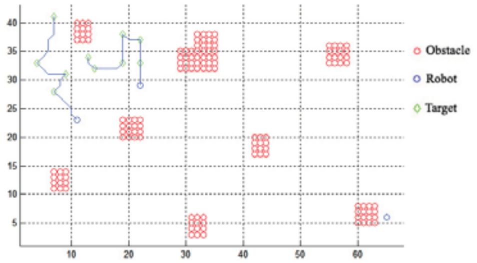

Fig. 4. Targets as checkpoints

To calculate the paths, the Genetic algorithm needs the number of targets $n_{targets}$, the number of quadrotors $n_{quads}$, and the initial positions of all of the above to create a list of all the targets and generate an array of random break points with $(n_{quads} - 1)$ elements. When applied to the target list, these break points will divide the list into $n_{quads}$ sub-lists representing the $n_{quads}$ paths travelled by the vehicles. The algorithm then needs to evaluate the fitness of the solutions and mutate the fittest genes to converge towards an optimal solution. Similarly to the Auction process, the genetic algorithm was modified so that it can choose to keep units out of the assignment if necessary.

*3) Maneuvering target:* The next step was to introduce moving targets (also called free-agents) in the environments and have the quadrotors react to it. Here, the objective is not to intercept the target anymore but rather to follow it from a given distance. To avoid predictability, the targets drive through the environment in random arcs and at variable speeds. Since the units are only moving according to the targets whereabouts, it is impossible for the system to plan a collision-free path ahead. An obstacle avoidance scheme based on the potential field method was therefore added to the system to safely follow the free-agents without hitting its surroundings (obstacles or other agents) [6].

To begin the pursuit, the user needs to fix a trailing distance $d_{trail}$ that the vehicle H needs to keep at all time with the target. Depending on the distance D to the target, this unit adapts its speed to keep up with it which is done by creating a distance-to-the-target dependent component $K_{H_d}$ to control its speed. To follow a target moving at $V_{free}$ this component would be:

$$\begin{aligned} K_{H_d} &= V_{free} + k_{H_d} \times (D - d_{trail}) \quad if\ D \geq d_{trail} \\ K_{H_d} &= V_{free} \times k_{H_d} \times (D - d_{trail}) \quad if\ D < d_{trail} \end{aligned} \tag{3}$$

To keep the unit aiming at the target, the vehicle has to maintain its heading aligned with the quad-to-target axis to keep the orientation error $e_{H_o}$ to zero. The term in Eq.4 is added to correct the orientation:

$$K_{H_\phi} = k_{H_\phi} \times e_{H_o} \tag{4}$$

The potential field obstacle avoidance is a method that converts the map known by the system into areas of attractive and repulsive potentials. The attractive field is usually generated by the target we are trying to reach but in our case, the vehicle wants to keep a certain distance with the free agent so the attractive force is excluded. The repulsive forces are generated by the known threats in order to push the vehicle away from them. Their magnitude decreases as the vehicle gets further away from them until a vicinity distance $d_0$ after which the obstacle will have no repulsive effect.

$$U_{rep_i}(q) = \begin{cases} \frac{1}{2}\gamma_{obst_i}\left(\frac{1}{d_{obst_i}(q)} - \frac{1}{d_0}\right)^\beta & if\ d_{obst_i}(q) < d_0 \\ 0 & if\ d_{obst_i}(q) \geq d_0 \end{cases} \tag{5}$$

Consider the quadrotor at the location $q = (x_{rob}, y_{rob})$ and given the linear nature of the problem, the overall potential results from the sum of the repulsive effects of all the obstacles:

$$U_{rep}(q) = \sum_{i\ \in obst} U_{rep_i}(q) = k_q \tag{6}$$

With that field in place, the vehicle is rejected as soon as it approaches an obstacle but with the absence of an attractive force from the target, the unit does not know in which direction to avoid the obstacle. To overcome that issue, the repulsive potentials from each obstacle are given an orientation to push the vehicle in the right direction as illustrated in Fig.5.

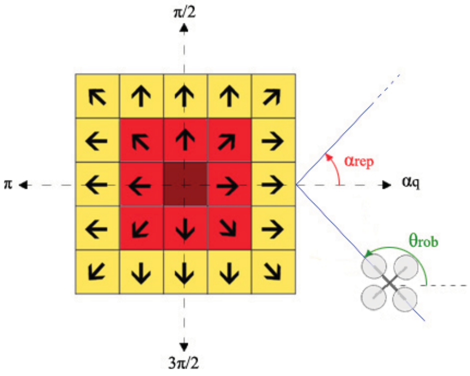

Fig. 5. Directions of rejection around an obstacle

Once again the effect on the quadrotor is converted into a new factor $K_{obst}$:

$$\begin{aligned} K_{H_{obst}} &= \frac{k_{obst} \times k_q}{\alpha_{rep}} \\ with\quad \alpha_{rep} &= mod\left[\theta_{rob} + \pi, 2\pi\right] - \alpha_q \end{aligned} \tag{7}$$

The 2D point mass model used so far is controlled through differential drive. For this particular case, the coefficients presented would be used as follow:

$$\begin{aligned} V_{H_L} &= K_{H_d} - (K_{H_\phi} - K_{obst}) \\ V_{H_R} &= K_{H_d} + (K_{H_\phi} - K_{obst}) \end{aligned} \tag{8}$$

$k_{H_d}$, $k_{H_\phi}$ and $k_{obst}$ were calibrated to ensure a smooth path around the obstacles while constantly aiming at the target ($k_{H_\phi} = R2D/5$, $k_{H_d} = 1$ and $k_{obst} = 100$).

*4) Surveillance:* Throughout this paper, the system has the ability the pick which units to assign and which to keep out of the assignment. The unassigned units can then divide the area to survey amongst them to cover it faster and more efficiently. When a new target is spotted (most likely a moving one for a realistic scenario) the system can be set to react in 2 ways.

- The closest unassigned unit is sent to the target. The remaining vehicles restart the division of the area to include the part left out by the assigned unit. This unit will follow the target wherever it goes.
- The unit whose surveillance zone includes the targets location is assigned to it while the others stay on their current path. When the target gets to another zone, the chasing agent goes back to surveillance and the agent whose zone has been entered starts chasing the target. This solution becomes interesting when each quadrotor is pre-assigned to a surveillance zone and cannot fly out of it. The reason can be that the vehicle needs to stay at all times close to a station (to charge or communicate information) in its own area.

## III. Initial Results

All the methods introduced previously were then centralized into a single coherent system accessible through a graphical user interface (GUI). The user can change the number of units deployed, add/remove fixed targets and free-agents, modify the collaboration method to deal with manoeuvring targets, and take control of a live vehicle. At this stage, the algorithms were tested in 2D scenarios so the physical platforms used for testing were ground robots.

A camera tracking device is installed to get the position of every object in the surveillance area. That position is sent to the central computer that can follow the movements of the live vehicle in real-time while the computer simulates the robot's odometry on its own. By fusing both information through a Kalman filter the system could accurately locate the vehicles and correct potential errors in their paths via the Kalman updates. For the implementation of the filter, it is important to specify that the kinematics of the system are linear and that each iteration of the filter will occur at fixed discrete time intervals, meaning that the time evolution of the state vector can be calculated by means of a state transition matrix. The accuracy of the filter was tested on several types of trajectories, from the simple straight line to a figure of 8, and the physical vehicle was always kept on its path. But in order to successfully extend to the quadrotor platform the filter needs to be robust.

The first series of tests consisted in creating systematic errors as would the IMU bias create on the quadrotor platform.

To simulate that, Fig.6 shows the path travelled by the robot $ROB_{real}$ with a wheel larger than the other (x1.5). The original path of the simulated vehicle $ROB_{sim}$ is travelled three times in a row to make sure the physical one returns to its original position.

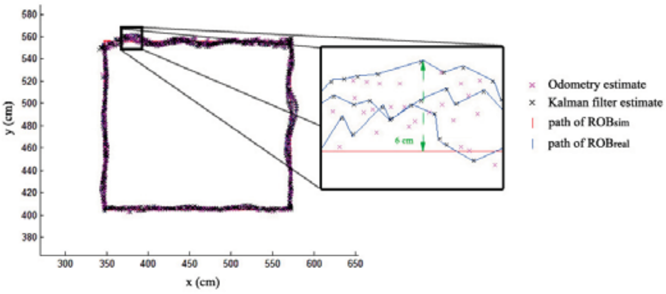

Fig. 6. Influence of a systematic error on a square path

Oscillations appear after the turns but they are rapidly damped in the straight segment. The maximum deviation from the original path was of 6cm representing only a third of the platform's width. This shows that the Kalman filter and on-board controller can keep the agent on track and on time even with sensor bias or physical damage.

To test the effects of non-systematic errors, the vehicle is returned to its calibrated state to travel along the same path. During a turn, one of the wheels is blocked to induce an error in heading then the robot is manually moved in the middle of its path to create a significant error in position. In both cases the vehicle finds its way back to the original path.

The discrete Kalman filter proves to be robust enough to overcome the effects of systematic and non-systematic errors.

## IV. Extension to the third dimension

Once the algorithms were extensively tested in their 2D environment to prove their accuracy and robustness, they were extended to the third dimension. The model of the vehicles was switched back to a proper quadrotor helicopter [7][8] and the previous methods were optimized for 3D applications towards health management.

### A. Quadrotor model

The quadrotor is very simply modelled as four rotors equipped at each end of a cross. All the propellers axes are parallel and fixed directly on the DC motors shaft. The blades have a fixed pitch and push the air downwards. Fig.7 shows the quadrotor structure in hover. Each propeller is defined by an orientation of rotation (blue circular vector), a rotating speed ($\Omega_1, \Omega_2, \Omega_3, \Omega_4$ for respectively the front, right, rear and left rotor) and a velocity (blue vertical vector) representing the amount of thrust created by the motor/propeller assembly. The fixed-body B-frame, in red, is set up to be front / left / up so that the altitude is measured positively as the quadrotor is climbing.

To take advantage of the body symmetry and keep the inertia matrix time-invariant, the equations of motion are formulated in the B-frame hence two assumptions can easily be made to simplify the model:

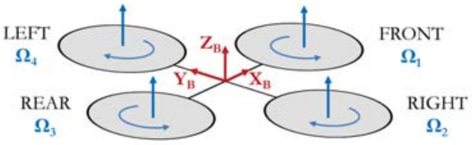

Fig. 7. Simplified quadrotor in hover

- The origin of the B-frame is coincident with the quadrotor's centre of mass.
- The quadrotor's axes of inertia coincide with the axes of the B-frame.

Under these assumptions and following the Newton-Euler formalism, the dynamics of a rigid body subject to external forces applied to its centre of mass can be expressed in the B-frame by Eq.9.

$$\begin{bmatrix} mI_{3\times3} & 0 \\ 0 & I \end{bmatrix} \begin{bmatrix} \dot{V} \\ \dot{\omega} \end{bmatrix} + \begin{bmatrix} \omega.mV \\ \omega.I\omega \end{bmatrix} = \begin{bmatrix} F \\ \tau \end{bmatrix} \tag{9}$$

To comply with real-time computation capabilities, the less influent effects such as the hub forces, ground effect and rolling moments were neglected and the thrust/drag coefficients were assumed constant. The matrix system (9) can then be rewritten in a state-space form $\dot{X} = f(X, U)$ where U is the input vector and X the state vector chosen as follows:

$$\begin{array}{l} X = [\,\phi\ \dot{\phi}\ \theta\ \dot{\theta}\ \psi\ \dot{\psi}\ x\ \dot{x}\ y\ \dot{y}\ z\ \dot{z}\,]^T \\ U = [\,U_1\ U_2\ U_3\ U_4\,]^T \end{array} \tag{10}$$

with

$$\begin{array}{l} U_1 = b\,(\Omega_1^2 + \Omega_2^2 + \Omega_3^2 + \Omega_4^2) \\ U_2 = l\,b\,(-\Omega_2^2 + \Omega_4^2) \\ U_3 = l\,b\ -(\Omega_1^2 + \Omega_3^2) \\ U_4 = d\,(-\Omega_1^2 + \Omega_2^2 - \Omega_3^2 + \Omega_4^2) \\ \Omega = -\Omega_1 + \Omega_2 - \Omega_3 + \Omega_4 \end{array} \tag{11}$$

From which we can derive the following equations of motion:

$$\begin{array}{l} \ddot{\phi} = \dot{\theta}\,\dot{\psi}\,\frac{I_{yy}-I_{zz}}{I_{xx}} - \dot{\theta}\,\Omega\,\frac{J_R}{I_{xx}} + U_2\,\frac{l}{I_{xx}} \\ \ddot{\theta} = \dot{\phi}\,\dot{\psi}\,\frac{I_{zz}-I_{xx}}{I_{yy}} + \dot{\phi}\,\Omega\,\frac{J_R}{I_{yy}} + U_3\,\frac{l}{I_y} \\ \ddot{\psi} = \dot{\phi}\,\dot{\theta}\,\frac{I_{xx}-I_{yy}}{I_{zz}} + \frac{U_4}{I_{zz}} \\ \ddot{x} = (s_\psi\,s_\phi\ + c_\psi\,s_\theta\,c_\phi)\,\frac{U_1}{m} \\ \ddot{y} = (-c_\psi\,s_\phi\ + s_\psi\,s_\theta\,c_\phi)\,\frac{U_1}{m} \\ \ddot{z} = -g + c_\theta\,c_\phi\,\frac{U_1}{m} \end{array} \tag{12}$$

A PID controller was added to the model to stabilize the model and then tested on the physical quadrotor. Without feedback from the camera tracking device presented above, the position controller was turned off for the first flights. The objective was to see if by simply controlling the throttle the attitude controller can stabilize the platform in hover. With the exact same PID coefficient as in the simulation, the flight was successful. A slight drift appeared on the X axis just like the simulation of a lone attitude controller would suggest but it was easily decreased by tuning the ESCs and the PID coefficients (all less than 10% away from their simulation value) and will be completely cancelled once the position controller is in place.

### B. Improvements on the 2D protocols

The A* path planner and the carrot following method were both kept for the guidance of the quadrotor platform. Compared to their previous centralized solution adopted for the 2D application, the decision-making is much more distributed. The quadrotor offers more processing power to run more complex algorithm so that both the path planning and tracking techniques could be run on-board. Apart from increasing the number of primitive movement at each iteration, the A* process stayed the same. Fig.8 shows the 3D path generated by the improved A* as well as the quadrotor following the carrot point as it travels the path.

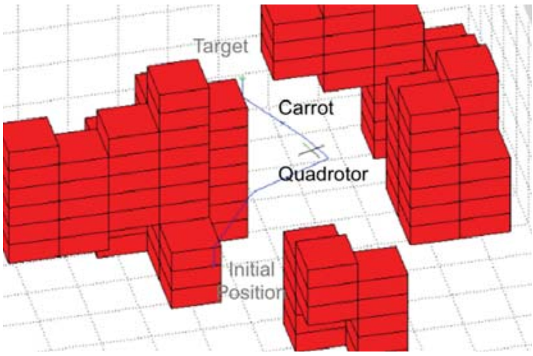

Fig. 8. Pure pursuit path following

On the other hand, significant changes were made to the pure pursuit to take more control over the carrot and facilitate the integration of a new Conflict Detection and Resolution scheme. The Distributed Reactive Collision Avoidance (DRCA) algorithm [9] is being developed to guarantee a conflict resolution scheme for $n$ nonholonmic vehicles, based on speed changes and lateral manoeuvres. It also distributes the computation load among the different subsystems. Consequently, the central computer can focus on a high-level task management and would be able to handle more units. Hence the overall system does not depend exclusively on the centralized intelligence making it more robust to eventual bugs.

Originally the DRCA takes into account the dynamic limitations of the platform in the conflict resolution scheme. Here the carrot is assumed to be a projection of quadrotor in the near future so that the avoidance process can be applied to the carrot instead of the vehicle. Since the carrot has no reality, it has no dynamic limitations. It can be created, moved and deleted freely to go around an obstacle or avoid an incoming friendly agent. The dynamics of the quadrotor will be handled by the controller and path tracking methods already in place. This will enable the generation of new avoidance trajectory and extend the effectiveness of the DRCA to more complex scenarios.

The Auction algorithm was kept to deal with the target assignment problems, and was improve to incorporate the case of $n_{targets} > n_{units}$ previously covered by the genetic algorithm. Though it was giving good results, the genetic algorithm is computationally heavy and does not fit the real time expectations of this work. The new Auction algorithm also has the ability to assign units as to optimize time rather than energy. The 2D version tried to minimize the added length of all the paths thus minimizing the power consumed by the swarm. Now the algorithm can choose to minimize the length of the longest path thus trying to optimize the time needed to reach all the targets.

## V. Further Work: Towards full autonomy

The quadrotor should be able to detect a faulty behaviour from its sensors and actuators. Thus the on-board decision making would be performed based on the current state of the vehicle and its priority level could be changed depending on the significance of the recorded problem. Once the central computer is aware of the issue, it can reassign the other agents to account for the vehicle in trouble.

The integrity of the swarm, the safety of its direct environment and the success of the mission will always prevail on the individual. In case of a minor issue however, the central intelligence can land the agent and warn the operator that it needs to be fixed or replaced.

## VI. Conclusion

In this paper we presented a set of algorithms grouped into a single method in order to control the behaviour of a multi-agent system. The work was first restricted to a two dimensional scenario to focus on the versatility of the target assignment and its real time capabilities. All the scenarios implemented were successfully analysed by the task manager and properly carried out by the vehicles. The algorithms were then extended to the third dimension and optimized to account for the unstable quadrotor dynamics. Significant modifications on the pure pursuit method enabled a smooth and safe trajectory in a dense environment. The path tracking algorithm will be further improved to incorporate a DRCA-inspired conflict resolution and avoidance protocols in partially known environments.

***Abstract*—This paper describes the development of a system for the rapid prototyping of high level control algorithms using an Arduino based commercial off the shelf autopilot called ArduPilot. It is capable of controlling multiple vehicle types, including fixed, and rotary wing aircraft as well as ground vehicles. The inner loop control is performed by ArduPilot, so the high level control can be rapidly prototyped and tested in Simulink, or an embedded system. The ability to conduct tests in software and hardware in the loop has also be developed, to enable safe testing of algorithms, which will speed up the development process. To show its functionality and ability to assist with the development process of algorithms, ArduPilot is used with a remote controlled aircraft in simulation and in real world testing to verify newly developed high level algorithms for UAVs.**

***Index Terms*—Autopilot; rapid prototyping; algorithm development; hardware in the loop; software in the loop.**

## I. INTRODUCTION

It is important to be able to test high level algorithms, in simulation first, and then eventually in the real world. To be able to test high level control, a system needs to be in place for this to be tested on. The advantage of performing Software In the Loop (SIL) and then Hardware In the Loop (HIL) testing before performing real world testing is widely recognized as much cheaper, less time consuming, and safer [1]. A system that allows a seamless transition from one stage to the next without reprogramming, or reconfiguring any part of the system would hugely reduce the time from conception to the final design. This paper describes a system for developing high level autonomous control functions of UAVs.

Developing a full autopilot system from scratch is difficult, as specialist knowledge is needed in electronic engineering, systems integration, and software engineering. By purchasing an open source Commercial Off The Shelf (COTS) autopilot system much time and effort was saved. ArduPilot [2] is a hobbyist “do-it-yourself” autopilot meant for use on remote controlled aircraft. It is capable of flying simple waypoints, or more importantly taking roll ($\phi$), pitch ($\theta$), rudder, and throttle commands from an external source. By using a communication protocol called MAVLink [3], any device, or system can give ArduPilot these commands over a number of different connection types. As the low level control is performed by this autopilot, it leaves the user the freedom to concentrate on the high level control.

This paper describes the ArduPilot autopilot, and the system developed to control it. SIL, and HIL testing is discussed, as well as the X-Plane simulation environment used in this testing. The use of Simulink, and embedded systems to perform high level control is described. An example is given to illustrate the full development cycle from SIL to HIL to real world testing, where a simple PID waypoint tracking algorithm is developed and tested safely and easily.

## II. ARDUPILOT

ArduPilot is a Arduino [4] based autopilot designed for the use by remote controlled aircraft hobbyists. It is designed to control fixed wing aircraft, and various rotary wing platforms, including single, tri, quad, hexa, and octa copters. The software is written in C++, and is completely open source with an active development community. The system enables the user to fly a series of predefined waypoints using a simple cross track error trajectory following algorithm. Or the user can fly the aircraft on a Fly by Wire (FBW) mode, where pitch and roll angles are commanded over the transmitter using ArduPilots inner loop instead of directly commanding servos. ArduPilot can communicate with a ground control station, where data can be gathered, waypoints, or even control gains can be updated. It communicates over a wireless serial connection, using a communication protocol called MAVLink [**?**], which was designed specifically for Micro Aerial Vehicles (MAVs).

The system hardware consists of two circuit boards shown in Fig. 1. The lower board has an ATmega2560 processor which runs the software, a failsafe multiplexer (that means there is always a hardware override if the processor fails) and all servo and receiver connections. The upper board houses the sensors, and telemetry ports. The sensors include a triple axis accelerometer, a dual and single axis gyro, barometric pressure sensor, triple axis magnetometer, also an externally connected GPS module. It is also capable of having an external pitot static sensor, for airspeed measurements. The full system on an aircraft set up for flight testing is shown in Fig. 2.

The ATmega2560 processor is relatively slow and only capable of executing 256 Kb of code. The autopilot software is written in C++ which is not that accessible a programming language. In its default state it is not an effective system for research.

Fig. 3. Flow diagram of the control structure on the whole system

There are many examples of autopilot systems developed by research organisations, to assist with their research goals. They are often made in house at considerable expense, and many run on embedded systems making for high development times [1], [5], [6], and [7]. There are other autopilots available, like Paparazzi [8], or MicroPilot [9]. These systems are expensive, they are not easy to manipulate and interface with, and by no means as cross platform compatible. Paparrazi has no standard hardware as the schematics are open source [10], requiring one to be specially ordered, or made in house. MicroPilot is a very small open architecture autopilot, which has an integrated Inertial Measurement Unit (IMU) and GPS. Although all the parameters and control gains can be altered, the code is closed source and can not be altered. An autopilot system meant for hobbyists is Attopilot [11], this system is quite expensive and is quite dated. AttoPilot uses thermopiles for attitude control in instead of the much more accurate and reliable IMU [12].

## III. System Configuration

ArduPilot has a number of different operating modes. The outer loop waypoint following mode (auto), the inner loop pitch, and roll angle hold (FBW), and manual override. If roll and pitch commands are sent to ArduPilot from an external source while in FBW mode, the higher level control loop can be performed on any platform of the users choice that is able to communicate over a serial connection. This gives huge flexibility to the user. As the ATmega2560 is simply not fast enough, and does not have enough storage, an external system to run more advance, more demanding code is needed.

The external system that this system has been primarily designed for is Simulink. A program that is used and understood by many engineers. It enables rapid prototyping of algorithms, and has an accessibility that is simply not offered when doing the same on an embedded system where the user must be familiar with C or C++.

The layout of the control system is shown in Fig. 3. ArduPilot's Attitude Heading Refrence System (AHRS) conducts sensor fusion and transmits the data over its serial telemetry port encoded in MAVLink format. A Simulink block has been developed for communication over MAVLink, it receives and decodes MAVLink messages, Simulink conducts high level control on the block outputs, to give pitch, roll angle, and throttle commands. The block then encodes these commands and resends them over the same serial connection. To enable wireless serial communication for flight tests, XBee wireless modules are used. As data and control signals are being transmitted wirelessly, this system relies on the wireless link to have high data integrity and low latency.

An embedded system can be used in place of Simulink if the wireless data link is a concern. By simply using the MAVLink wrapper discussed in Section V an embedded system can do exactly the same job as Simulink by directly connecting its serial port to that of ArduPilot's. This enables all the control to be performed on board the aircraft but over two components, mitigating XBee signal issues, also enabling a higher data rate.

## IV. Software and hardware in the loop

Before performing real world testing, it is important to verify code functionality, which is commonly done through SIL, and then HIL testing. Putting algorithms through the full development cycle of SIL, HIL, and then flight testing is a good systematic debugging method, which significantly reduces risk. This process can be shown in Fig. 4. SIL enables any bugs in the software, to be ironed out, then HIL brings to light bugs which come about due to the software's interaction with the hardware, and the wireless communication

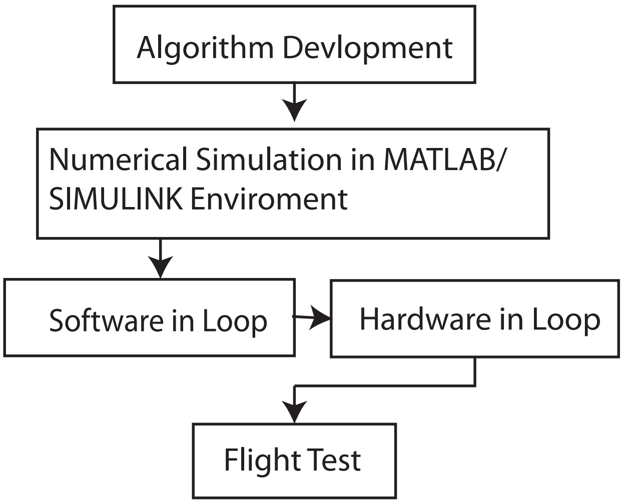

Fig. 4. The development cycle for high level control for UAS

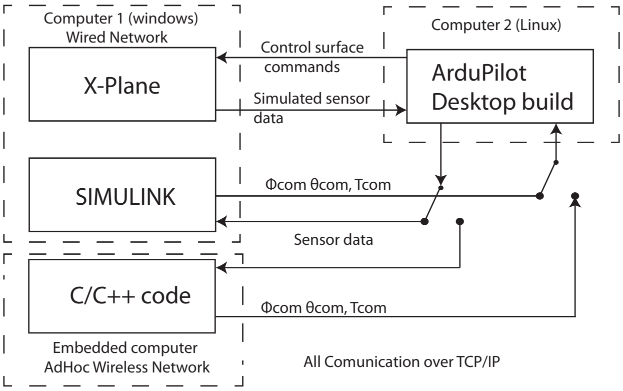

Fig. 5. Flow diagram for ArduPliots SIL testing, use with Simulink or and embedded system

system. Finally fight testing shows the functionality of the communications system at range, and issues the system has in the real environment, like wind.

The SIL system is shown in Fig. 5. The open source ArduPilot code has a desktop build, which means that, instead of the code being compiled on the Arduino on the ArduPilot, it is complied on a normal desktop computer running LINUX. This simulated ArduPilot communicates with a simulated aircraft in the X-Plane flight simulator using a plugin that enables communication over a TCP/IP network connection using the MAVLink Protocol. The X-Plane aircraft model is controlled by the desktop build of ArduPilot, and in turn ArduPilot is controlled by an external system like Simulink or an embedded system running the users high level control algorithms. This SIL method enables development to be undertaken without any ArduPilot hardware.

HIL (shown in Fig. 6) is much the same, but the actual ArduPliot hardware is used and sensor data is faked. The communication between X-Plane and ArduPilot is now done over a virtual serial connection, provided by the USB to serial chip. ArduPilot is now controlled over its telemetry port connected to Simulink, or a ground station using a XBee wireless serial transmitter, or to an embedded system directly.

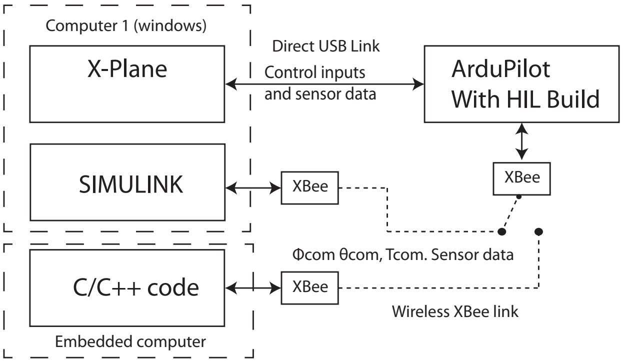

Fig. 6. Flow diagram for ArduPliots HIL testing, use with Simulink or and embedded system

When it comes time to conduct actual flight tests there is no need for reconfiguration of software hardware or communications, apart from ArduPilot needs to be mounted to the aircraft, and wired to the receiver and servos. As ArduPilot and MAVLink have been abstracted to such a high level, throughout the whole development cycle none of the ArduPilot code, or high level control ran externally needs to change at all to move to the next stage. All that changes is if the aircraft is real or simulated, where ArduPilot software is ran, and how the components of the system physically communicate with one another.

## V. Communication

As has been mentioned previously, the communications between all components of the system use a protocol called MAVLink. MAVLink is a very lightweight, header-only message marshalling library for MAVs, in C/C++. It encodes data structures into high efficiency data packets which use binary instead of ASCII encoding, yielding faster data transfer and higher data integrity. Any device that can communicate in MAVLink can talk to ArduPilot. A C++ wrapper has been developed that abstracts MAVLink so it can communicate over any physical transport layer, currently available is communication over serial, TCP/IP, UDP, and Write to file. This has facilitated the seamless transition in the testing phase from SIL through HIL to flight testing, by simply having each component change the physical means of sending MAVLink encoded data.

XBee converts a serial stream to wireless using a protocol called Zigbee. A large outdoor 15 dB omni directional 2.4Ghz antenna is used on the ground, and a striped down 8 dB antenna on the aircraft. This means that the small 60 mW power of the XBee can communicate with an aircraft a mile away in any direction and orientation. The series 2.5 XBees used are point to multi point in a communication mesh. A master module is attached to the ground station receiving data from as many as 255 other XBees. Due to the high gain

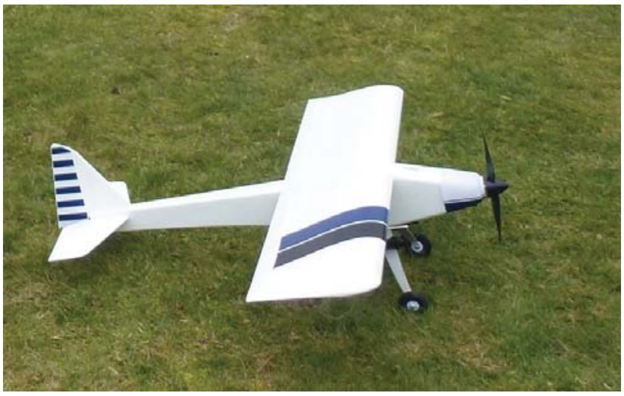

Fig. 7. WOT4 testing aircraft

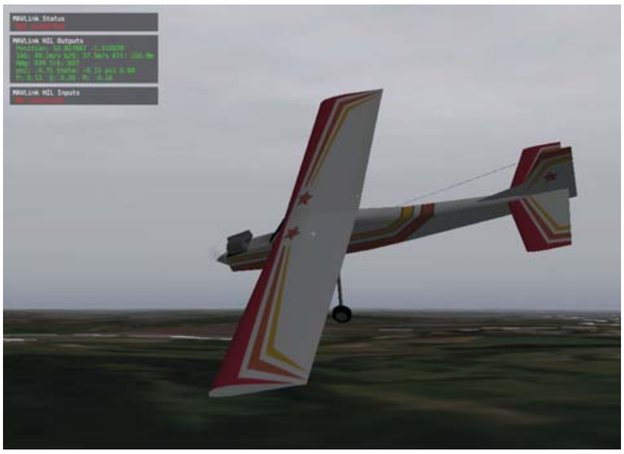

Fig. 8. X-Plane RC Plane model of WOT4

antennas, and the meshing ability of XBee 2.5 multi vehicle test are possible.

## VI. Experimental Studies

The platform chosen for the initial experiments is a WOT4 model aircraft. The WOT4 is an inexpensive option for the initial flight tests. This aircraft has been chosen as it is large enough to carry Ardupilot but small enough to keep risk at an acceptable level during the initial flight testing. It is made from Expanded Poly Olefin (EPO) foam with is extremely strong, durable, and very light. The WOT4 is capable of carrying of 500g payload, so would be capable of carrying a camera and video transmitter equipment. Ardupilot is easily able to fit inside the fuselage, close to the center of gravity of the aircraft, and out of the airflow to minimise drag. A pitot static probe, and sensor is mounted half way along the wing out of prop wash, to measure the airspeed of the aircraft. The WOT4 is shown in Fig. 7.

For SIL and HIL, an X-Plane model of the WOT4 has been developed, so algorithms could be tested on a representative model. The model was developed using X-Plane's plane maker, using the aircrafts dimensions, power, and wing cross section, to give an approximate representation of the aircraft. A graphical representation of the model can be seen in Fig. 8.

To test the functionality of the full system from SIL to real world testing, step tests are performed as well as tests on speed hold, and altitude hold controllers. Finally a simple PID waypoint tracking algorithm is performed.

Using the MAVLink Simulink block aircraft state information can be read, and roll, pitch angle, rudder and throttle commands sent to and from ArduPilot. The speed, altitude hold, and waypoint tracking are also programed in Simulink.

Illustrated in Fig. 9 is the step response of the WOT4 in roll, in SIL, HIL, and real world. From flying straight and level a 60° roll angle is commanded, then a -60 ° angle is commanded. The response in SIL and HIL were of course similar as they use the same model in X-Plane, the real world response only differed slightly. This simple test shows the fundamentals of the system functioning, including Ardupilots inner loop control, MAVLink, and communications downlink functionality.

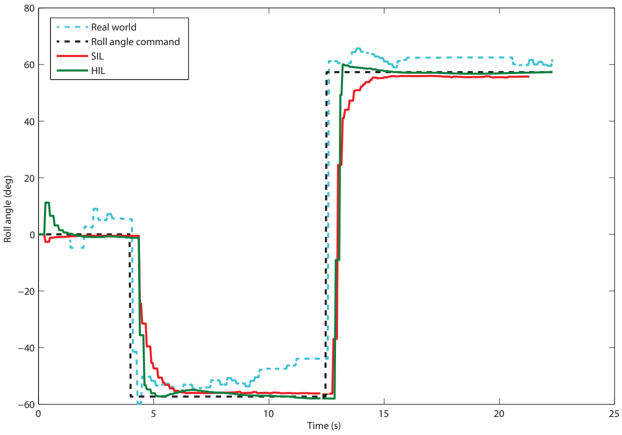

Fig. 9. Step response for roll angle for the WOT4, in SIL, HIL, and real world

To demonstrate the ability of Simulink to perform outer loop control, both speed hold, and heading hold control are tested. Also they are needed for more advanced outer loop control. Both are based on simple PID controllers, where speed is controlled with pitch angle, and heading is controlled with roll angle. Once again this was put through the whole development cycle. Fig. 10 shows the aircraft responding to step commands in airspeed. Fig. 11 shows the aircraft responding to step commands in heading. As good data integrity, and speed is important in off board control, these tests show that Xbee, and Simulink are capable of this. As wireless communication is the weak link in this system and as simple off board control functions perfectly, there is no reason that the system could not now perform more complex control algorithms.

A simple PID waypoint tracking algorithm was implemented in Simulink, to make an aircraft fly around user defined waypoints. It uses the haversign formula [13] to calculate the heading between the aircraft's, and waypoint's latitude and

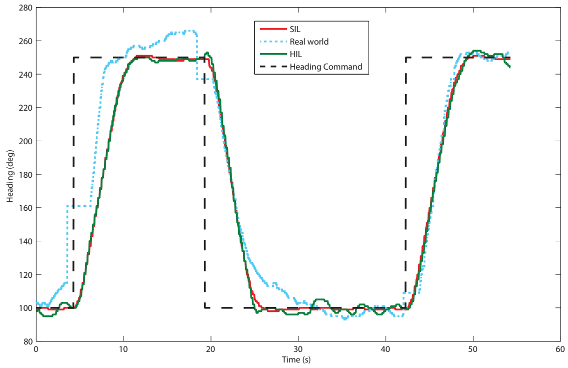

Fig. 10. Step response for heading hold controller for the WOT4, in SIL, HIL, and real world

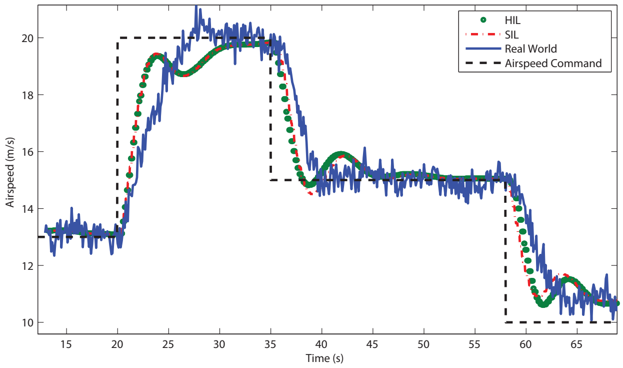

Fig. 11. Step response for speed hold controller for the WOT4, in SIL, HIL, and real world

longitude. Eq. (1), and Eq. (2) shows how the bearing ($\theta$) and the distance (d) between two points on the earth surface defined by latitude and longitude can be calculated.

$$a = s^2(\frac{\delta lat}{2}) + c(lat_1)c(lat_2)s^2(\frac{\delta lng}{2})$$

$$c = 2\arctan(\frac{\sqrt{a}}{\sqrt{1-a}}) \qquad (1)$$

$$d = R_e c$$

$$\theta = \arctan(\frac{s(\delta lng)c(lat_2)}{c(lat_1)s(lat_2) - s(lat_1)c(lat_2)c(\delta lng)}) \qquad (2)$$

Where cos and sin are abbreviated to c and s respectively. Where $R_e$ is the radius of the earth which is 6378.1 Km, and $\delta lat$, and $\delta lng$ is difference between the aircraft's latitude and longitude and that of the origin or the waypoint the distance and heading is to be measured. $lat_2$, and $lng_2$ are the latitude, and longitude of the aircraft, and $lat_1$, and $lng_1$ are the latitude, and longitude of the next waypoint.

This bearing is then used as the heading command to make the aircraft fly directly at the next waypoint. The aircraft is flown around a sqaure circuit at 200 m height above ground, and at 15 m/s. Fig. 12 shows the 2D path flown by the WOT4 in SIL HIL, and in real world testing. It is in this flight test that the greatest difference between the simulated WOT4 and the real WOT4 is observed, but the simulated tests proved that the algorithms worked successfully.

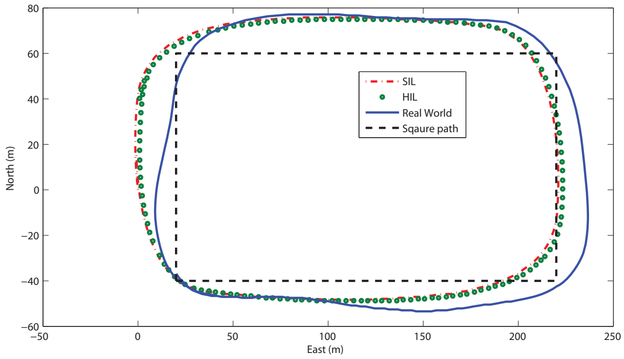

Fig. 12. Simple PID waypoint tracking algorithm tracking a 100x200m square path, in SIL, HIL, and real world

## VII. Conclusion

A system has been developed that enables research in the field of UAS to quickly develop and test high level control algorithms. By using a COTS autopilot, the full system is cheap and easy to integrate into a range of vehicles. As ArduPilot is a well developed system it is extremely reliable, and robust which makes flight testing swift and safe. The results from SIL, HIL testing have with relative accuracy, predicted the performance of the WOT4 in real world tests. The control system developed in Simulink needed no modification between simulation and real world tests. These show that this is a good technique for safely testing algorithms in simulation before moving the to actual vehicles. As the high level control was carried out off board, on a ground control station, and relied on a wireless data link occasionally there were a few data packets drops. The aircraft never got further than 300m away so if operating at further distances, or at higher data rates, an embedded system can be used to conduct the high level control with the same ease.

***Abstract*—This study proposes an optimal resource allocation algorithm of multiple UAVs with cooperative path planning using a geometric approach. The focus of the resource allocation is on mission and task completion, also known as feasibility whilst coping with operational and physical constraints of UAVs. Therefore, this study first introduces a geometric path planning algorithm based on Pythagorean Hodgraphs (PH). Using Bernstein Bzier polynomials, the path planning algorithm can generate feasible and safe (obstacle and inter-collision free) paths which can also meet position and orientation constraints of UAVs. We then optimise the resource allocation based on Evolutionary Game Particle Swarm Optimisation (EGPSO) and paths generated by the geometric planning. The input parameter of the optimal allocation problem is the allocation policy and the performance index is chosen to be the total flight time of the UAVs. Here the flight time is computed from the path produced by the path planning algorithm. The optimal allocation algorithm changes the allocation policy and finds the best allocation policy which minimise the performance index. The performance of the proposed algorithm is investigated by numerical examples simulated under realistic scenarios.**

## I. Introduction

Inexpensive unmanned aerial vehicles (UAVs) have considerable potential for use in remote sensing operations. They are cheaper and more versatile than manned vehicles, and are ideally suited for dangerous, long and/or monotonous missions that would be inadvisable or impossible for a human pilot. Groups of UAVs are of special interest due to their ability to coordinate simultaneous coverage of large areas, or cooperate to achieve common goals. Specific applications under consideration for groups of co-operating UAVs include, but not limited, border patrol, search and rescue, surveillance, mapping and environmental monitoring. In these applications, the group of UAVs becomes a mobile resource/sensor and consequently routes and tasks for each UAV need to be properly and optimally assigned in order to cooperatively achieve their mission. Therefore, this study addresses the vehicle routing problem of of multiple UAVs.

The vehicle routing problem, has been mainly handled in the operational research area ([1], [2], [3], [4]) and can be generally classified by two categories: one is the Traveling Salesman Problem (TSP) which finds a shortest circular trip through a given number of cities, and the other is the Chinese Postman Problem (CPP) finding the shortest path with considering path constraints on an entire network of road. The TSP using multiple UAVs can be considered as a task assignment problem to minimise the cost of time or energy for a certain mission by assigning each target to an UAV, for which binary linear programming ([5]), iterative network flow ([6]), tabu search algorithm ([7]) and receding horizon control ([8]) have been proposed. Recently, [9] proposed a route optimisation algorithm for multiple searchers to detect one or more probabilistically moving targets incorporating other factor such as environmental and platform-specific effects. Meanwhile, the CPP is normally used for ground vehicle applications such as road maintenance, snow disposal ([10]), boundary coverage ([11]), and graph searching and sweeping ([12], [13]). Since the general vehicle routing algorithms approximate their path to a straight line shape to reduce computational load, the physical constraints imposed on the vehicle are not to be addressed.

In order to mitigate this issue, this study divides the routing problem into two parts: the first part is to design cooperative path planning and the second one is to find the optimal resource allocation policy based on the paths obtained in the first part. Cooperative path planning algorithm is designed using the differential geometry concepts, especially Pythagorean Hodographs (PH) curves, which was proposed in our previous study [14]. Path planning algorithms based on differential geometry examine the evolution of guidance geometry over time to derive curvature satisfying the guidance goals. Guidance command such as a manoeuvre profile can be then computed using the derived curvature of the guidance geometry. One of main advantages of this approach is that the number of design parameters can be significantly reduced whilst maintaining the guidance performance. Therefore, this approach will enable us not only to design fast and more lightweight algorithms, but also to generate safe and feasible paths for multiple UAVs. This would be preferred for integration of path planning with the optimal resource allocation. Since reaching targets at the same instant with specific orientations could improve the overall effectiveness and survivability of the UAVs, simultaneous arrivals with predefined orientations are considered as constraints with the physical ones such as obstacle avoidance and the maximum turning rate of of the UAVs.

The performance index for the optimal resource allocation problem is the total flight time of the multiple UAVs since

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

this is necessary to have a manageable task in the available time. The total flight time for each candidate allocation is computed by using the velocity profile and paths generated by cooperative path planning and this is used to find the optimal allocation policy. The optimisation method implemented in this paper is Evolutionary Game Particle Swarm Optimisation (EGPSO) which is proposed in our previous study [15]. The proposed EGPSO algorithm integrates the Evolutionary Game Theory (EGT) concepts with those of Particle Swarm Optimisation to find the optimal weight of the coefficients considering the entire swarm fitness. Moreover, it is shown that this algorithm efficiently works in the general allocation problem [15].

The overall structure of this paper is given as: Section II briefly introduces a target tracking filter design, trajectory classification to model the behaviour of ground vehicles, and behaviour recognition algorithm using string matching theory. Section III introduces rule-based decision making algorithm to find suspicious or anomalous behaviour based on a fuzzy logic. Section IV presents numerical simulation results of behaviour monitoring for both military and civilian traffic scenario using realistic ground vehicle trajectory data. Lastly, conclusions and future works are addressed in Section V.

## II. Problem Formulation

### A. Scenario

The scenario considered in this study is similar to that in our previous paper [14]. In the scenario, it is assumed that a group of $N$ UAVs leaves from a base and they have to reach the target area at the same time with predetermined orientations. The individual start and finish points for each UAV are represented by position coordinates $(x, y)$ and orientation by angle $\theta$. These are assumed to be known a priori. The UAVs are assumed to be of same type and are flying at same the speed at constant altitude. Each UAV has the same maximum bound on its curvature and the environment has static obstacles. The UAVs are required to avoid collision with other UAVs and with other objects in the air-space, as well as avoiding the static obstacles. The allocation of the UAVs needs to be optimised.

### B. Optimal Allocation Problem

Let us first consider a path between a single UAV from the base to the target position with no constraints. The starting point $P_s$ is at the base position and the finishing point $P_f$ is at the target position. The path connecting the poses is represented by the label $r$. The path planner produces a path connecting the start pose $P_s(x_s, y_s, \theta_s)$ and the finish pose $P_f(x_f, y_f, \theta_f)$.

$$P_s(x_s, y_s, \theta_s) \xrightarrow{r(t)} P_f(x_f, y_f, \theta_f) \tag{1}$$

where $t$ is a path length parameter.

Extending equation (1) to account for a group of $N$ UAVs gives:

$$P_{si}(x_{si}, y_{si}, \theta_{si}) \xrightarrow{r_i(t)} P_{fi}(x_{fi}, y_{fi}, \theta_{fi}), \tag{2}$$

$$\max|\kappa_i| < \kappa_{max}, \coprod_{safe}, \coprod_{length}, i = 1 \dots N, \tag{3}$$

where $\kappa$ is the path curvature, $\kappa_{max}$ is the maximum curvature bound obtained from the maximum turning rate, and $\coprod_{\text{safe}}$ and $\coprod_{\text{length}}$ are the constraints on safety and path length respectively.

The safety constraints are described as:

$$\begin{aligned} \coprod_{length} \quad : \quad & d(P_i(t), P_j(t)) > d_{sep}, \\ & d(P_i(t), O_k(t)) > d_{sep} \\ & i \neq j = 1 \dots N, k = 1, \dots, n_o \end{aligned} \tag{4}$$

where $P_i(t)$ and $O_k(t)$ are the positions of the $ith$ UAV and the $kth$ obstacle, $n_o$ the number of obstacles, and $d_{sep}$ the minimum separation distance. To enable simultaneous arrivals, the constraint on length is given as:

$$\begin{aligned} \coprod_{length} : s_i(t_{fi}) &= s_{cm}, i = 1 \dots N \\ s_i(t_{fi}) &= \int_{t_{si}}^{t_{fi}} \sqrt{\dot{x}_i(t)^2 + \dot{y}_i(t)^2} dt, \end{aligned} \tag{5}$$

where $s_{cm}$ is a common path length which is automatically obtained regarding to the allocation.

The optimal allocation problem is then formulated as: minimising the following performance index

$$J = \Sigma_1^N \int_{t_{si}}^{t_{fi}} dt \tag{6}$$

subject to equation (2) and (3).

## III. Cooperative Path Planning Using Pythagorean Hodographs Curves

One of well known path planning approaches based on the differential geometry concepts is Dubins path planning [14], [16]. The Dubins trajectory ([17]) is the shortest path connecting two configurations represented by position and pose under the constraints of a bound on curvature or turning radius. The Dubins path is a composite curve of both lines and circles and is easy to produce. However, it lacks a smooth variation of curvature. Mathematically, the Dubins path provides only tangent continuity, $C^1$. The curvature continuity is important as the curvature is proportional to the lateral acceleration of the UAV. Therefore, curvature discontinuity results in an abrupt maneouvre of the UAV. A smooth motion needs curvature continuity $C^2$. Therefore, it is necessary to seek for an alternate path with curvature continuity. The equation of curvature is:

$$\kappa(t) = \frac{\dot{\mathbf{r}} \times \ddot{\mathbf{r}}}{|\dot{\mathbf{r}}|^3}, \quad \dot{\mathbf{r}} = \frac{d\mathbf{r}}{dt}, \ddot{\mathbf{r}} = \frac{d^2\mathbf{r}}{dt^2} \tag{7}$$

From the equation (7), the curvature is a function of first two derivatives of a curve, $\mathbf{r}(t)$, so the path needs to be at least twice continuously differentiable, that is $C^2$ continuity. There are many polynomial curves which can provide $C^2$ continuity. However, we choose Pythagorean Hodograph (PH) curve known for its rational properties.

A smoother curve can be produced by using techniques such as PH, where basis curves are used to piece together using Bernstein Bézier polynomials. For a planar parametric curve, $\mathbf{r}(t) = \{x(t), y(t)\}$, the hodographs are $\dot{x}(t)$ and $\dot{y}(t)$ so the velocity vectors of a curve are its hodograph. The path-length of the curve $\mathbf{r}(t)$ is:

$$s = \int_{t_1}^{t_2} \sqrt{\dot{x}^2 + \dot{y}^2} dt = \int_{t_1}^{t_2} |\dot{\mathbf{r}}(t)| dt \tag{8}$$

where $s$ is the path-length, $t$ is a parameter such that $t \in [t_1, t_2]$ and $\dot{x} = \frac{dx}{dt}$, $\dot{y} = \frac{dy}{dt}$, and $\dot{r} = \frac{dr}{dt}$ . The term inside the square root in equation (8) is the sum of the square of the hodographs of the curve, $\mathbf{r}(t)$. For the PH path the path-length is an integral of a polynomial $\sigma(t)$ such that:

$$\begin{aligned} \sigma(t) &= \sqrt{\dot{x}^2 + \dot{y}^2} \\ s &= \int_{t_1}^{t_2} |\sigma(t)| dt \end{aligned} \tag{9}$$

The PH curve can be produced by selecting two Bernstein polynomials $u(t)$ and $v(t)$ such that:

$$\begin{aligned} \dot{x}(t) &= u^2(t) - v^2(t) && (10) \\ \dot{y}(t) &= 2u(t)v(t) && (11) \\ & && (12) \end{aligned}$$

This gives:

$$|\sigma(t)| = u^2(t) + v^2(t) \tag{13}$$

Note that the PH path thus provides exact calculation of path length and it's curvature, as well as the orders of the two polynomials, $u(t)$ and $v(t)$, determine the order of PH curves. In this research, we use a fifth order PH curve as this is the lowest order curve which has inflexion points which can provide sufficient flexibility [**?**]. For a fifth order PH curve, $u(t)$ and $v(t)$ can be approximated as second order polynomials:

$$\begin{aligned} u(t) &= \sum_{k_u=0}^{2} u_k \binom{2}{k_u} (1-t)^{(2-k_u)} t^{k_u}; && (14) \\ v(t) &= \sum_{k_v=0}^{2} b_k \binom{2}{k_v} (1-t)^{(2-k_v)} t^{k_v}; && (15) \end{aligned}$$

Hence the curve, $\mathbf{r}(t)$, is given by Berstein form:

$$\mathbf{r}(t) = \sum_{k=0}^{5} P_k \binom{5}{k} (1-t)^{(5-k)} t^k; \tag{16}$$

where $P_k(x_k, y_k),\ k = 0, 1, 2, 3, 4, 5$ are control points. Note that these control points determine the curve $\mathbf{r}(t)$ and can be derived as:

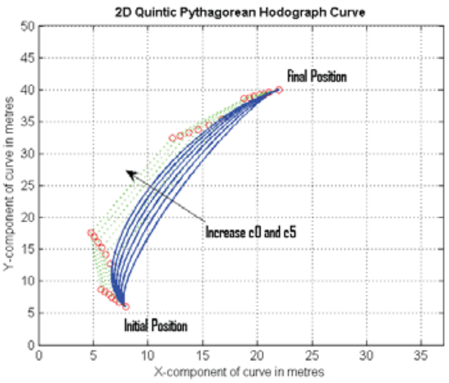

Fig. 1. PH paths

$$P_1 = P_0 + \frac{1}{5}\begin{pmatrix} u_0^2 - v_0^2 \\ 2u_0v_0 \end{pmatrix} \tag{17a}$$

$$P_2 = P_1 + \frac{1}{5}\begin{pmatrix} u_0u_1 - v_0v_1 \\ u_0v_1 + u_1v_0 \end{pmatrix} \tag{17b}$$

$$P_3 = P_2 + \frac{1}{5}\begin{pmatrix} u_1^2 - v_1^2 \\ 2u_1v_1 \end{pmatrix} + \frac{1}{15}\begin{pmatrix} u_0u_2 - v_0v_2 \\ u_0v_2 + u_2v_0 \end{pmatrix} \tag{17c}$$

$$P_4 = P_3 + \frac{1}{5}\begin{pmatrix} u_1u_2 - v_1v_2 \\ u_1v_2 + u_2v_1 \end{pmatrix} \tag{17d}$$

$$P_5 = P_4 + \frac{1}{5}\begin{pmatrix} u_2^2 - v_2^2 \\ 2u_2v_2 \end{pmatrix} \tag{17e}$$

When the initial and final configurations (pose and heading) for each vehicles are known, $P_k(x_k, y_k),\ k = 0, 1, 2, 3, 4, 5$ can be specified. From the configurations, $P_0$, $P_1$, $P_4$, $P_5$ are directly obtained as:

$$\begin{aligned} P_0 &= (x_s, y_s) && (18a) \\ P_5 &= (x_f, y_f) && (18b) \\ P_1 &= P_0 + (1/5) * d_0 && (18c) \\ P_4 &= P_5 - (1/5) * d_5 && (18d) \end{aligned}$$

where

$$\begin{aligned} d_0 &= c_0(\cos(\theta_s), \sin(\theta_s)) && (19) \\ d_5 &= c_5(\cos(\theta_f), \sin(\theta_f)) && (20) \end{aligned}$$

where $c_0 \in (0, \infty]$ and $c_5 \in (0, \infty]$. Note that when $c_0$ and $c_5$ are specified, the control points $(P_0, P_1, P_4, P_5)$ in (18) are fixed by configuration. Moreover, $u_i$ and $v_i$ for $i = 1, 2, 3$ are also uniquely derived from equation (17), which implies that $P_2$ and $P_3$ are also fixed. Therefore, the number of control parameters reduces to two of $c_0$ and $c_5$ whilst maintaining the continuity of the curve. Increasing the values of $c_0$ and $c_5$ will increase the length of tangent vectors $P_0 = |\boldsymbol{P_0P_1}|$ and $P_5 = |\boldsymbol{P_5P_4}|$ and in turn $P_2$ and $P_3$ get shifted to meet the PH condition (17). This is shown in figure 1. As shown in this figure, varying the two control parameters controls the curvature, which in turn will determine the space curve.

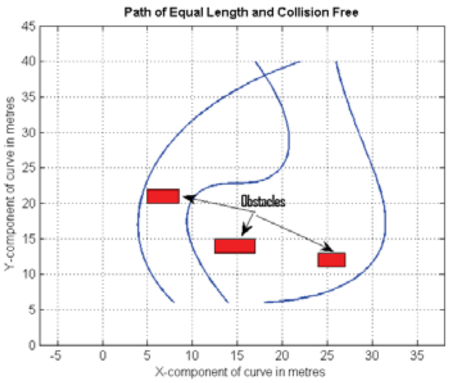

Fig. 2. PH paths, all equal in length and avoiding obstacles

For simultaneous arrival, the paths are required to be made equal in path if UAV speeds are constant and same. The variable speed UAVs can have difference in path lengths. This is achieved by increasing the shorter paths to that of the longest one. The path lengths of the flyable and safe paths are calculated using (8). For $N$ number of UAVs, with the length of each path $s_i$, the set of path lengths $\Sigma$ is:

$$\Sigma = \{s_i\}, \quad i = 1, \dots, N \tag{21}$$

The longest of the safe flyable path is the reference path. That is the maximum of $\Sigma$. The path lengths of $(N-1)$ UAVs are increased to that of the reference path. Lengths of the PH path is increased by changing the control parameters of $c_0$ and $c_5$:

$$\text{Find } c_0 \text{ and } c_5\text{, such that} \quad s_i - \max s_i = 0, \quad i = 1, \dots N-1 \tag{22}$$

Obstacles as well as collisions can be also avoided by using the parametric freedom of $c_0$ and $c_5$. Such a set of paths (equal length and collision free) is shown in figure 2

## IV. Resource Allocation using EGPSO

The approach, which is used to solve the allocation of the tasks to the UAVs in this paper, is a Discrete Particle Swarm Optimisation (DPSO) combined to Evolutionary Game Theory (EGT). One of the main implementation issues of DPSO is the choice of inertial, individual and social coefficients. In order to resolve this problem, those coefficients are optimised by using a dynamical approach based on EGT. The strategies are either to keep going with only inertia, or only with individual, or only with social coefficients. Since the optimal strategy is usually a mixture of the three coefficients, the fitness of the swarm can be maximized when an optimal rate for each coefficient is obtained. This algorithm is described in our previous study [15]. In this method, all the particles $X = (t_i)_{i \in [1 \dots T]}$ are considered as a vector of feasible solution, where the $t_i$ denote the tasks $i \in [1 \dots T]$ and $T$ is the number of tasks to achieve. The index of the vector represents the id of the UAV. Moreover, permuting the elements of $X$ in this representation gives all the possible solutions so it could enable to deal with high dimensional problems. The single constraint of assigning one UAV to one task does not enable us to deal with the common DPSO algorithm described by Eberhart and Kennedy in [18]. Due to the context and the application, it was required to adapt the form of the particles according to the problem.

### A. Swarm organisation

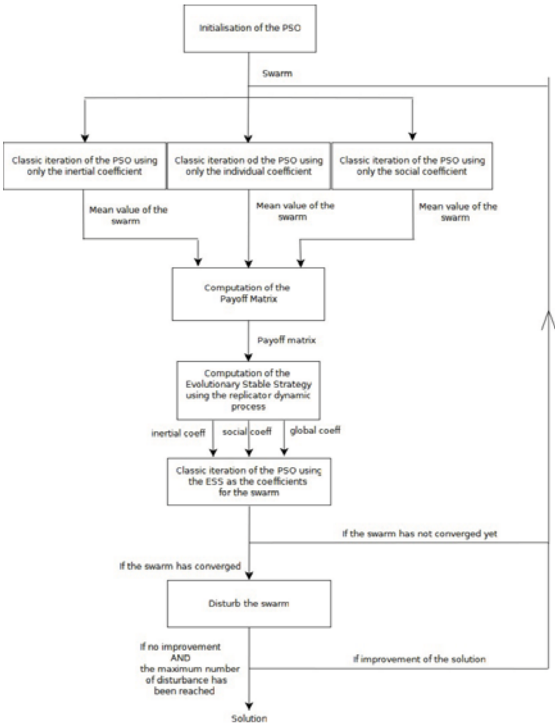
In the PSO algorithm, the establishment of the networks is a key point to maximise the exploration and the global efficiency of the algorithm to solve a problem. In this paper, in order to assigned the tasks to the UAVs, three different swarms are used. Each of them has its own features. One will adopt only inertial behaviour ($c_1 \neq 0$ and $c_2 = c_3 = 0$). One will adopt only selfish behaviour ($c_2 \neq 0$ and $c_1 = c_3 = 0$). One will adopt only social behaviour ($c_3 \neq 0$ and $c_1 = c_2 = 0$). Then the last one is following the common behaviour of the PSO with the coefficients determined by the result of EGT and the four previous swarms. The coefficients are chosen dynamically according to the current state of all the other swarms.

### B. Particle movement

Using the common process of the PSO, the probability of movement toward another solution is introduced. To guarantee that the particles are moving on the feasible solution space and won't need to be repaired, we use an a priori method. In fact, the particles are built in such a way that the solution space is obtained by permuting feasible solutions. One of the key issue when it is required to convert the PSO into DPSO, is the computation of the velocity. Indeed, in discrete space, the velocity does not really makes sense and it was essential to adapt it to discrete case. The main approach used in [18], [19], [20], [21] is the sigmoid function which enables to convert a velocity into a probability. The proposed method is based on that principle, and set the sigmoid function as $s(v_{id}^t) = 1 - \frac{2}{1+e^{v_{id}^t}}$, $(\forall v_{id}^t \in \mathbb{R}_+)$ $(s_{id}^t \in [0,1])$. Once all the probabilities of change for a particle are obtained, the final step is to draw a random number and compare it to each coefficient of probability. All the coefficients greater than the random number are selected as potential candidate for a permutation. Then we draw randomly two particle coefficients and permute them. (In case we obtain a random number greater than only one coefficient, we consider the particle won't move).

### C. Principle of EGT in the determination of the DPSO coefficients

In order to improve the convergence speed of the DPSO, it is proposed to combine it with EGT. If this way has already been investigated by Miranda and Fonseca in [22] to improve the local exploration of the particles, then by Di Chio in [23] and Liu and Wang [24]. The proposed approach is considering the global swarm's welfare instead of the particle's welfare. Thus, like described in IV-A, there are 3 available strategies to play: inertial, individual, or social. Each swarm will play one pure strategy and will provide its welfare to the others. Then, the EGT process, which is based on the replicator dynamic [15], find the equilibrium strategy which enables to the main swarm to improve or keep its mean welfare.



Initialisation of the PSO

## V. Numerical Simulations

In numerical simulations, a swarm of four UAVs is considered for mission deployment. All the UAVs will start from certain starting point at the same time and will reach the goal point at the same time. The goal points of each UAV will be determined from the optimal allocation. During their flights from starting position to finishing position all the UAVs will avoid inter-collisions and collisions with known obstacles. The proposed path planning algorithm will plan safe and flyable flight paths for all the UAVs in the group. For this simulation, the initial poses, the curvature constraints and the safety radii of all the UAVs are summarised in table I. The final poses, which represent targets, are given in table II. All the known static obstacles are given in the terrain database. For simplicity, all the obstacles are assumed to be of rectangular shape in this simulation. The locations of the obstacle are described by the coordinates of their vertices. The vertices of the obstacle1, obstacle2 and obstacle 3 are given table III. The optimal allocation obtained is $[2, 1, 4, 3]$ which represent the first UAV is allocated to the $2nd$ target, the $2nd$ UAV is assigned to the $1st$ target, and so on. The optimal paths of the UAVs are shown in figure 4. As shown in the figure, there is neither inter-collision between UAVs, nor collision with obstacles. The curvature constraint is also satisfied. The length of all the paths are made equal to the longest path by further change of curvature of each path. In this simulation the lengths of each path comes out to be $[36.8, 37.3, 39.7, 36.2]$ meters.

TABLE I
Numerical simulation conditions

| *UAVs* | *Position (m)* | *Heading (deg)* | *$\kappa$ (m)* | *Safety Radius* |
|---|---|---|---|---|
| UAV1 | (8, 6) | 130 | -1/13, +1/3 | 1 |
| UAV2 | (14, 6) | 124 | -1/13, +1/3 | 1 |
| UAV3 | (18, 6) | 3 | -1/13, +1/3 | 1 |
| UAV4 | (25, 6) | 20 | -1/13, +1/3 | 1 |

TABLE II
Final poses

| *No.* | *Position (m)* | *Heading (deg)* |
|---|---|---|
| 1 | (22, 40) | 24 |
| 2 | (17, 40) | 120 |
| 3 | (26, 40) | 113 |
| 4 | (10, 40) | 40 |

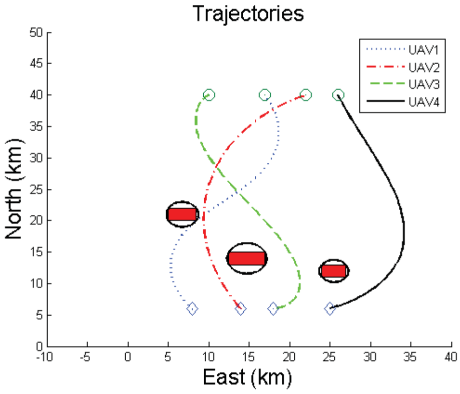

Fig. 4. Optimal PH paths, all equal in length and avoiding obstacles

TABLE III
Location of the known obstacles

| *Obstacles* | *Vertex1* | *Vertex2* | *Vertex3* | *Vertex4* |
|---|---|---|---|---|
| Obstacle1 | (5, 20) | (5,22) | (8.5, 22) | (8.5, 20) |
| Obstacle2 | (12.5, 13) | (12.5, 15) | (17, 15) | (17, 13) |
| Obstacle3 | (24, 11) | (24, 13) | (27, 13) | (27, 11) |

In order to examine the performance of the optimal resource allocation, the optimal result is compared to an arbitrary allocation, $[3, 4, 2, 1]$. The paths for the allocation are shown figure 5. The performance improvement of the optimal allocation compare to the arbitrary allocation is $12.12\%$.

## VI. Conclusions

In this paper, optimal resource allocation with 2D path planning algorithm (2D Path Planner) is proposed. In order to consider operational and physical constraints of the UAVs in the resource allocation design procedure, the proposed algorithm consists of two parts: cooperative path planning based on Pythagorean Hodograph quintic and optimal resource allocation using Evolutionary Game Particle Swarm Optimisation (EGPSO). The algorithm successfully calculated safe

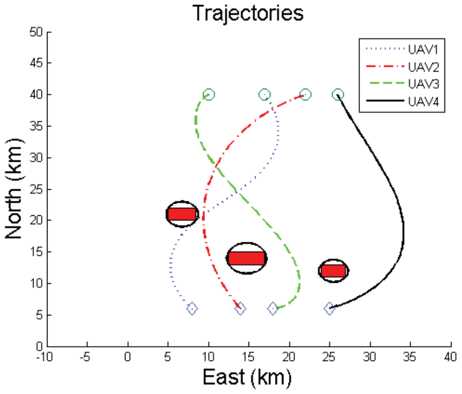

Fig. 5. PH paths for an arbitrary allocation, all equal in length and avoiding obstacles

and flyable paths (feasible paths) for all the UAVs in the group and optimally allocated the UAVs to a group of targets. The performance of the proposed algorithm is evaluated using numerical simulations.

***Abstract*—Tri-rotor UAVs are more efficient compared to quadrotors in regard to the size and power requirement, yet, tri-rotor UAVs are more challenging in terms of control and stability. In this paper, we propose the design and control of a novel tri-rotor UAV. The proposed platform is designed to achieve six degree of freedom using a thrust vectoring technique with the highest level of flexibility, manoeuvrability and minimum requirement of power. The proposed tri-rotor has a triangular shape of three arms where at the end of each arm, a fixed pitch propeller is driven by a DC motor. A tilting mechanism is employed to tilt the motor-propeller assembly and produce thrust in the desired direction. The three propellers can be tilted independently to achieve full authority of torque and force vectoring. A feedback linearization associated with $\mathscr{H}_\infty$ loop shaping design is used to synthesize a controller for the system. The results are verified via simulation.**

## I. Background and Motivation

In recent decades, Unmanned Aerial Vehicles (UAVs) have attracted growing attention in research due to their wide applications and large potential [1]. Aiming for more efficiency in term of size, autonomy, maneuverability and other factors, various conventional and non-conventional structure designs and configurations of UAV systems are proposed, see [2] and the literature therein. One such design that attracts increasing interest is the vertical-take-off-and-landing (VTOL) tri-rotor configuration.

Tri-rotor vehicles are systems with a three rotors arrangement. This configuration has been proposed as less-expensive with more flexibility and great agility [3], [4]. Compared to quadrotors, tri-rotor UAVs are smaller in size, less complex, less costly and have longer flight time due to the reduction in number of motors [5], which makes tri-rotor vehicles ideal for deployment in various research projects and missions [6].

On another perspective, thrust vectoring has been used in designs to maximize the capability of UAVs [7]. Thrust vectoring is of significant benefit in some applications to arbitrarily orient the vehicle body with respect to the vehicle acceleration vector [8]. In addition, thrust vectoring mechanism is used to give UAVs the capability of taking-off and landing in very narrow areas [9]. In small aircrafts and UAVs, a simple technique of tilt-rotor mechanism can be used to obtain thrust vectoring, where propulsion units are inclined in certain angles using an additional control motor to get the desired thrust in different directions. In general, tilt-rotor mechanism is used in tri-rotor systems to control the horizontal forces and yaw torque of the vehicle. Typically, one rotor only, referred to as the tail rotor, has the ability to tilt to control the yaw moment, see for example [6].

Dynamics of tri-rotor vehicles are highly coupled and nonlinear, which makes the control design of these vehicles the key for successful flight and operations [5]. Compared to quadrotor systems, the yaw control of tri-rotor systems is a further challenge due to the asymmetric configuration of the system. For instance, the reactive yaw moments in quadrotor systems is decoupled from pitch and roll moments which simplifies the yaw control design in such systems. In contrary, pitch, roll and yaw moments are highly coupled in tri-rotor systems. Moreover, attitude control of these vehicles is more challenging compared to quadrotor systems due to gyroscopic and Coriolis terms. In [5], the authors propose a tri-rotor system of which the control design is implemented by four loops for attitude control and guidance. This control design is complicated with coupling between attitude and position control loops and high computation load. The authors in [3] propose a tri rotor configuration in which all rotors of the system tilt simultaneously to the same angle to attain yaw control. The control design considers only the attitude stabilization and neglects the trajectory tracking. The control algorithm in [4] is based on nest saturation for decoupled channels where the configuration of the vehicle makes the separate control of attitude and position possible. The control design of the tri-rotor UAV proposed in [10] discusses only the hovering position. In [11], the attitude of the proposed tri-rotor UAV is controlled by using differential thrust concept between the rotors. The control system design in [12] controls the yaw angle of the proposed tri-rotor UAV by differentially tilting the two main rotors in the plane of symmetry while a fixed up-right propeller is used at the tail to control the pitch moment.

Few researchers have identified the structure of tri-rotor UAV combined with full independent tilt-rotor capability. In this paper, we propose a novel tri-rotor platform, herein referred to as the Tri-rotor UAV, and then we discuss the design and control of the proposed system. The proposed vehicle can achieve full authority of torque and force vectoring by employing three rotors and three servos for tilt-rotor mechanism. This structure gives the vehicle high level of maneuverability and

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

flexibility for translational motion as well as attitude control.

The rest of the paper is organized as follows. In Section II, a functional description of the vehicle and its design is discussed. A mathematical model that captures the dynamics of the UAV and govern the behaviour of the system is derived in Section III. The control system design is presented in Section IV and the simulation results is shown in Section V. The paper ends by conclusion in Section VI.

## II. System Structure and Design

The structure of the proposed Tri-rotor UAV is depicted in Figure 1. The vehicle has a triangular structure of three arms and at the end of each arm, a force generating unit is mounted to produce part of the required controlling force/torque. All three arms are identical of length $l$ and the three force generating units are also identical. Each force generating unit consists of a fixed pitch propeller driven by a Brushless DC (BLDC) motor to generate thrust. The three motors can be powered by a single battery pack or three separate packs located at the center of the body. The propeller-motor assembly is attached to the body arm via a servo motor that can rotate in a vertical plane to tilt the propeller-motor assembly with an angle $\alpha_{s_i}$ in the range $\frac{-\pi}{2} \leq \alpha_{s_i} \leq \frac{\pi}{2}$, $i = 1,2,3$ to produce a horizontal component of the generated force, see Figure 2. All three propellers can be tilted independently to give full authority of thrust vectoring. The system has six degree of freedom in which all movements can be achieved independently and directly by changing the norm of the generated thrust and the tilting angles. This configuration enables the vehicle body to stay aligned in the required direction regardless of the movement the UAV makes.

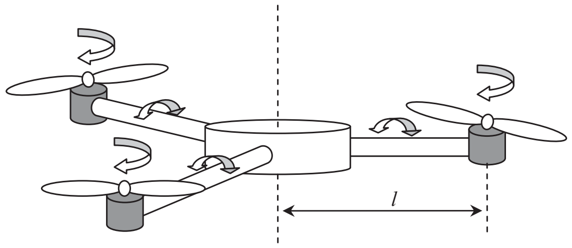

Figure 1. The design of the Tri-rotor UAV (3D view).

## III. Mathematical Modeling

To develop the dynamic model of the UAV, we consider the following right hand coordinate systems shown in Figure 3:
$e$: the generalized earth coordinate system of axes $X_e$, $Y_e$, $Z_e$.
$b$: the body fixed coordinate system in which the origin coincides with the centre of mass of the UAV. The axes of frame $b$ are denoted by $X_b$, $Y_b$, $Z_b$. In addition, we choose three right hand coordinate systems $l_i$ of axes $X_{l_i}$, $Y_{l_i}$, $Z_{l_i}$ with $i = 1,2,3$. These coordinate systems are termed as local coordinate systems and located at the locations of the three propellers, see Figure 4. The origin of each local coordinate system coincides with the joining point between the UAV arm and the propulsion unit where $X_{l_i}$ is extended outside the $i^{th}$ arm of the UAV and $Z_{l_i}$ is along the BLDC motor shaft axis when the tilting angle is zero.

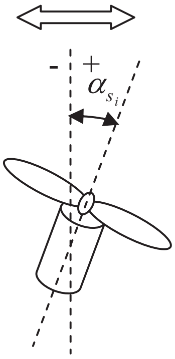

Figure 2. Front view of one arm.

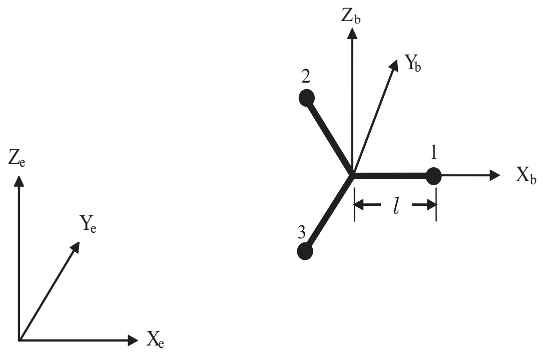

Figure 3. Coordinate systems used to develop the UAV dynamic model.

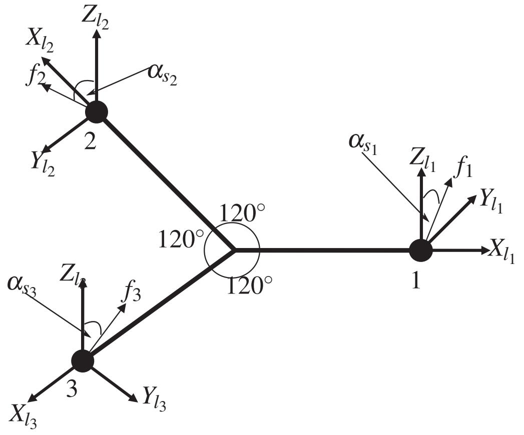

Figure 4. Local coordinate systems at the three propulsion units.

The rotation matrices between the defined coordinate systems are denoted by:
$\boldsymbol{R}_e^b$: the rotational matrix from frame $e$ to frame $b$.
$\boldsymbol{R}_{l_i}^b$: the rotational matrix from coordinate system $l_i$ to coordinate system $b$, $i = 1,2,3$.

In the sequel, we use superscript $b$, $e$ and $l_i$ to denote the coordinate system in which vectors are expressed. The subscript $i$ refers to the $i^{th}$ BLDC motor, servo motor or propeller as applies where $i = 1,2,3$.

In order to obtain the dynamic equations of the UAV, we need to obtain forces and torques acting on the vehicle. We assume very fast actuators and therefore the dynamics of the actuators are neglected.

*Forces*

There are two main forces acting on the UAV which are the propulsive force and the gravitational force.

*The propulsive force:* The total propulsive force $F_{p_\Sigma}$ is equal to the algebraic sum of the three individual propulsive forces generated from propellers. The individual propulsive forces of the three propellers expressed in the local coordinate systems can be written as [13]:

$$F_{p_i}^{l_i} = \begin{bmatrix} 0 \\ k_f \omega_{m_i}^2 \sin(\alpha_{s_i}) \\ k_f \omega_{m_i}^2 \cos(\alpha_{s_i}) \end{bmatrix}, \; i = 1,2,3. \tag{1}$$

where $k_f$ is the thrust to speed constant of the propeller and it is identical for all three propellers, $\omega_{m_i}$ is the rotational speed of the $i^{th}$ BLDC motor (we assume direct driving of the propeller, i.e., the rotational speed of the motor equals the rotational speed of the propeller) and $\alpha_{s_i}$ is the tilting angle of the $i^{th}$ Servo motor.

In the body coordinate system, the individual propulsive forces are given by:

$$F_{p_i}^{b} = \boldsymbol{R}_{l_i}^{b} F_{P_i}^{l_i}, \; i = 1,2,3. \tag{2}$$

From Figure 4, we can obtain the rotation matrices from the local coordinate systems $l_1$, $l_2$ and $l_3$ to the body coordinate system $b$ as:

$$\boldsymbol{R}_{l_1}^{b} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \boldsymbol{R}_{l_2}^{b} = \begin{bmatrix} -\frac{1}{2} & -\frac{\sqrt{3}}{2} & 0 \\ \frac{\sqrt{3}}{2} & -\frac{1}{2} & 0 \\ 0 & 0 & 1 \end{bmatrix}, \boldsymbol{R}_{l_3}^{b} = \begin{bmatrix} -\frac{1}{2} & \frac{\sqrt{3}}{2} & 0 \\ \frac{-\sqrt{3}}{2} & -\frac{1}{2} & 0 \\ 0 & 0 & 1 \end{bmatrix}. \tag{3}$$

Using Eq.(3), the total propulsive force is:

$$\begin{aligned} F_{p_\Sigma}^{b} &= F_{p_1}^{b} + F_{p_2}^{b} + F_{p_3}^{b} & (4) \\ &= k_f \boldsymbol{H}_f \rho. & (5) \end{aligned}$$

where

$$\boldsymbol{H}_f = \begin{bmatrix} 0 & -\frac{\sqrt{3}}{2} & \frac{\sqrt{3}}{2} & 0 & 0 & 0 \\ 1 & -\frac{1}{2} & -\frac{1}{2} & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 & 1 \end{bmatrix}, \rho = \begin{bmatrix} \omega_{m_1}^2 \sin(\alpha_{s_1}) \\ \omega_{m_2}^2 \sin(\alpha_{s_2}) \\ \omega_{m_3}^2 \sin(\alpha_{s_3}) \\ \omega_{m_1}^2 \cos(\alpha_{s_1}) \\ \omega_{m_2}^2 \cos(\alpha_{s_2}) \\ \omega_{m_3}^2 \cos(\alpha_{s_3}) \end{bmatrix}. \tag{6}$$

*The gravity force:* The gravitational force in the generalized earth coordinate system is given as:

$$F_g^e = \begin{bmatrix} 0 \\ 0 \\ -gM_{tot} \end{bmatrix}. \tag{7}$$

where $g$ is the gravitational acceleration and $M_{tot}$ is the total mass of the UAV.

In the body coordinate system, we have:

$$F_g^b = \boldsymbol{R}_e^b F_g^e. \tag{8}$$

Using the general notation of rotation angles for the UAV attitude: Roll $\phi_v$, Pitch $\theta_v$ and Yaw $\psi_v$ around the axes $X_e$, $Y_e$ and $Z_e$ respectively, the gravity force in the body system is given by:

$$F_g^b = gM_{tot}H_g \tag{9}$$

where

$$H_g = \begin{bmatrix} \sin(\theta_v) \\ -\sin(\phi_v)\cos(\theta_v) \\ -\cos(\phi_v)\cos(\theta_v) \end{bmatrix}. \tag{10}$$

Now, the total force acting on the UAV and expressed in the body coordinate system is:

$$\begin{aligned} F^b &= F_{p_\Sigma}^b + F_g^b & (11) \\ &= k_f \boldsymbol{H}_f \rho + gM_{tot}H_g. & (12) \end{aligned}$$

*Torques*

The two main torques acting on the UAV are the propulsive torque and the drag torque.

*The propulsive torque:* The propulsive torque is the torque resulting from the generated propulsive force around the center of mass of the vehicle. For the case of the Tri-rotor UAV, we have three identical arms and then the components of the propulsive torque are:

$$\tau_{p_i}^b = \bar{l}_i^b \times F_{p_i}^b, \; i = 1,2,3. \tag{13}$$

where $\bar{l}_i^b$ is the vector of the $i^{th}$ arm between the center of mass of the UAV and the propulsion unit expressed in the body coordinate system. $F_{b_i}^b$ is obtained from Eq. (2).

Now, the total propulsive torque expressed in the body coordinate system is:

$$\begin{aligned} \tau_{p_\Sigma}^b &= \tau_{p_1}^b + \tau_{p_2}^b + \tau_{p_3}^b & (14) \\ &= k_f \boldsymbol{H}_t \rho & (15) \end{aligned}$$

where

$$\boldsymbol{H}_t = l \begin{bmatrix} 0 & 0 & 0 & 0 & \frac{\sqrt{3}}{2} & -\frac{\sqrt{3}}{2} \\ 0 & 0 & 0 & -1 & \frac{1}{2} & \frac{1}{2} \\ 1 & 1 & 1 & 0 & 0 & 0 \end{bmatrix}, \tag{16}$$

$l$ is the length of the vehicle's arm measured between the center of mass of the UAV and the propulsion unit (identical for the three arms) and $\rho$ is defined in Eq. (6).

*The drag torque:* The drag torque is defined as the torque resulting from the aerodynamic drag forces exerted by the ambient fluid (air) on the propeller. Drag torque is in the opposite direction to the direction of rotation. In our case, the resulting drag torque on the $i^{th}$ propeller can be approximated by $\tau_{d_i} = -k_t \omega_{m_i}^2$ [14], where $k_t$ is the drag torque to speed constant resulting from the rotation of the propeller and $\omega_{m_i}$ is the rotational speed of the motor (we consider the BLDC motors drives the propeller directly). In the local coordinate systems $l_i$, the drag torque can be written as:

$$\tau^{l_i}_{d_i} = \begin{bmatrix} 0 \\ -k_t\omega^2_{m_i}\sin(\alpha_{s_i}) \\ -k_t\omega^2_{m_i}\cos(\alpha_{s_i}) \end{bmatrix}, \; i = 1,2,3. \tag{17}$$

In the body coordinate system, the individual drag torques can be represented as:

$$\tau^b_{d_i} = \boldsymbol{R}^b_{l_i}\tau^{l_i}_{d_i}, \tag{18}$$

Using definitions (3), the total drag torque in the body system is given by:

$$\tau^b_{d_\Sigma} = \tau^b_{d_1} + \tau^b_{d_2} + \tau^b_{d_3} \tag{19}$$

$$= -k_t\boldsymbol{H}_f\rho, \tag{20}$$

where $\boldsymbol{H}_f$ and $\rho$ are defined in (6).

Now, the total torque acting on the Tri-rotor and expressed in the body coordinate system is:

$$\tau^b = \tau^b_{p_\Sigma} + \tau^b_{d_\Sigma} \tag{21}$$

$$= \left(k_f\boldsymbol{H}_t - k_t\boldsymbol{H}_f\right)\rho. \tag{22}$$

*Dynamic Model:* Assuming that the Tri-rotor UAV is a rigid body of fixed mass, the vehicle's motion can be described by the Newton-Euler second's law in the body coordinate system as:
for translational motion: $F^b = M_{tot}\left(\dot{\upsilon}^b_v + \boldsymbol{S}(\omega^b_v)\upsilon^b_v\right)$,
for rotational motion: $\tau^b = \boldsymbol{I}^b_v\dot{\omega}^b_v + \boldsymbol{S}(\omega^b_v)\boldsymbol{I}^b_v\omega^b_v$,
where $\upsilon^b_v$ is the translational velocity of the UAV, $\omega^b_v$ is the angular velocity of the UAV, $\boldsymbol{S}(\omega^b)$ is the skew matrix of the vector $\omega^b_v$ and $\boldsymbol{I}^b_v$ is the inertia matrix of the UAV all with respect to the fixed body coordinate system. Assuming no mass change over time, $\boldsymbol{I}^b_v$ is fixed.

Now, Substituting $F^b$ and $\tau^b$ from (12) and (22) gives:

$$k_f\boldsymbol{H}_f\rho + gM_{tot}H_g = M_{tot}\left(\dot{\upsilon}^b_v + \boldsymbol{S}(\omega^b_v)\upsilon^b_v\right) \tag{23}$$

$$(k_f\boldsymbol{H}_t - k_t\boldsymbol{H}_f)\rho = \boldsymbol{I}^b_v\dot{\omega}^b_v + \boldsymbol{S}(\omega^b_v)\boldsymbol{I}^b_v\omega^b_v \tag{24}$$

Let $\eta_v$ and $\lambda^e_v$ be the attitude vector and the position vector of the UAV related to the earth coordinate system and defined as:

$$\eta_v = \begin{bmatrix}\phi_v & \theta_v & \psi_v\end{bmatrix}^T, \; \lambda^e_v = \begin{bmatrix}x_v & y_v & z_v\end{bmatrix}^T.$$

To fully describe the dynamic equations of the UAV, we have the following relations from [15]:

$$\dot{\eta}_v = \boldsymbol{\Psi}\omega^b_v \;,\; \dot{\lambda}^e_v = (\boldsymbol{R}^b_e)^{-1}\upsilon^b_v$$

where $\boldsymbol{\Psi}$ is the rotational matrix between the angular velocity expressed in the body coordinate system $\omega^b_v$ and the angular velocity in the earth coordinate system $\dot{\eta}_v$. $\boldsymbol{\Psi}$ is given in [15] as:

$$\boldsymbol{\Psi} = \begin{bmatrix} 1 & \sin(\phi_v)\tan(\theta_v) & \cos(\phi_v)\tan(\theta_v) \\ 0 & \cos(\phi_v) & -\sin(\phi_v) \\ 0 & \sin(\phi_v)\sec(\theta_v) & \cos(\phi_v)\sec(\theta_v) \end{bmatrix}, \; \frac{-\pi}{2} < \theta_v < \frac{\pi}{2}. \tag{25}$$

From the properties of the rotation matrix we have $(\boldsymbol{R}^b_e)^{-1} = \boldsymbol{R}^e_b$, where $\boldsymbol{R}^e_b$ is the rotation matrix from the body coordinate system $b$ to the earth coordinate system $e$.

Finally, the dynamic model of the UAV can be written as:

$$\dot{\upsilon^b}_v = gH_g - \boldsymbol{S}(\omega^b_v)\upsilon^b_v + \frac{k_f}{M_{tot}}\boldsymbol{H}_f\rho \tag{26}$$

$$\dot{\omega^b}_v = -(\boldsymbol{I}^b_v)^{-1}\boldsymbol{S}(\omega^b_v)\boldsymbol{I}^b_v\omega^b_v + (\boldsymbol{I}^b_v)^{-1}(k_f\boldsymbol{H}_t - k_t\boldsymbol{H}_f)\rho \tag{27}$$

$$\dot{\eta}_v = \boldsymbol{\Psi}\omega^b_v \tag{28}$$

$$\dot{\lambda}^e_v = \boldsymbol{R}^e_b\upsilon^b_v \tag{29}$$

This model of the UAV is written in the compact form in which every state variable is a vector of three components, i.e., $x \in \mathbb{R}^{12}$, where:

$$\upsilon^b_v = \begin{bmatrix} u \\ v \\ w \end{bmatrix}, \; \omega^b_v = \begin{bmatrix} p \\ q \\ r \end{bmatrix}, \; \eta_v = \begin{bmatrix} \phi_v \\ \theta_v \\ \psi_v \end{bmatrix}, \; \lambda^e_v = \begin{bmatrix} x_v \\ y_v \\ z_v \end{bmatrix}.$$

Equations (26) - (29) show a nonlinear model with coupling between the translational and rotational dynamics of the UAV. Moreover, there is coupling between inputs and output channels in which all inputs act on all outputs. The system coupling along with the nonlinearity of the system makes the control design of the proposed Tri-rotor UAV a real challenge compared with other UAV configurations. On the other hand, if we consider the control problem of the UAV to be position tracking with attitude regulating, then the system is square in which we have six actuators (three BLDC motor speeds and three servo angles) and six outputs (3D position and three attitude angles). This highlights the positive aspect of the proposed configuration in terms of controller design compared to other UAV systems that are in general underactuated systems such as quadrotors.

## IV. Control System Design

In this section we consider the control design for the proposed Tri-rotor UAV using input-output feedback linearisation and $\mathscr{H}_\infty$ Loop Shaping Design Procedure (LSDP). The control design of the system can be seen as a tracking problem for the position and attitude of the vehicle via the speed of the BLDC motors and the angles of the servo motors. In this case, the system is fully actuated having six outputs and six inputs. The proposed control algorithm is a centralized $\mathscr{H}_\infty$ controller that stabilizes and tracks simultaneously all outputs, i.e., 3D position and three attitude angles. The motivation behind such a centralized control design is to synthesize a robust controller that can compensate for any unmodeled coupling between channels and attenuate cross-coupling noises and disturbances. Moreover, the implementation of such a design is simple via a single feedback loop structure.

In the sequel and for simplicity of expression, the superscript $b$ and $e$ as well as the subscript $v$ are not written unless it is necessary to avoid ambiguity. We consider the vector $\rho$ as the input vector for the UAV system, i.e., $u = \rho$, and we have the output as $y = \begin{bmatrix}\eta & \lambda\end{bmatrix}^T$

To implement input-output feedback linearization, we have:

$$\dot{y} = y^{(1)} = \begin{bmatrix} \dot{\eta} \\ \dot{\lambda} \end{bmatrix} = \begin{bmatrix} \boldsymbol{\Psi}\omega \\ \boldsymbol{R}^e_b\upsilon_v \end{bmatrix} \tag{30}$$

and

$$\ddot{y} = y^{(2)} = \begin{bmatrix} \dot{\boldsymbol{\Psi}}\omega + \boldsymbol{\Psi}\dot{\omega} \\ (\dot{\boldsymbol{R}}_b^e)\upsilon + \boldsymbol{R}_b^e\dot{\upsilon} \end{bmatrix} \tag{31}$$

From the general properties of the rotation matrix, we have $\dot{\boldsymbol{R}}_b^e = \boldsymbol{R}_b^e\boldsymbol{S}(\omega^b)$ [16], and then we write:

$$\begin{aligned} y^{(2)} &= \begin{bmatrix} \dot{\boldsymbol{\Psi}}\omega + \boldsymbol{\Psi}(-\boldsymbol{I}^{-1}\boldsymbol{S}(\omega)\boldsymbol{I}\omega + \boldsymbol{I}^{-1}(k_f H_t - k_t \boldsymbol{H}_f)\rho) \\ \boldsymbol{R}_b^e\boldsymbol{S}(\omega)\upsilon + \boldsymbol{R}_b^e(gH_g - \boldsymbol{S}(\omega)\upsilon + \frac{k_f}{M_{tot}}\boldsymbol{H}_f\rho) \end{bmatrix} \\ &= \begin{bmatrix} \left(\dot{\boldsymbol{\Psi}} - \boldsymbol{\Psi}\boldsymbol{I}^{-1}\boldsymbol{S}(\omega)\boldsymbol{I}\right)\omega \\ g\boldsymbol{R}_b^e H_g \end{bmatrix} + \begin{bmatrix} \boldsymbol{\Psi}\boldsymbol{I}^{-1}\left(k_f\boldsymbol{H}_t - k_t\boldsymbol{H}_f\right) \\ \frac{k_f}{M_{tot}}\boldsymbol{R}_b^e\boldsymbol{H}_f \end{bmatrix}\rho \end{aligned} \tag{32}$$

where

$$\dot{\boldsymbol{\Psi}} = \frac{\partial\boldsymbol{\Psi}}{\partial\phi_v}\dot{\phi}_v + \frac{\partial\boldsymbol{\Psi}}{\partial\theta_v}\dot{\theta}_v \tag{33}$$

and $\dot{\phi}_v$, $\dot{\theta}_v$ are obtained from Eq. (28) as: $\dot{\eta} = \boldsymbol{\Psi}\omega^b$.

We define the decoupling matrix $\boldsymbol{\beta}(x)$ as:

$$\boldsymbol{\beta}(x) = \begin{bmatrix} \boldsymbol{\Psi}\boldsymbol{I}^{-1}\left(k_f H_t - k_t\boldsymbol{H}_f\right) \\ \frac{k_f}{M_{tot}}\boldsymbol{R}_b^e\boldsymbol{H}_f \end{bmatrix} \tag{34}$$

We have $\det[\boldsymbol{\beta}(x)] \neq 0$ and the inverse $\boldsymbol{\beta}^{-1}(x)$ exists always[1] for all $x \in \mathbb{R}^{12}$ where $x$ represents the states of the system. The relative degree of the system in the compact form is $r = r_1 + r_2 = 2 + 2 = 4$ which is equal to the number of states in the compact form of the dynamic equations, and there is no zero dynamics.

To linearize the system, we choose a new control input $\vartheta = \begin{bmatrix} \vartheta_1 \\ \vartheta_2 \end{bmatrix}$, and we write our desired linearized dynamics as: $y^{(2)} = \vartheta$.

From Eq. (32) we can write the feedback linearisation law as:

$$u = \boldsymbol{\beta}^{-1}\left(\vartheta - \begin{bmatrix} \left(\dot{\boldsymbol{\Psi}} - \boldsymbol{\Psi}\boldsymbol{I}^{-1}\boldsymbol{S}(\omega)\boldsymbol{I}\right)\omega \\ g\boldsymbol{R}_b^e H_g \end{bmatrix}\right). \tag{35}$$

The centralized input-output feedback linearization handles the coupling without the need for strict assumption on operating point to decouple the system. The linearized model in the compact form is given as:

$$\dot{\zeta} = \begin{bmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{bmatrix}\zeta + \begin{bmatrix} 0 & 0 \\ 1 & 0 \\ 0 & 0 \\ 0 & 1 \end{bmatrix}\vartheta \tag{36}$$

$$y = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix}\zeta \tag{37}$$

where

$$\zeta = \begin{bmatrix} \eta \\ \dot{\eta} \\ \lambda \\ \dot{\lambda} \end{bmatrix} \in \mathbb{R}^{12},\ y = \begin{bmatrix} \eta \\ \lambda \end{bmatrix} \in \mathbb{R}^6,\ \vartheta = \begin{bmatrix} \vartheta_1 \\ \vartheta_2 \end{bmatrix} \in \mathbb{R}^6.$$

The linearized plant is a double integrator representing single degree of freedom for transitional and rotational motion.

To control the linearized system, the $\mathscr{H}_\infty$ loop-shaping design is invoked to synthesize a controller for the linearized system. An algorithm proposed in [17] is invoked to simultaneously optimize the synthesis of loop-shaping weights and a stabilizing controller. This algorithm captures the design specification in a systematic manner while trying to maximize the robust stability margin of the closed-loop system. We fix the pre-compensator weight to a low-pass filter on all channels and use the algorithm to optimize an identical post-compensator weights for all channels. The optimized post-compensator for each channel is $w_2 = 105(s+0.6)/(s+8)^2$. The achieved robust stability margin is 0.51 which means a tolerance of approximately 51% of coprime factor uncertainty.

## V. Simulation Results

To demonstrate numerical results, we simulate the Tri-rotor UAV along with the designed controller in Simulink. Figure 5 depicts the block digram for the simulation where $\begin{bmatrix} \eta_r & \lambda_r \end{bmatrix}^T$ is the desired reference attitude and position respectively.

Figure 6 shows the singular values of the linearized plant, the shaped plant and the synthesized controller.

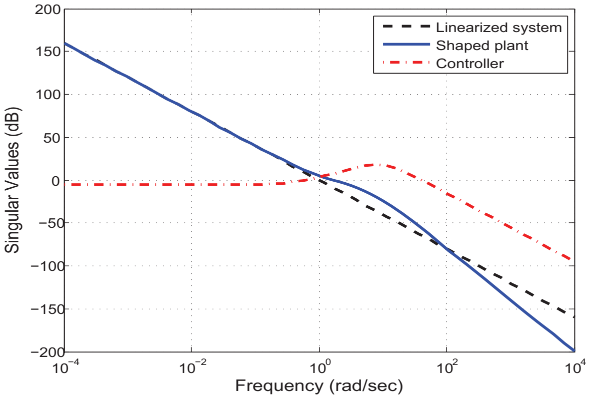

Figure 6. Singular value plots for the linearized system, the shaped system and the controller.

Figure 7 depicts the performance of the UAV for a scenario of horizontal hovering at height of 5 m where the vehicle was at a non-zero initial position and attitude as shown. The speed of the BLDC motors and the angles of the servo motors to stabilize the vehicle and track the references are shown in Figure 8. The controller shows good performance with tracking in all channels. The controller succeeds to maintain the stability of the vehicle and follow the reference trajectory for all initial conditions of the vehicle. The settling time

[1] It is always assumed that $-\pi/2 < \theta_v < \pi/2$.

of the system is about 3 s which is acceptable taking into considering the slow dynamics of the vehicle. The servos and BLDC motors are not saturated and operate within their physical limits of ±90° for the servos and 12000 rpm for the BLDC motors, where these limits come from the technical specifications of the real actuators used in the Tri-rotor UAV.

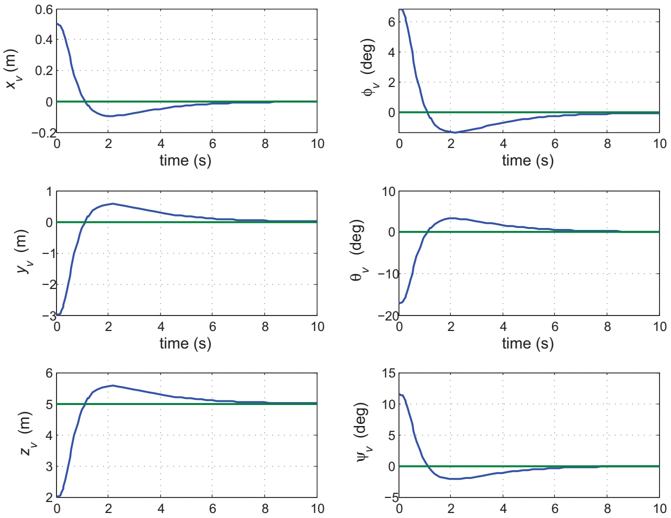

Figure 7. Simulation plots of the UAV position and attitude using the synthesized controller of $\mathscr{H}_\infty$ loop shaping control associated with classical feedback linearization.

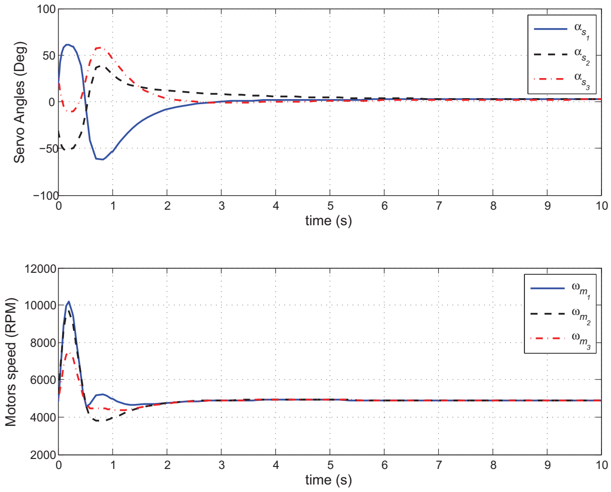

Figure 8. The performance of the actuators (servos and BLDC motors) to track the specified reference input of $(0,0,0)$ deg for attitude, and $(0,0,5)$ m for position coming from non-zero initial point.

## VI. Conclusion

In this paper, a novel tri-rotor UAV is proposed. The proposed UAV has six actuators with full authority of thrust and torque vectoring. The mathematical model of the proposed design is non-linear and it indicates coupling between translational and rotational motion. The nonlinear model of the UAV is linearized by a centralized input-output feedback linearization. This procedure cancels the nonlinearity of all channels simultaneously without further conditions for specific operating point which is the case when we handle channels individually. The linearized plant is a double integrator that is controlled using $\mathscr{H}_\infty$ loop-design procedure. The result is verified via simulations. More complex feedback linearization techniques (such as robust feedback linearization in [18]) can be used in the same manner to avoid linearizing the system to a double integrator.

***Abstract*—This paper presents a singular perturbation control strategy for regulating the longitudinal flight dynamics of an Unmanned Air Vehicle (UAV). The proposed control strategy is based on a four-time-scale (4TS) decomposition that includes the altitude, velocity, pitch, and flight path angle dynamics, with the control signals being the elevator deflection and the throttle position. The nonlinear control strategy drives the system to follow references in the aerodynamic velocity and the flight path angle. In addition, the control strategy permits to select the desired dynamics for all the singularly perturbed subsystems. Numerical results are included for a realistic nonlinear UAV model, including saturation of the control signals.**

## I. Introduction

Historically, classical linear control techniques have been sufficient to obtain reasonable control responses of aerospace systems, but the evolution of the aerospace industry, and the consequent improvement of technologies, have increased the performance requirements of all systems in general, which has called for better control designs that can deal with more complex systems. Specifically, in the area of aerospace systems, a wide range of different nonlinear control techniques have been studied to deal with the nonlinear dynamics of such systems. From singular perturbation [1], [2], feedback linearization [3], dynamic inversion [4], sliding mode control [5], or backstepping control methods [6], [7], to name a few. Neural Networks (NN) are also included within the realm of nonlinear control techniques, and seem to provide improved robustness properties under system uncertainties. Some of works include Adaptive Critic Neural Network (ACNN) based controls, originally presented by Balakrishnan and Biega [8], and later extended to many other aerospace systems [9].

One of the most challenging tasks in control is the modeling of systems in which the presence of parasitic parameters, such as small time constants, is often the source of a increased order and stiffness [10]. The stiffness, attributed to the simultaneous occurrence of slow and fast phenomena, gives rise to time-scales, and the suppression of the small parasitic variables results in degenerated, reduced-order systems called singularly perturbed systems (SPS), that can be stabilized separately, thus simplifying the burden of control design of high-order systems.

The application of singular perturbation and time-scale techniques in the aerospace industry can be traced back to the 1960s when it was first applied to solve complex flight optimization problems [11]. Since then, singular perturbation and time-scale techniques have been extensively used in the aerospace industry as described in the extense literature review conducted by Naidu and Calise [10]. In recent years these techniques have been also extended to UAVs [2], [12].

The objective of this paper is to develop a singular perturbation control strategy for the longitudinal dynamics of an aircraft, that be able to follow references in aerodynamic velocity and flight path angle, using as control actuators the elevator deflection and the throttle position. In addition, the proposed singular perturbation control strategy permits to select the desired closed-loop dynamics of each of the resulting reduced-order and boundary-layer subsystems using a time-scale analysis similar to those presented in [2], [13]. Simulations are included for a realistic UAV model including nonlinear dynamics and actuator saturation on both the elevator deflection and throttle setting. The model used corresponds to the Cefiro aircraft [14], an UAV recently designed and constructed by the authors at the University of Seville.

This paper is structured as follows: Section II presents the flight dynamics used throughout this work; Section III presents the time scales selection; Section IV describes the proposed 4-time-scale analysis; the singular perturbed control strategies are presented in Section V; numerical results for the UAV model considered in this paper are given in Section VI; and finally, some conclusions are drawn in Section VII.

## II. Model Definition

The problem discussed in this article considers a constant-mass UAV with an electrical propulsion plant, for which the point-mass longitudinal flight dynamics equations are

$$\dot{h} = V\sin\gamma, \tag{1}$$

$$\dot{V} = \frac{1}{m}\left(T - D - mg\sin\gamma\right), \tag{2}$$

$$\dot{\theta} = q, \tag{3}$$

$$\dot{\gamma} = \frac{1}{mV}\left(L - mg\cos\gamma\right). \tag{4}$$

$$\dot{q} = \frac{M}{I_y}, \tag{5}$$

where $h$ is the altitude; $V$ the aerodynamic speed; $\gamma$ the flight path angle; $\theta$ the pitch angle; $q$ the pitch rate; $T$, $D$, and $L$ the thrust, drag, and lift forces, respectively; $M$ the total pitch moment; $m$ and $I_y$ the mass and the moment of inertia of the UAV. The thrust-force model used is given by

$$T = \delta_T(T_0 + T_1 V + T_2 V^2), \qquad (6)$$

where $\delta_T$ is the throttle setting, $0 \leq \delta_T \leq 1$ and $T_0, T_1, T_2$ are known coefficients obtained through wind tunnel experiments. The lift, drag and pitch moment are given by the following expressions

$$L = q_\infty S C_L,\ D = q_\infty S C_D,\ M = q_\infty S c C_M, \qquad (7)$$

where $q_\infty = 1/2\rho V^2$ is the dynamic pressure; $S$ is the reference wing area, $c$ is the wing mean aerodynamic chord, and $C_L$, $C_D$ and $C_M$ are the lift, drag and pitch moment coefficients, which are given by the following standard models [15], [16] that have been widely used in the literature [11], [17], [18]

$$\begin{aligned} C_L &= C_{L_0} + C_{L_\alpha}\alpha + C_{L_\delta}\delta, & (8)\\ C_D &= C_{D_0} + kC_L^2, & (9)\\ C_M &= C_{M_0} + C_{M_\alpha}\alpha + C_{M_\delta}\delta + C_{M_q}q, & (10) \end{aligned}$$

where $\alpha$ is the angle of attack, given by $\alpha = \theta - \gamma$, $\delta$ is the elevator deflection, $-40^\circ \leq \delta \leq 40^\circ$, and $C_{L_0}$, $C_{L_\alpha}$, $C_{L_\delta}$, $C_{D_0}$, $k, C_{M_0}$, $C_{M_\alpha}$, $C_{M_\delta}$, and $C_{M_q}$ are known aerodynamic coefficients. In this paper the simplifying assumption of constant air density is considered, and, therefore, the altitude equation becomes decoupled from the rest, and can be solved a posteriori. Equations (1–5) are expanded using Eqns. (8–10), resulting in

$$\begin{aligned} \dot{h} &= V\sin\gamma, & (11)\\ \dot{V} &= \delta_T(a_1 + a_2V^2 + a_3V) + V^2\left[a_4 + a_5 + a_6(\theta-\gamma)\right.\\ &+ \left. a_7(\theta-\gamma)^2 + a_8\delta + a_9\delta^2 + a_{10}(\theta-\gamma)\delta\right]\\ &+ a_{11}\sin\gamma, & (12)\\ \dot{\theta} &= q, & (13)\\ \dot{\gamma} &= V\left[a_{12} + a_{13}(\theta-\gamma) + a_{14}\delta\right] + \frac{a_{11}}{V}\cos\gamma, & (14)\\ \dot{q} &= V^2\left[a_{15} + a_{16}(\theta-\gamma) + a_{17}\delta + a_{18}q\right], & (15) \end{aligned}$$

where $a_1 = T_0/m$, $a_2 = T_2/m$, $a_3 = T_1/m$, $a_4 = -c_2C_{D_0}$, $a_5 = -c_1C_{L_0}^2$, $a_6 = -2c_1C_{L_0}C_{L_\alpha}$, $a_7 = -c_1C_{L_\alpha}^2$, $a_8 = -2c_1C_{L_0}C_{L_\delta}$, $a_9 = -c_1C_{L_\delta}^2$, $a_{10} = -2c_1C_{L_\alpha}C_{L_\delta}$, $a_{11} = -g$, $a_{12} = c_2C_{L_0}$, $a_{13} = c_2C_{L_\alpha}$, $a_{14} = c_2C_{L_\delta}$, $a_{15} = c_3C_{M_0}$, $a_{16} = c_3C_{M_\alpha}$, $a_{17} = c_3C_{M_\delta}$, $a_{18} = c_3C_{M_q}$ with $c_1 = \rho Sk/(2m)$, $c_2 = \rho S/(2m)$, and $c_3 = \rho Sc/(2I_y)$.

The underactuated structure of the system requires that two variables need to be used as references. In this work, the nonlinear control strategy will seek to drive the system to follow references in the aerodynamic velocity and the flight path angle, that is $V = V_{ref}$ and $\gamma = \gamma_{ref}$.

## III. TIME SCALES SELECTION

The appropriate selection of time scales is an important aspect of the singular perturbation and time-scales theory [10], [19]–[21], and can be categorized into three approaches: 1) direct identification of small parameters (such as small time constants); 2) transformation of state equations; and 3) linearization of the state equations. Ardema [19] proposes a rational method of identifying time scales separations that does not rely on an *ad hoc* selection of time scales based largely on physical insight and past experiences with similar problems. The proposed method only requires a knowledge of the state equations. Considering a dynamical systems of the form

$$\dot{x} = f(x,u),\ u \in U, \qquad (16)$$

subject to suitable boundary conditions, where $x$ is an $n$-dimensional state vector, $u$ an $r$-dimensional control vector, and $U$ the set of admissible controls. It is assumed that bounds have been established on the components of the state vector, either by physical limitations or by a desire to restrict the state to a certain region of state space, $x_{i,m} \leq x_i \leq x_{i,M}$, with $x_{i,m}$ and $x_{i,M}$ representing the minimum and maximum values of the state variables. As noted in [19], most *ad hoc* assessments of time-scale separation are based on the concept of state variable speed [11], [22]. The speed of a state variable $x_i$ is defined as the inverse of the time it takes that variable to change across a specified range of values, which can be expressed as

$$S_i = \frac{\dot{x}_i}{\Delta x_i} = \frac{f_i(x,u)}{\Delta x_i}. \qquad (17)$$

where $\Delta x_i = x_{i,M} - x_{i,m}$. Two methods are proposed [19] to determine if two variables are candidates for time-scale separation, which is ultimately defined if the two variables have widely separated speeds. In this work, the method that considers a reference value of the state in the region of interest, $\bar{x}$, is adopted, hence

$$S_i = \frac{1}{\Delta x_i}\max_{u\in U} f_i(\bar{x},u). \qquad (18)$$

Since the maneuvers being considered for the UAV are those of climb performance, the reference states can be selected as those associated to the condition of maximum rate of climb $V_{v_{max}}$, condition that has been investigated in [14]. The bounds for the UAV model considered in this article [14] are therefore: $0 \leq h \leq 1000$, where the maximum altitude is defined by desired operation limits; $V_m \leq V \leq V_{max}$, with $V_m = 1.2 * V_{stall}$, and $V_{max}$ obtained in the performance analysis [14]; $-\gamma_{d_{max}} \leq \gamma \leq \gamma_{V_m}$, where $\gamma_{d_{max}}$ represents the maximum descent glide angle, and $\gamma_{V_m}$ represents the maximum flight path angle at $V_m$; $\alpha_{trim_{V_m}} \leq \alpha \leq \alpha_{trim_{V_{max}}}$, where $\alpha_{trim_{V_m}}$ and $\alpha_{trim_{V_{max}}}$ corresponds to the trim angle for $V_m$, and $V_{max}$, respectively; $\theta_m \leq \theta \leq \theta_M$ with $\theta_m = \gamma_m + \alpha_m$ and $\theta_M = \gamma_M + \alpha_M$; and finally, the bounds for the pitch rate $q_m \leq q \leq q_M$ are selected by desired operation limits.

From [14], the UAV being studied in this article has the following geometric properties, $S = 1.088\ m^2$, $c = 0.393\ m$, $m = 23.186\ kg$, $I_y = 7.447\ kgm^2$, $C_{D_0} = 0.0286$, $k = 0.0426$. From the stability analysis conducted in [14], the derivatives are: $C_{L_0} = 0.408$, $C_{M_0} = 0.0617$, $C_{L_\alpha} = 3.823$ per rad, $C_{M_\alpha} = -0.455$ per rad, $C_{L_\delta} = 0.284$ per rad, $C_{M_\delta} = -0.914$ per rad, $C_{M_q} = -13.590$ s/rad, $T_0 = 127.53N$, $T_1 = -2.9052 \times 10^{-1}Ns/m$ and $T_2 = -5.9616 \times 10^{-2}Ns^2/m^2$.

From the performance study in [14], it can be obtained that the maximum vertical climb speed is $V_{v_{max}} = 27.00$ m/s, the reference horizontal speed is $\bar{V} = 22.90\ m/s$, the stall velocity is given by $V_{stall} = 14.38\ m/s$, for $C_{L_{max}} = 1.65$, the maximum velocity $V_{max} = 38.47\ m/s$, the flight path angle for $\bar{V}$ is given $\gamma_{\bar{V}} = 19.06^\circ$, the gliding angle for minimum flight path angle is given by $\gamma_{V_d} = -7.63^\circ$, the trim angles for $\bar{V}$ are given by $\alpha_{trim_{\bar{V}}} = 3.47°$ and $\delta_{trim_{\bar{V}}} = 2.14°$ respectively. The final bounds and *speeds* of the state variables are resumed in Table I. It can be seen four clearly differentiated time-scales, since the *speeds* for altitude and velocity dynamics are not that separated, therefore, it will be assumed that they move in the same stretched time scale, and will be denoted by the augmented state vector $\chi = [h\ V]$.

TABLE I
BOUNDS AND *speeds* OF THE STATE VARIABLES.

| Variable | $x_{i,m}$ | $x_{i,M}$ | $\Delta x_i$ | $\bar{x}_i$ | $S_i$ |
|---|---|---|---|---|---|
| $h$ [m] | 0 | 1000 | 1000 | 200 | 0.0074 |
| $V$ [m/s] | 17.25 | 38.47 | 21.21 | 22.90 | 0.011 |
| $\theta$ [deg] | −7.58 | 32.84 | 40.42 | 22.53 | 0.41 |
| $\gamma$ [deg] | −4.53 | 23.31 | 27.83 | 19.06 | 2.21 |
| $\alpha$ [deg] | −3.06 | 9.53 | 12.59 | 3.47 | $N/A$ |
| $q$ [deg/s] | −264.44 | 264.44 | 528.88 | 0 | 82.43 |

With this in mind, Eqns. (11–15) are rewritten as a four-time-scale (4TS) singular perturbed model of the form

$$
\begin{aligned}
\dot{\chi} &= f_\chi(\chi, \theta, \gamma, \delta, \delta_T),\ \chi \in B_\chi, && (19)\\
\varepsilon_1 \dot{\theta} &= f_\theta(q),\ \theta \in B_\theta, && (20)\\
\varepsilon_1 \varepsilon_2 \dot{\gamma} &= f_\gamma(\chi, \theta, \gamma, \delta),\ \gamma \in B_\gamma, && (21)\\
\varepsilon_1 \varepsilon_2 \varepsilon_3 \dot{q} &= f_q(\chi, \theta, \gamma, q, \delta),\ q \in B_q, && (22)
\end{aligned}
$$

with $B_\chi, B_\theta, B_\gamma, B_q$ denoting closed sets of the variables $\chi$, $\theta$, $\gamma$ and $q$, respectively, being $\chi$ the slowest variable, $\theta$ the intermediate variable, $\gamma$ the fast variable, and $q$ the ultra-fast variable, and holding that $0 < \varepsilon_1\varepsilon_2\varepsilon_3 \ll \varepsilon_1\varepsilon_2 \ll \varepsilon_1 \ll 1$. In order to express the original set of differential Eqns. (11–15) in the standard 4TS singular perturbation formulation, a series of algebraic modifications using the *speeds* of the different variables are conducted. Let consider the different *speeds* as if they were the inverse of the inertias multiplying the time derivatives such $I_h = 1/S_h = 133.722$, $I_V = 1/S_V = 89.221$, $I_\theta = 1/S_\theta = 2.411$, $I_\gamma = 1/S_\gamma = 0.451$, $I_q = 1/S_q = 0.012$, where it can be easily identified that $I_V >> I_\theta >> I_\gamma >> I_q$, therefore, in order to express the equations of the 4TS in the correct multi-time singular perturbation formulation, all the perturbation parameters are normalized with respect to the slowest coefficient, that is $I_h$, yielding the parasitic constants selected for this problem given by $\varepsilon_1 = I_\theta/I_h = 1.803\times10^{-2}$, $\varepsilon_1\varepsilon_2 = I_\gamma/I_h = 3.375\times10^{-3}$, and $\varepsilon_1\varepsilon_2\varepsilon_3 = I_q/I_h = 9.0722 \times 10^{-5}$, resulting in

$$
\begin{aligned}
\dot{h} &= V \sin\gamma, && (23)\\
\dot{V} &= \delta_T \left(a_1 + a_2 V^2 + a_3 V\right) + V^2 \left[a_4 + a_5 + a_6 (\theta - \gamma)\right.\\
&+ \quad a_7 (\theta - \gamma)^2 + a_8 \delta + a_9 \delta^2\\
&+ \quad \left.a_{10} (\theta - \gamma) \delta\right] + a_{11} \sin\gamma, && (24)\\
\varepsilon_1 \dot{\theta} &= \varepsilon_1 q, && (25)\\
\varepsilon_1 \varepsilon_2 \dot{\gamma} &= V \left[\bar{a}_{12} + \bar{a}_{13} (\theta - \gamma) + \bar{a}_{14} \delta\right] + \frac{\bar{a}_{11}}{V} \cos\gamma, && (26)\\
\varepsilon_1 \varepsilon_2 \varepsilon_3 \dot{q} &= V^2 \left[\bar{a}_{15} + \bar{a}_{16} (\theta - \gamma) + \bar{a}_{17} \delta + \bar{a}_{18} q\right], && (27)
\end{aligned}
$$

with $\bar{a}_{11} = \varepsilon_1\varepsilon_2 a_{11}$, $\bar{a}_{12} = \varepsilon_1\varepsilon_2 a_{12}$, $\bar{a}_{13} = \varepsilon_1\varepsilon_2 a_{13}$, $\bar{a}_{14} = \varepsilon_1\varepsilon_2 a_{14}$, $\bar{a}_{15} = \varepsilon_1\varepsilon_2\varepsilon_3 a_{15}$, $\bar{a}_{16} = \varepsilon_1\varepsilon_2\varepsilon_3 a_{16}$, $\bar{a}_{17} = \varepsilon_1\varepsilon_2\varepsilon_3 a_{17}$, and $\bar{a}_{18} = \varepsilon_1\varepsilon_2\varepsilon_3 a_{18}$. In addition, the following approximations are considered in this article (which have been widely used in the literature for aircraft trajectory optimization using singular perturbation techniques [11])

$$
\sin\gamma \cong \gamma - \frac{\gamma^3}{6},\ \cos\gamma \cong 1 - \frac{\gamma^2}{2}, \qquad (28)
$$

The following section describes the four-time-scale analysis that will permit to derive the singular perturbation control strategy.

## IV. 4-Time-Scale Analysis

This section presents a sequential time-scale methodology that provides an approach in which, for a specific class of singularly perturbed nonlinear systems, a step-by-step procedure can be employed to design the proper control laws that guarantee a desired degree of stability of each of the time-scale subsystems. The approach is based on the sequential time-scale analysis similar to the one presented in [2], [13], which is an extension of the two-time-scale analysis presented in [1]. The approach consists in decomposing the original singularly perturbed system, Eqns. (23–27), denoted as $\Sigma_{SIFU}$ for simplicity, into a sequential set of two-time-scale (2TS) SPS. Each one of the letters in $\Sigma_{SIFU}$ denotes a time scale, Slow, Intermediate, Fast, and Ultrafast, and will be used as a reference to describe each time-scale subsystem or combination. The time-scale decomposition is achieved by applying, in a sequential manner, the associated stretched time scales for each of the subsystems, resulting in reduced order models. The time-scale decomposition is started by applying first the stretched time scale given by $\tau_3 = t/(\varepsilon_1\varepsilon_2\varepsilon_3)$, resulting in a 2TS SPS formed by the reduced order $\Sigma_{SIF}$-subsystem

$$
\begin{aligned}
\dot{h} &= V\left(\gamma - \frac{\gamma^3}{6}\right), && (29)\\
\dot{V} &= \delta_T \left(a_1 + a_2 V^2 + a_3 V\right) + V^2 \left[a_4 + a_5 + a_6 (\theta - \gamma)\right.\\
&+ \quad a_7 (\theta - \gamma)^2 + a_8 \delta + a_9 \delta^2\\
&+ \quad \left.a_{10} (\theta - \gamma) \delta\right] + a_{11}\left(\gamma - \frac{\gamma^3}{6}\right), && (30)\\
\varepsilon_1 \dot{\theta} &= \varepsilon_1 H_q(\theta, \gamma, \delta), && (31)\\
\varepsilon_1 \varepsilon_2 \dot{\gamma} &= V \left[\bar{a}_{12} + \bar{a}_{13} (\theta - \gamma) + \bar{a}_{14} \delta\right] + \frac{\bar{a}_{11}}{V}\left(1 - \frac{\gamma^2}{2}\right), && (32)
\end{aligned}
$$

and the boundary layer (fast), denoted as $\Sigma_U$-subsystem for simplicity, given by

$$
\frac{dq}{d\tau_3} = V^2 \left[\bar{a}_{15} + \bar{a}_{16} (\theta - \gamma) + \bar{a}_{17} \delta + \bar{a}_{18} q\right], \qquad (33)
$$

where $H_q(\theta, \gamma, \delta)$ represents the quasi-steady-state equilibrium (QSSE) of the boundary layer $\Sigma_U$-subsystem when setting $\varepsilon_3 = 0$, that is $0 = f_q(\chi, \theta, \gamma, q, \delta) \rightarrow \bar{q} = H_q(\theta, \gamma, \delta)$, resulting in

$$
\bar{q} = H_q(\theta, \gamma, \delta) = -\frac{\bar{a}_{15} + \bar{a}_{16}(\theta - \gamma) + \bar{a}_{17}\delta}{\bar{a}_{18}}. \qquad (34)
$$

Recall that in the space of configuration of the boundary layer $\Sigma_U$-subsystem, the variables, $\chi$, $\theta$, and $\gamma$, are treated like fixed parameters. The time scale analysis continues recognizing that the reduced order $\Sigma_{SIF}$-subsystem, Eqns. (29–32), can be decomposed again into a 2TS SPS by applying the stretched time scale $\tau_2 = t/(\varepsilon_1\varepsilon_2)$, resulting in a new reduced order (slow) subsystem, denoted as $\Sigma_{SI}$-subsystem for simplicity, defined as

$$\begin{aligned}
\dot{h} &= V\left(H_\gamma - \frac{H_\gamma^3}{6}\right), && (35)\\
\dot{V} &= \delta_T\left(a_1 + a_2V^2 + a_3V\right) + V^2\left[a_4 + a_5 + a_6\left(\theta - H_\gamma\right)\right.\\
&+ a_7\left(\theta - H_\gamma\right)^2 + a_8\delta + a_9\delta^2\\
&+ \left. a_{10}\left(\theta - H_\gamma\right)\delta\right] + a_{11}\left(H_\gamma - \frac{H_\gamma^3}{6}\right), && (36)\\
\varepsilon_1\dot{\theta} &= -\frac{\varepsilon_1\left(\bar{a}_{15} + \bar{a}_{16}(\theta - H_\gamma) + \bar{a}_{17}\delta\right)}{\bar{a}_{18}}, && (37)
\end{aligned}$$

and with a new boundary layer (fast) subsystem, denoted as $\Sigma_F$-subsystem for simplicity, given by

$$\frac{d\gamma}{d\tau_2} = V\left[\bar{a}_{12} + \bar{a}_{13}\left(\theta - \gamma\right) + \bar{a}_{14}\delta\right] + \frac{\bar{a}_{11}}{V}\left(1 - \frac{\gamma^2}{2}\right), \quad (38)$$

where $H_\gamma(\chi, \theta, \delta)$ represents the QSSE of the boundary layer $\Sigma_F$-subsystem when setting $\varepsilon_2 = 0$, that is $0 = f_\gamma(\chi, \theta, \gamma, \delta) \to \bar{\gamma} = H_\gamma(\chi, \theta, \delta)$, resulting in

$$\bar{\gamma} = H_\gamma(\chi, \theta, \delta) = A_1 \pm A_2\sqrt{A_3 + A_4\theta + A_5\delta}, \quad (39)$$

with $A_1 = -a_{13}V^2/a_{11}$, $A_2 = 1/a_{11}$, $A_3 = a_{13}^2V^4 + 2a_{11}a_{12}V^2 + 2a_{11}^2$, $A_4 = 2a_{11}a_{13}V^2$ and $A_5 = 2a_{11}a_{14}V^2$, where it can be shown that the positive solution is the valid one, and where $\chi$, and $\theta$ are treated like fixed parameters. Finally, it can be recognized that the $\Sigma_{SI}$-subsystem can be decomposed one more time into another 2TS SPS by considering the last stretched time scale $\tau_1 = t/\varepsilon_1$, resulting in a new reduced order (slow) subsystem, denoted as $\Sigma_S$-subsystem for simplicity, and given by

$$\begin{aligned}
\dot{h} &= V\left(\bar{H}_\gamma - \frac{\bar{H}_\gamma^3}{6}\right), && (40)\\
\dot{V} &= \delta_T\left(a_1 + a_2V^2 + a_3V\right) + V^2\left[a_4 + a_5 + a_6\left(H_\theta - \bar{H}_\gamma\right)\right.\\
&+ a_7\left(H_\theta - \bar{H}_\gamma\right)^2 + a_8\delta + a_9\delta^2\\
&+ \left. a_{10}\left(H_\theta - \bar{H}_\gamma\right)\delta\right] + a_{11}\left(\bar{H}_\gamma - \frac{\bar{H}_\gamma^3}{6}\right), && (41)
\end{aligned}$$

with the boundary layer $\Sigma_I$-subsystem given by

$$\frac{\mathrm{d}\theta}{\mathrm{d}\tau_1} = -\frac{\varepsilon_1\left(\bar{a}_{15} + \bar{a}_{16}(\theta - H_\gamma) + \bar{a}_{17}\delta\right)}{\bar{a}_{18}}, \quad (42)$$

where $H_\theta(\chi, \delta)$ represents the QSSE of the boundary layer $\Sigma_I$-subsystem when setting $\varepsilon_1 = 0$, that is $0 = f_\theta(\chi, \theta, \delta) \to \bar{\theta} = H_\theta(\chi, \delta)$, resulting in

$$H_\theta(\chi, \delta) = A_6 \pm A_7\sqrt{A_8 + A_9\delta} + A_{10}\delta, \quad (43)$$

with $A_6 = A_2^2A_4/2 - \bar{a}_{15}/\bar{a}_{16} + A_1$, $A_7 = A_2/(2\bar{a}_{16})$, $A_8 = \bar{a}_{16}^2A_2^2A_4^2 - 4\bar{a}_{15}\bar{a}_{16}A_4 + 4\bar{a}_{16}^2A_3 + 4\bar{a}_{16}^2A_1A_4$, $A_9 = 4\bar{a}_{16}^2A_5 - 4\bar{a}_{16}\bar{a}_{17}A_4$, and $A_{10} = \bar{a}_{17}/\bar{a}_{16}$. Recall also that $\bar{H}_\gamma(\chi, H_\theta, \delta)$ results from substituting the QSSE $H_\theta$ into Eq.(39), and given by

$$\bar{H}_\gamma(\chi, H_\theta, \delta) = A_1 \pm A_2\sqrt{A_3 + A_4H_\theta + A_5\delta}, \quad (44)$$

where $\chi$ is treated as a fixed parameter. The control strategy that will be presented in the following section uses this time-scale separation strategy to obtain a sequential control strategy that permits to stabilize each of the different subsystems ($\Sigma_S$, $\Sigma_I$, $\Sigma_F$ and $\Sigma_U$).

## V. Sequential Singular Perturbation Control Strategy

The control strategy goal consists in designing feedback control laws permits to follow known references in velocity ($V_{ref}$) and flight path angle ($\gamma_{ref}$). Following $\gamma_{ref}$ is attained by ensuring desired pitch rate, flight path angle and pitch angle dynamics with the use of the elevator deflection ($\delta$), while following $V_{ref}$ is achieved with the throttle position ($\delta_T$). The use of sequential time-scale decomposition permits to design control strategies for $\delta$ based on the sum of three components, $\delta = \delta_\theta + \delta_\gamma + \delta_q$, where each component is specifically designed to stabilize each one of the associated boundary layer subsystems, that is, $\delta_q = \Gamma_q(\chi, \theta, \gamma, q)$ for the ultrafast subsystem, Eq. (33), $\delta_\gamma = \Gamma_\gamma(\chi, \theta, \gamma)$ for the fast subsystem, Eq. (38), and $\delta_\theta = \Gamma_\theta(\chi, \theta)$ for the intermediate subsystem, Eq. (42).

In order to guarantee the validity of the sequential control strategy, a series of requirements on the control strategies need to be satisfied. The ultra-fast feedback control $\delta_q$ is designed to satisfy two crucial requirements, as seen in [1]: when the ultra-fast feedback function, $\delta_q$, is applied to the boundary layer Eq. (33), the closed-loop system should remain a standard SPS, which translates to that the equilibrium of the boundary layer

$$0 = f_q(\chi, \theta, \gamma, q, \Gamma_\theta + \Gamma_\gamma + \Gamma_q), \quad (45)$$

should have a unique root given by $\bar{q} = H_q(\theta, \gamma, \Gamma_\theta + \Gamma_\gamma)$ in $B_\chi \times B_\theta \times B_\gamma \times B_q$. This requirement assures that the choice of $\Gamma_q$ will not destroy this property of function $f_q$ in the open-loop system. The second requirement on $\Gamma_q(\chi, \theta, \gamma, q)$ is that it be *inactive* for $\bar{q} = H_q(\theta, \gamma, \Gamma_\theta + \Gamma_\gamma)$, that is

$$\Gamma_q\left[\chi, \theta, \gamma, H_q(\chi, \theta, \gamma, \Gamma_\theta + \Gamma_\gamma)\right] = 0. \quad (46)$$

Similarly, two requirements need to be satisfied by the (fast) control feedback $\delta_\gamma$ such that when applied to the boundary layer Eq. (38), the closed-loop system should remain a standard singularly perturbed system, which translates to that the equilibrium of the boundary layer

$$0 = f_\gamma(\chi, \theta, \gamma, \Gamma_\theta + \Gamma_\gamma), \quad (47)$$

should have a unique root given by $\bar{\gamma} = H_\gamma(\chi, \theta, \Gamma_\theta)$ in $B_\chi \times B_\theta \times B_\gamma$. This requirement assures that the choice of $\Gamma_\gamma$ will not destroy this property of function $f_\gamma$ in the open-loop system. The second requirement in $\delta_\gamma$, is that it be *inactive* for $\bar{\gamma} = H_\gamma(\chi, \theta, \Gamma_\theta)$, that is

$$\Gamma_\gamma\left[\chi, \theta, H_\gamma(\chi, \theta, \Gamma_\theta)\right] = 0. \quad (48)$$

With this in mind, the control strategy starts by applying the stretched time-scale $\tau_3$ resulting in the reduced order $\Sigma_{SIF}$-subsystem, Eqns. (29–32) with the boundary layer $\Sigma_U$-subsystem given by Eq. (33), and with the quasi-steady-state equilibrium given by Eq. (34). The reduced order order $\Sigma_{SIF}$-subsystem can be decomposed again by applying the stretched time-scale $\tau_2$ resulting in the reduced order $\Sigma_{SI}$-subsystem, Eqns. (35–37), and the boundary layer $\Sigma_F$-subsystem given by Eq. (38), with the equilibrium $H_\gamma(\chi, \theta, \delta_\theta)$ given by Eq. (39). The $\Sigma_{SI}$-subsystem, Eqns. (35–37), can be decomposed again by applying the last stretched time-scale $\tau_1$, resulting in the new reduced order $\Sigma_S$-subsystem, Eqns. (40–41), with the boundary layer $\Sigma_I$-subsystem given by Eq. (42).

Recall that according to Eqns. (46) and (48), $\Gamma_q$ and $\Gamma_\gamma$ become *innactive* when appearing in their respective equilibria in the $\Sigma_I$-subsystem, thus becoming $\delta = \delta_\theta$. The control signal $\delta_\theta$ is therefore selected as a feedback linearization signal for a target system of the form

$$\frac{\mathrm{d}\theta}{\mathrm{d}\tau_1} = -\tilde{b}_\theta \left(\theta - \theta_{ref}\right), \tag{49}$$

where $\tilde{b}_\theta = \varepsilon_1 b_\theta$ , with $b_\theta$ being the desired transient response for the $\Sigma_I$-subsystem, and $\theta_{ref}$ defined in terms of $V_{ref}$ and $\gamma_{ref}$ by the equilibrium analysis of the problem given by Eqns. (11–15). The control signal is therefore selected as

$$\begin{aligned} \delta_\theta &= B_1 \pm B_2 \sqrt{B_3 + B_4\theta + B_5\left(\theta - \theta_{ref}\right)} + B_6\theta \\ &+ B_7\left(\theta - \theta_{ref}\right), \end{aligned} \tag{50}$$

with $B_1 = \bar{a}_{16}^2 A_2^2 A_5/(2\bar{a}_{17}^2) - \bar{a}_{15}/\bar{a}_{17} + \bar{a}_{16}A_1/\bar{a}_{17}$, $B_2 = -\bar{a}_{16}A_2/(2\bar{a}_{17}^2)$, $B_3 = \left(\bar{a}_{16}A_2A_5\right)^2 - 4\bar{a}_{15}a_{17}A_5 + 4\bar{a}_{16}\bar{a}_{17}A_1A_5 + 4\bar{a}_{17}^2A_3$, $B_4 = 4\bar{a}_{17}^2A_4 - 4\bar{a}_{16}\bar{a}_{17}A_5$, $B_5 = 4\bar{a}_{17}\bar{a}_{18}A_5\tilde{b}_\theta$, $B_6 = -\bar{a}_{16}/\bar{a}_{17}$, and $B_7 = \bar{a}_{18}\tilde{b}_\theta/\bar{a}_{17}$, and where it can be shown that that positive solution of Eq. (50) is the right one. With the boundary layer $\Sigma_I$-subsystem stabilized and $\delta_\theta$ defined, the reduced order $\Sigma_S$-subsystem can be stabilized by selecting a feedback linearization control signal $\delta_T$ such that the velocity dynamics has a desired target dynamics of the form

$$\dot{V} = -b_V\left(V - V_{ref}\right), \tag{51}$$

with $b_V$ being the desired transient response for the $\Sigma_S$-subsystem, thus selecting

$$\begin{aligned} \delta_T &= -\frac{1}{a_1 + a_2V^2 + a_3V}\left[\left(a_4 + a_5\right)V^2 + V^2\left[\left(a_6\right.\right.\right. \\ &+ \left. a_7\left(H_\theta - \bar{H}_\gamma\right) + a_{10}\delta_\theta\right)\left(H_\theta - \bar{H}_\gamma\right) + \left(a_8 + a_9\delta_\theta\right)\delta_\theta\big] \\ &+ \left. a_{11}\left(\bar{H}_\gamma - \frac{\bar{H}_\gamma^3}{6}\right) + b_V\left(V - V_{ref}\right)\right]. \end{aligned} \tag{52}$$

The $\Sigma_F$-subsystem, Eq. (38) is stabilized by selecting the control signal $\delta_\gamma$, recalling that needs to satisfy Eqns. (47–48). This is achieved by substituting first $\delta_\theta$ into the $\Sigma_F$-subsystem, and rewriting the result in terms of its equilibrium $H_\gamma$, Eq. (39), by identifying that the original system is a function of the two possible solutions, that is

$$\frac{\mathrm{d}\gamma}{\mathrm{d}\tau_2} = -\frac{\bar{a}_{11}}{2V}\left[\gamma - H_\gamma(\chi,\theta,\delta_\theta)\right]\left[\gamma - \tilde{H}_\gamma(\chi,\theta,\delta_\theta)\right] + V\bar{a}_{14}\delta_\gamma, \tag{53}$$

Note also that according to Eq. (46), $\Gamma_q$ becomes *innactive* when appearing in its equilibrium in the $\Sigma_F$-subsystem, thus, $\delta = \delta_\theta + \delta_\gamma$, with $\delta_\theta$ being given by the control signal that stabilizes the $\Sigma_I$-subsystem, Eq. (50). Note that $H_\gamma(\chi,\theta,\delta_\theta)$ represents the positive solution of Eq. (39), while $\tilde{H}_\gamma(\chi,\theta,\delta_\theta)$ represents the disregarded negative solution, but both being necessary to complete the solution. The control signal $\delta_\gamma$ it is selected as a feedback linearization control signal for a selected target system of the form

$$\frac{\mathrm{d}\gamma}{\mathrm{d}\tau_2} = -\tilde{b}_\gamma\left[\gamma - H_\gamma(\chi,\theta,\delta_\theta)\right], \tag{54}$$

where $\tilde{b}_\gamma = \varepsilon_1\varepsilon_2 b_\gamma$, with $b_\gamma$ being the desired transient response for the $\Sigma_F$-subsystem. The choice of this target dynamics will satisfy that the choice of $\Gamma_\gamma$ will not destroy the property that the closed-loop system should have a unique equilibrium $\bar{\gamma} = H_\gamma(\chi,\theta,\Gamma_\gamma)$, and that $\Gamma_\gamma$ it be *inactive* for $\bar{\gamma} = H_\gamma(\chi,\theta)$, resulting in

$$\delta_\gamma = \frac{\left(\gamma - H_\gamma\right)\left[-\tilde{b}_\gamma + \frac{\bar{a}_{11}}{2V}\left(\gamma - \tilde{H}_\gamma\right)\right]}{\bar{a}_{14}V}. \tag{55}$$

With control signal $\delta_\gamma$ selected, the control signal $\delta_q$ that stabilizes the $\Sigma_U$-subsystem can be selected by ensuring requirements (45-46). Recall that for the $\Sigma_U$-subsystem, $\delta = \delta_\theta + \delta_\gamma + \delta_q$, therefore, by substituting $\delta_\theta$ and $\delta_\gamma$, Eqns. (50) and (55), respectively, into the $\Sigma_U$-subsystem, and rewriting it using the definition of the $H_q$ QSSE, Eq. (34), results in

$$\frac{\mathrm{d}q}{\mathrm{d}\tau_3} = V^2\left[\bar{a}_{18}\left[q - H_q(\chi,\theta,\gamma,\delta_\theta + \delta_\gamma)\right] + \bar{a}_{17}\delta_q\right]. \tag{56}$$

Similarly, in order to satisfy Eqns. (45-46) on the control signal $\delta_q$, lets choose a feedback linearization control signal for a selected target system of the form

$$\frac{\mathrm{d}q}{\mathrm{d}\tau_3} = -\tilde{b}_q\left[q - H_q(\chi,\theta,\gamma,\delta_\theta + \delta_\gamma)\right], \tag{57}$$

where $\tilde{b}_q = \varepsilon_1\varepsilon_2\varepsilon_3 b_q$ , with $b_q$ being the desired transient response for the $\Sigma_U$-subsystem, resulting in

$$\delta_q = -\frac{\left(\tilde{b}_q + \bar{a}_{18}V^2\right)\left[q - H_q(\chi,\theta,\gamma,\delta_\theta + \delta_\gamma)\right]}{V^2\bar{a}_{17}}. \tag{58}$$

This finalizes the control strategy with the control signals given by $\delta = \delta_\theta + \delta_\gamma + \delta_q$, Eqns. (50), (55), and (58), respectively, and $\delta_T$, Eq. (52). Following section provides some simulation results.

## VI. Numerical Results

This section presents some results corresponding to the simulations conducted to analyze the proposed control law. The numerical simulation uses a fourth-order Runge-Kutta fixed step integration method, with a time step of 0.001 seconds, written in the $MATLAB$ interface. The analysis includes variation in the references $V_{ref}$ and $\gamma_{ref}$. Actuator saturations are also included, namely $-40^\circ \leq \delta \leq 40^\circ$, and $0 \leq \delta_T \leq 1$.

Different cases will be considered: varying $V_{ref}$, while maintaining $\gamma_{ref} = 0$; varying $\gamma_{ref}$, while maintaining $V_{ref} = const$; and varying both $\gamma_{ref}$ and $V_{ref}$. Results for this last case are presented in Fig. 1 and 2, where constant acceleration and deceleration references are also generated, with 30 seconds per maneuver. Figure 1 shows the states: the altitude and aerodynamic airspeed, on the top row, pitch and flight path angle on the middle row, angle of attack and pitch rate on the bottom row; and Fig. 2 shows the control: elevator deflection and throttle position. The different variable reference set points are presented with a thinner red line. Note that it is also included a reference in altitude given by $h_{ref} = V_{ref}\sin\gamma_{ref}$, despite that the control strategy is focused on following both by separate, but serves to indicate that future control strategies will be derived so follow altitude profiles. Despite the complex reference profiles, the control strategy is able to follow them in both aerodynamic velocity and flight path angle. Also note that saturations are avoided by selecting the appropriate desired dynamic coefficients, $b_V = b_\theta = b_\gamma = b_q = 0.35$.

## VII. Conclusions

The presented control strategy permits to drive the UAV to follow variable references in both aerodynamic velocity and flight path angle by using a sequential strategy that permits to easily obtain appropriate feedback control laws that stabilize each of the subsystems. The control strategy provides a closed-form solution. The simulations were conducted using a realistic model of the Cefiro aircraft developed by the Dept. of Aerospace Engineering at the University of Seville [14], which will the platform where the future flight tests and validation of the control strategies will be conducted.

*Abstract*— **The key feature of Networked Control Systems (NCSs) is that the information is exchanged through a network among control system components. Transmitting control signals through shared networks induces time delays and data losses which may destabilize the system. This time delay may be constant periodic or random. The random time delay can be modeled using Markov Chains and the NCS can be modeled as Markovian jump system. The stochastic stability of the system has the form of Bilinear Matrix Inequality (BMI). The V-K iteration algorithm is used to solve the BMI and hence to design the stabilizing controller. A modified V-K iteration algorithm is presented in this paper where the decay rate is maximized in both the V- and K-loops. The V-K algorithm method is applied to the cart and inverted pendulum problem which shows that the decay rate is improved with the modified algorithm.**

***Keywords-component; networked control system, time delay, Markov , random time delay, jump, stability***

## I. Introduction

The advances in communication and network technology, and the availability of high speed computers have resulted in an increasing interest in NCSs. This type of control systems can be defined as a control system where the control loop is closed through a real-time communication network [1]. In NCSs the reference input, plant output and control input are exchanged through a real-time communication network as shown in Figure 1. The main advantages of NCSs are modularity, simplified wiring, low cost, reduced weight, decentralization of control, integrated diagnosis, simple installation, quick and easy for maintenance [2], flexible expandability with low cost. NCSs are able to easily fuse global information to make intelligent decisions over large physical spaces.

As the control loop is closed through a communication network the time delay and data dropout are unavoidable. This may degrade the performance of NCSs or even destabilize the system. In general, the control systems with time delays can be classified into time delay independent where the stability is not affected by the time delay and time delay dependent where the time delay affects the stability [3]. Time delay, no doubt, increases the complexity in the analysis and the design of NCSs. There are many methods in the literature for studying the stability of NCS, see for example [4]-[5]. Among these methods is the Markovian jump system approach which is mostly used to study the stability and stabilization of system with abrupt changes due to the variations in the system structure or partly system failure. In this way the system will have a number of models or modes and jumps from one mode to another in a random fashion and in many cases the jump parameter can be modeled using Markov Chains. In NCS the time delay can be random and because there is a correlation between the previous, current and next time delay, the time delay can be modeled as a Markov Chain.

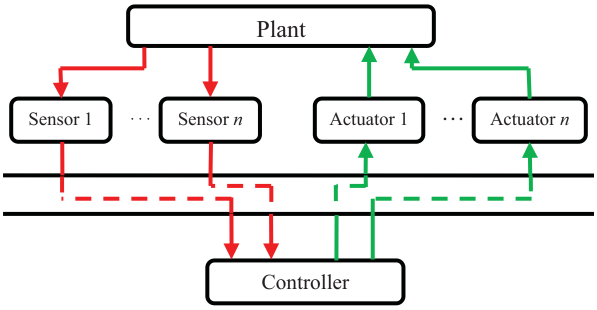

Figure 1. A Typical networked control system

The application of the discrete-time jump system in NCSs has been addressed in many papers, see for example [6-9]. In [6-8] the discrete-time model is augmented and the generated output feedback problem is formulated as BMI which is solved using the V-K iteration algorithm. In this paper we adopt the algorithm in [8] with some modification to the V-K iteration loop. The method in [8] is limited to time delays which are less than the sampling period and in [6][7] the method is extended to time delays larger than the sampling period. From control engineering point of view when the time delay larger than the sampling time the system performance is not acceptable. In [10] the authors use the discrete model for the plant and both the time delay between the sensor to controller and from the controller to the actuator are considered. The discrete mode dependent Lyapunov function has been used to derive a stabilizing switching controller. In [9] the authors concentrate on the problem of the random data drop outs and the sufficient conditions for the mean square stability are derived. The stability analysis and controller design with two random time delays are studied in [10-13]. In [12][13] the NCS is modeled where both the time delays are considered. The controller depends on the current sensor to controller time delay and the previous controller to actuator time delay and hence the controller depends on the three random variables, $\tau_k$ , $d_k$ , $d_{k-\tau_{k+1}}$ , which are interdependent. The resulting system cannot be regarded as the standard Discrete-Time Markovian Jump Linear System (DTMJLS). The derived theorem is in a set of LMI with nonlinear LMI constraint which are non-convex and can be solved by iterative algorithm such as the Cone Complementary Linearization (CCL). The optimal stochastic control is studied in [14] where the optimal stochastic controller is derived when the time delay is random. The use of the model predictive control in NCS has been studied in [15-17] where both the sensor to controller and controller to actuator time delays are considered.

The paper starts from the model of the NCS as DTMJLS is presented where the time delay is modeled as Markov Chain. Then the stability of the system is formulated as BMIs. The V-K algorithm is explained to solve the BMIs and it is tested on the cart and inverted pendulum problem.

## II. Mathematical Modelling of NCS with Time Delay

### A. NCS Systems with State Feedback Controller

The model of a single loop networked control system is shown in Figure 2. The measured plant signals are transmitted through the network and they will suffer random time delays and some of them may be lost. The random time delay makes the system to have the nature of a stochastic hybrid system. The discrete time-invariant plant model is given by:

$$\mathbf{x}(k+1) = \mathbf{A}_d\mathbf{x}(k) + \mathbf{B}_d\mathbf{u}(k) \qquad (1)$$

where $\mathbf{x}(k) \in \Re^n$ the system state vector, $\mathbf{u}(k) \in \Re^m$ the system control input, and the matrices $\mathbf{A}_d$ and $\mathbf{B}_d$ are given by:

$$\mathbf{A}_d = e^{\mathbf{A}h} \qquad \mathbf{B}_d = \int_0^h e^{\mathbf{A}(h-s)}\mathbf{B}ds \qquad (2)$$

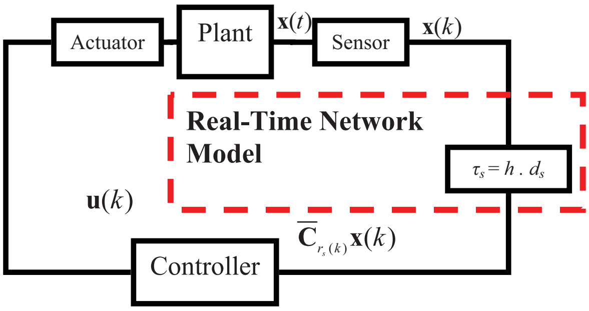

Figure 2. The networked control system.

In the model shown in Figure 2 the time delays are lumped together between the sensor and the controller. In many of the published work in the literature the time delay between the controller and the actuator is neglected. For the following analysis the following assumptions are required and are made:

Assumption 1:

- The sensors are clock driven. The actuator and the controller are event driven; which means that the sensors sample the plant states periodically and the actuators and the controllers use the data as soon as they arrive.
- The data are sent as a single packet.
- The data are received in chronological order which means that old data are disregarded.

The mode-dependent switching state feedback control law is given by:

$$\mathbf{u}(k) = \mathbf{K}(r_s(k))\mathbf{x}(k - r_s(k)) \qquad (3)$$

where $\tau(k) = r_s(k) \cdot h$ , $h$ is the sampling period and $r_s(k)$ is a bounded random integer sequence governed by Markov Chains with $0 \le r_s(k) \le d_s < \infty$, and $d_s$ is the finite delay bound. By augmenting the state variable:

$$\overline{\mathbf{x}}(k) = \begin{bmatrix}\mathbf{x}(k)^T & \mathbf{x}(k-1)^T & \cdots & \mathbf{x}(k-d_s)^T\end{bmatrix}^T$$

where $\overline{\mathbf{x}}(k) \in R^{(d_s+1)n}$ , applying the controller (3) into (1) the closed-loop system becomes:

$$\overline{\mathbf{x}}(k+1) = (\overline{\mathbf{A}} + \overline{\mathbf{B}}\mathbf{K}(r_s(k))\overline{\mathbf{C}}(r_s(k)))\overline{\mathbf{x}}(k) \qquad (4)$$

where;

$$\overline{\mathbf{A}} = \begin{bmatrix} \mathbf{A} & \mathbf{0} & \cdots & \mathbf{0} & \mathbf{0} \\ \mathbf{I} & \mathbf{0} & \cdots & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{I} & \cdots & \mathbf{0} & \mathbf{0} \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ \mathbf{0} & \mathbf{0} & \cdots & \mathbf{I} & \mathbf{0} \end{bmatrix} \overline{\mathbf{B}} = \begin{bmatrix} \mathbf{B} \\ \mathbf{0} \\ \mathbf{0} \\ \vdots \\ \mathbf{0} \end{bmatrix}$$

$$\overline{\mathbf{C}}(r_s(k)) = \begin{bmatrix}\mathbf{0} & \cdots & \mathbf{0} & \mathbf{I} & \mathbf{0} & \cdots & \mathbf{0}\end{bmatrix}$$

$\overline{\mathbf{C}}(r_s(k))$ incorporates the time delay into the model and has all elements being zero except for the $r_s(k)$th block being an identity matrix. The closed-loop system (4) can be rewritten as;

$$\overline{\mathbf{x}}(k+1) = \mathbf{A}_{cl}(r_s(k))\overline{\mathbf{x}}(k) \qquad (5)$$

### B. NCS with Dynamic Output Feedback Controller

Stabilizing the plant (1) with a dynamic controller as shown in Figure 3, the dynamic controller model is given by:

$$\begin{aligned}\mathbf{z}(k+1) &= \mathbf{F}\mathbf{z}(k) + \mathbf{G}\mathbf{y}(k) \\ \mathbf{v}(k) &= \mathbf{H}\mathbf{z}(k) + \mathbf{J}\mathbf{y}(k)\end{aligned} \qquad (6)$$

In the case of the dynamic controller, both the time delay from the sensors to the controller and from the controller to the actuators are considered. Augmenting the controller states as;

$$\overline{\mathbf{z}}(k) = \left[\mathbf{z}(k)^T \quad \mathbf{v}(k)^T \quad \cdots \quad \mathbf{v}(k-d_{ca})^T\right]^T$$

The controller model with the augmenting states is then given by:

$$\begin{aligned} \overline{\mathbf{z}}(k+1) &= \overline{\mathbf{F}}\overline{\mathbf{z}}(k) + \overline{\mathbf{G}}\mathbf{y}(k) \\ \mathbf{u}(k) &= \overline{\mathbf{H}}(r_{ca}(k))\overline{\mathbf{z}}(k) + \overline{\mathbf{K}}(r_{ca}(k))\mathbf{y}(k) \end{aligned} \qquad (7)$$

where;

$$\overline{\mathbf{F}} = \begin{bmatrix} \mathbf{F} & \mathbf{0} & \cdots & \mathbf{0} & \mathbf{0} \\ \mathbf{H} & \mathbf{0} & \cdots & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{I} & \cdots & \mathbf{0} & \mathbf{0} \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ \mathbf{0} & \mathbf{0} & \cdots & \mathbf{I} & \mathbf{0} \end{bmatrix} \overline{\mathbf{G}} = \begin{bmatrix} \mathbf{G} \\ \mathbf{J} \\ \mathbf{0} \\ \vdots \\ \mathbf{0} \end{bmatrix}$$

$$\overline{\mathbf{H}}(r_{ca}(k)) = \begin{cases} [\mathbf{H} \quad \mathbf{0} \quad \cdots \quad \mathbf{0} \quad \mathbf{0} \quad \cdots \quad \mathbf{0}] & \text{if} \quad r_{ca}(k) = 0 \\ [\mathbf{0} \quad \cdots \quad \mathbf{0} \quad \mathbf{I} \quad \mathbf{0} \quad \cdots \quad \mathbf{0}] & \text{if} \quad r_{ca}(k) \neq 0 \end{cases}$$

$$\overline{\mathbf{K}}(r_{ca}(k)) = \begin{pmatrix} \mathbf{J} & \text{if} \quad r_{ca}(k) = 0 \\ \mathbf{0} & \text{if} \quad r_{ca}(k) \neq 0 \end{pmatrix}$$

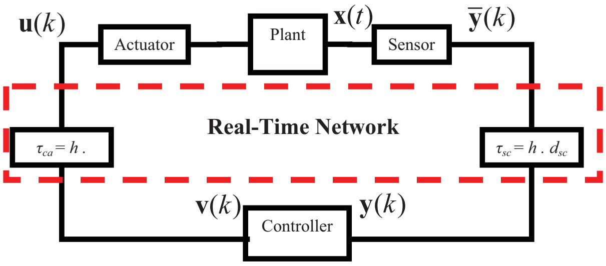

Figure 3. Networked control system with both time delays from sensor to controller and from controller to actuator are taking into account

When the time stamping is used, $\mathbf{F}$, $\mathbf{G}$, $\mathbf{H}$ and $\mathbf{J}$ are replaced by $\mathbf{F}(\tau_{sc})$, $\mathbf{G}(\tau_{sc})$, $\mathbf{H}(\tau_{sc})$, and $\mathbf{J}(\tau_{sc})$. The augmented plant model with output feedback can be described by:

$$\begin{aligned} \tilde{\mathbf{x}}(k+1) &= \tilde{\mathbf{A}}\tilde{\mathbf{x}}(k) + \tilde{\mathbf{B}}\mathbf{u}(k) \\ \mathbf{y}(k) &= \mathbf{C}\tilde{\mathbf{C}}(r_{sc}(k))\tilde{\mathbf{x}}(k) \end{aligned} \qquad (8)$$

Augmenting both the plant states and controller states as: $\overline{\mathbf{x}}(k) = \left[\tilde{\mathbf{x}}(k)^T \quad \overline{\mathbf{z}}(k)^T\right]^T$. The closed loop system with the plant (8) and the controller (7) becomes;

$$\overline{\mathbf{x}}(k+1) = (\overline{\mathbf{A}} + \overline{\mathbf{B}}\mathbf{K}(r_{ca}(k))\overline{\mathbf{C}}(r_{sc}(k)))\overline{\mathbf{x}}(k) \qquad (9)$$

where;

$$\overline{\mathbf{A}} = \begin{bmatrix} \tilde{\mathbf{A}} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} \overline{\mathbf{B}} = \begin{bmatrix} \tilde{\mathbf{B}} & \mathbf{0} \\ \mathbf{I} & \mathbf{0} \end{bmatrix} \overline{\mathbf{C}}(r_{sc}(k)) = \begin{bmatrix} \mathbf{0} & I \\ \mathbf{C}\tilde{\mathbf{C}}(r_{sc}(k)) & \mathbf{0} \end{bmatrix}$$

$$\mathbf{K}(r_{ca}(k)) = \begin{bmatrix} \tilde{\mathbf{F}} & \tilde{\mathbf{G}} \\ \tilde{\mathbf{H}}(r_{ca}(k)) & \tilde{\mathbf{K}}(r_{ca}(k)) \end{bmatrix}$$

Equation (9) can be written as;

$$\overline{\mathbf{x}}(k+1) = \mathbf{A}_{cl}(r_{sc}(k), r_{ca}(k))\overline{\mathbf{x}}(k) = \mathbf{A}_{cl}(r_s(k))\overline{\mathbf{x}}(k) \qquad (10)$$

The two time delays are random and bounded, $\tau_{scm} \geq \tau_{sc} \geq 0$ and $\tau_{cam} \geq \tau_{ca} \geq 0$. These can be modelled as two homogeneous Markov Chains and they jump from mode to mode according to their transition probabilities $P_{sc}$ and $P_{ca}$ respectively. The random variable $\tau_{sc}$ and $\tau_{ca}$ can be converted to single random variable, $r(k)$ where the transition probability, $P$, is given by Kronecker product of the $P_{sc}$ and $P_{ca}$ as;

$$P = P_{sc} \otimes P_{ca} \qquad (11)$$

For simplicity (10) can be written as:

$$\mathbf{x}(k+1) = \mathbf{A}(r(k))\mathbf{x}(k) \qquad (12)$$

Equations (5) and (10) are standard DTMJLS. Equation (5) is a jump system with one mode which is the sensor to the controller time delay while the system in (10) has two modes which are the sensor to the controller and the controller to the actuator time delays. The system matrix will be $\mathbf{A}_{cl}(r(k))$□$\{\mathbf{A}_{cl}(0),\ldots,\mathbf{A}_{cl}(d)\}$ according to the jump parameter $r(k)$□$\theta = \{0,\ldots,d\}$. In order to stabilize the system with mode-independent or mode-dependent controller the mean square stability must be established.

### *C. The model of the random time delay as Markov Chain*

The random time delay is modelled as a finite state Markov process with the following properties:

$$\begin{aligned} &P\{r_s(k+1) = j \;\;|\;\; r_s(k) = i\} = p_{ij} && 0 \leq i, j \leq d_s \\ &0 \leq p_{ij} \leq 1 && \sum_{j=0}^{d} p_{ij} = 1 \end{aligned} \qquad (13)$$

where $d_s$ is the number of modes and $r_s(k)$ is the Markovian process. The general transition probability matrix is given by:

$$P = \begin{bmatrix} p_{00} & p_{01} & 0 & 0 & \cdots & 0 \\ p_{10} & p_{11} & p_{12} & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ \vdots & \vdots & \vdots & \vdots & \vdots & 0 \\ p_{d0} & p_{d1} & p_{d2} & p_{d3} & \cdots & p_{d_s d_s} \end{bmatrix} \qquad (14)$$

The constraint (13) means the summation of the probabilities in every row is one. The assumption made is that the old data are discarded. Suppose that at instant $k$ we received $\mathbf{x}(k)$, at $k$+1 if there is no new data then the old data will be used by the controller, but if we receive $\mathbf{x}(k$ -1) at $k$ +1 then it will be older than $\mathbf{x}(k)$ and hence $\mathbf{x}(k\ -1)$ must be discarded, this can be interpreted as;

$$p\{r_s(k+1) > r_s(k)+1\} = 0 \qquad (15)$$

From (15) the time delay can increase only at one step but it can decrease as many steps as can be seen from (14). The diagonal elements in (14) represent the probability of successive equal time delays or in other words the probability that the network remain in the same state. The upper diagonal elements represent the possibility of receiving longer delays or increasing the network load. The zero elements represent the discard of the old data.

## III. The Stability of the Discrete-Time Markovian Jump Linear System (DTMJLS)

The Mean Square stability of the Markovian Jump Systems is equivalent to the Asymptotic Wide Sense Stationary Stability (AWSS) [18]. For the jump system the stochastic stability, mean square stability and the exponential mean square stability are all equivalent and every condition implies the almost sure (asymptotic) stability.

Definition 1: [6]

The system (12) is mean square stable if for every initial condition state, $(\mathbf{x}_0, r_0)$,

$$\lim_{k\to\infty} \mathrm{E}\left[\|\mathbf{x}(k)\|^2\right] = 0 \qquad (16)$$

Definition 2: [6]

The system (12) is mean square stable with decay rate $\beta$ [19] if for every initial condition state, $(\mathbf{x}_0, r_0)$,

$$\lim_{k\to\infty} \beta^k \mathrm{E}\left[\|\mathbf{x}(k)\|^2\right] = 0 \qquad \beta > 1 \qquad (17)$$

The necessary and sufficient conditions for mean square stability for jump system are given in the following theorem.

Theorem 1 [18]: The mean square stability of system (12) is equivalent to the existence of symmetric positive definite matrices $\mathbf{Q}_0, \ldots, \mathbf{Q}_d$ satisfying any one of the following 4 conditions:

$$\mathbf{A}_i\left(\sum_{j=0}^{d} p_{ji}\mathbf{Q}_\mathbf{j}\right)\mathbf{A}_i^T < \mathbf{Q}_i, \qquad i = 0,\cdots,d$$

$$\mathbf{A}_j^T\left(\sum_{i=0}^{d} p_{ji}\mathbf{Q}_i\right)\mathbf{A}_j < \mathbf{Q}_j, \qquad j = 0,\cdots,d$$

$$\sum_{j=0}^{d} p_{ji}\mathbf{A}_j\mathbf{Q}_j\mathbf{A}_i^T < \mathbf{Q}_i, \qquad i = 0,\cdots,d$$

$$\sum_{j=0}^{d} p_{ji}\mathbf{A}_i^T\mathbf{Q}_j\mathbf{A}_i < \mathbf{Q}_j, \qquad i = 0,\cdots,d$$

Where $i$=0,…,$d$ represents the number of the modes. The conditions 1-4 are equivalent for studying the stability of the DTMJLS but for the controller design each condition will lead to a different controller. Choosing condition (4) in Theorem 1 and replacing $\mathbf{Q}_i$ by $\alpha\mathbf{Q}_i$ (where the decay rate or Lyapunov Exponent, $\beta = 1/\alpha$ and $\lim_{k\to\infty}\beta^k M(k) = 0$) on the right hand side, the closed-loop system becomes:

$$\sum_{j=0}^{d} p_{ji}(\mathbf{A}_i + \mathbf{B}_i\mathbf{K}_i\mathbf{C}_i)^T\mathbf{Q}_j(\mathbf{A}_i + \mathbf{B}_i\mathbf{K}_i\mathbf{C}_i) < \alpha\mathbf{Q}_j, \ i=0,\ldots,d \ (18)$$

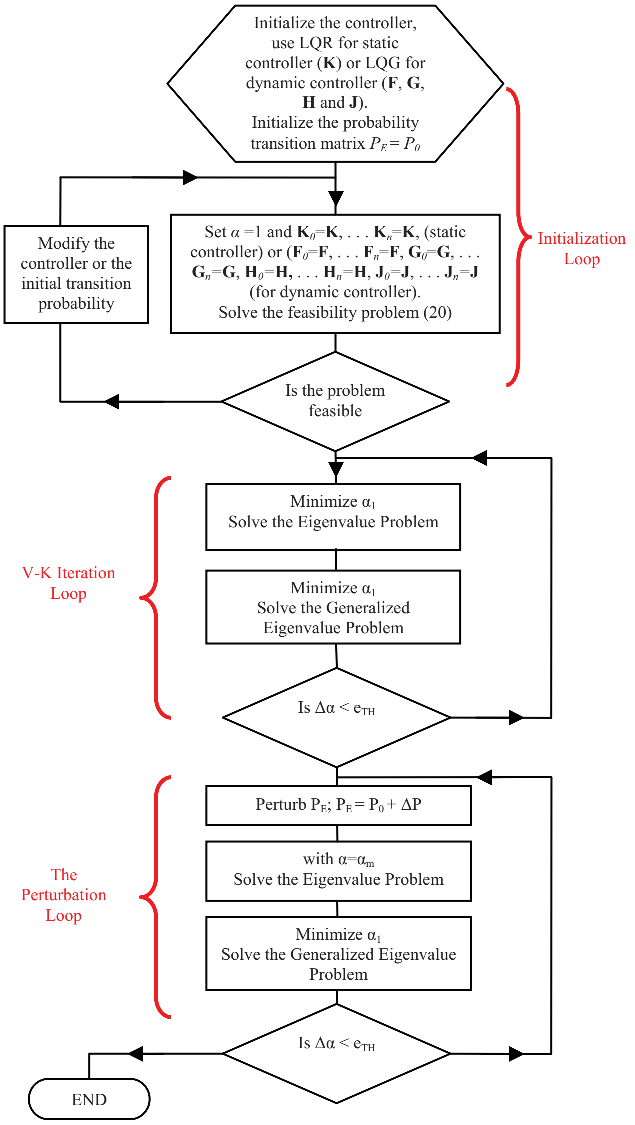
The coupled equations (18) are BMIS which are non convex and finding a global optimal solution is very difficult. However many control problems are formulated as BMIs, there are a few methods for solving the BMIs. For example the path-following linearization method reported in [20] can be used where each matrix is perturbed and the higher order terms are neglected. The most widely used techniques for the solution is by iteration methods such the D-K, G-K and V-K iteration algorithms [21]. If we fix $\mathbf{K}_i$ ($i$=0,…,d) then we have a Generalized Eigenvalue Problem (GEVP) and if we fix $\mathbf{Q}_i$ ( i=0,…,d) then we have Eigenvalue Problem (EVP) [8]. Both of these problems can be solved very efficiently using the Matlab LMI toolbox. Using Schur complement to (18) then we have:

$$\begin{bmatrix} \alpha\mathbf{Q}_j & (\mathbf{A}_0 + \mathbf{B}_0\mathbf{K}_0\mathbf{C}_0)^T & \cdots & (\mathbf{A}_d + \mathbf{B}_d\mathbf{K}_d\mathbf{C}_d)^T \\ (\mathbf{A}_0 + \mathbf{B}_0\mathbf{K}_0\mathbf{C}_0) & p_{j0}^{-1}\mathbf{Q}_0^{-1} & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ (\mathbf{A}_d + \mathbf{B}_d\mathbf{K}_d\mathbf{C}_d) & 0 & \cdots & p_{jd}^{-1}\mathbf{Q}_d^{-1} \end{bmatrix} > 0 \qquad (19)$$

## IV. The V-K Iteration Algorithm

In the V-K algorithm the BMI is divided into two LMI's and by solving these two LMI's a local optimal solution can be found. The problem solution process is divided to three basic problems which are: FP (Feasibility Problem), EVP, and GEVP that can be solved using the Matlab LMI toolbox. In the V-K algorithm, the problem is iterated between the EVP and the GEVP. The proof of the algorithm convergence is given in [21]. The detailed algorithm is shown in the flowchart in Figure 4. The algorithm starts with the initialization, then if the solution is feasible the EVP and GEVP are iterated until the desired transition matrix is reached. In this improved algorithm the decay rate is maximized in both the EVP and GEVP. The initial transition probability matrix is:

$$P_0 = \begin{bmatrix} 1 & 0 & \ldots & 0 \\ 1 & 0 & \ldots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 1 & 0 & \ldots & 0 \end{bmatrix} \approx \begin{bmatrix} 1-n\cdot\in & \in_1 & \ldots & \in_n \\ 1-n\cdot\in & \in_1 & \ldots & \in_n \\ \vdots & \vdots & \ddots & \vdots \\ 1-n\cdot\in & \in_1 & \ldots & \in_n \end{bmatrix}$$



Initialize the controller, use LQR for static controller (**K**) or LQG for dynamic controller (**F**, **G**, **H** and **J**). Initialize the probability transition matrix $P_E = P_0$
Modify the controller or the initial transition probability
Set $\alpha$ =1 and $\mathbf{K}_0$=**K**, . . . $\mathbf{K}_n$=**K**, (static controller) or ($\mathbf{F}_0$=**F**, . . . $\mathbf{F}_n$=**F**, $\mathbf{G}_0$=**G**, . . . $\mathbf{G}_n$=**G**, $\mathbf{H}_0$=**H**, . . . $\mathbf{H}_n$=**H**, $\mathbf{J}_0$=**J**, . . . $\mathbf{J}_n$=**J** (for dynamic controller). Solve the feasibility problem (20)
Initialization Loop
Is the problem feasible
V-K Iteration Loop
Minimize $\alpha_1$ Solve the Eigenvalue Problem
Minimize $\alpha_1$ Solve the Generalized Eigenvalue Problem
Is $\Delta\alpha < e_{TH}$
The Perturbation Loop
Perturb $P_E$; $P_E = P_0 + \Delta P$
with $\alpha=\alpha_m$ Solve the Eigenvalue Problem
Minimize $\alpha_1$ Solve the Generalized Eigenvalue Problem
Is $\Delta\alpha < e_{TH}$
END

Figure 4. The V-K iteration algorithm

It should be noted that the initial controller is designed for the free delay system. To get an initial feasible solution we have to start from small time delays and perturb the transition probability matrix toward higher time delays. The perturbation $\in$ should be very small positive number in the order of 0.005. An example of the perturbation matrix is:

$$\Delta P_0 = \begin{bmatrix} -s & s & 0 & \dots & 0 \\ 0 & 0 & 0 & \dots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \dots & 0 \end{bmatrix} \quad \Delta P_1 = \begin{bmatrix} 0 & 0 & 0 & \dots & 0 \\ -s & s & 0 & \dots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \dots & 0 \end{bmatrix}$$

As can be seen the sum of the perturbation through any row is zero. More aggressive initial transition probability matrix can be used. In [7][8] the perturbation is around 0.01 but even with this small perturbation sometimes the problem is divergent and we need to use smaller perturbation, for example around 0.005. Also for the two modes, the two probability matrices are perturbed at the same time while in our algorithm they are perturbed separately.

Example 1

The pendulum mass is denoted by $m$ and the cart mass is $M$, the length of the pendulum rod is $L$. The open loop system is unstable. The states are defined as $x_1 = x$, $x_2 = \dot{x}$, $x_3 = \theta$, $x_4 = \dot{\theta}$. The linearized model can be given as:

$$\dot{\mathbf{x}} = \begin{bmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & \dfrac{-mg}{M} & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & \dfrac{(M+m)g}{ML} & 0 \end{bmatrix} \mathbf{x} + \begin{bmatrix} 0 \\ \dfrac{1}{M} \\ 0 \\ \dfrac{-1}{ML} \end{bmatrix} u = \mathbf{A}\mathbf{x} + \mathbf{B}u$$

$$\mathbf{y} = \begin{bmatrix} x \\ \theta \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix} \mathbf{x} = h(x,u)$$

The parameters used are: $M$=1 kg, $m$ = 0.4 kg, L = 0.7 m. The sampling time is $h = 0.1$ s. The time delay is bounded by 2: $r_s(k) \in \{0,1,2\}$. The initial condition is $x$ = 0 and $\theta$ = 0.1. After sampling the system with 0.1 s sampling rate, the system matrices are given by:

$$\mathbf{A} = \begin{bmatrix} 1 & 0.1 & -0.0199 & -0.0007 \\ 0 & 1 & -0.4049 & -0.0199 \\ 0 & 0 & 1.0996 & 0.1033 \\ 0 & 0 & 2.0247 & 1.0996 \end{bmatrix} \quad \mathbf{B} = \begin{bmatrix} 0.0050 \\ 0.1009 \\ -0.0073 \\ -0.1476 \end{bmatrix}$$

The required transition probability is given by:

$$P = \begin{bmatrix} 0.5 & 0.5 & 0 \\ 0.3 & 0.6 & 0.1 \\ 0.3 & 0.6 & 0.1 \end{bmatrix}$$

Using the LQR matlab function with **Q**=**I** and **R**=1. The controller is given by:

$$\mathbf{K}_{LQR} = \begin{bmatrix} 0.5943 & 1.4745 & 28.7321 & 6.7849 \end{bmatrix}$$

with the required transition probability and the LQR controller does not stabilize the system with the time delay because the solution is infeasible, the initial transition probability and the perturbation matrix are chosen as:

$$P_0 = \begin{bmatrix} 0.499 & 0.499 & 0.002 \\ 0.4 & 0.5 & 0.1 \\ 0.4 & 0.5 & 0.1 \end{bmatrix} \quad \Delta P_i = \begin{bmatrix} 0 & 0 & 0 \\ -0.005 & 0.005 & 0 \\ -0.005 & 0.005 & 0 \end{bmatrix}$$

After 20 iterations the desired transition matrix is reached and the stabilizing controller is given as:

$$\mathbf{K} = \begin{bmatrix} 0.3181 & 0.7972 & 21.2058 & 5.4654 \end{bmatrix}$$

Note that the process can be started with any $P$ and $\mathbf{K}_{LQR}$ as long as they give feasible solution. Using Theorem 1 [22] the MADB using the LQR controller is 0.1210 s. With the stabilizing controller that takes the random time delay into consideration, Theorem 1 [22] gives 0.1420 s which shows an improvement in the stability margin with the new controller. The V-K iteration loop took 4-iterations and the perturbation loop took 20 iterations, the minimum decay rate is 0.8837. By changing the EVP loop by making an inner loop for minimizing α, the minimum attained decay rate is 0.8645 and the delay margin increased to 0.1563 s. The system response is shown in Figure 5. In the simulation the nonlinear dynamics is used. The stabilizing controller with the improved algorithm is:

$$\mathbf{K} = \begin{bmatrix} 0.2823 & 0.7050 & 20.5227 & 4.9714 \end{bmatrix}$$

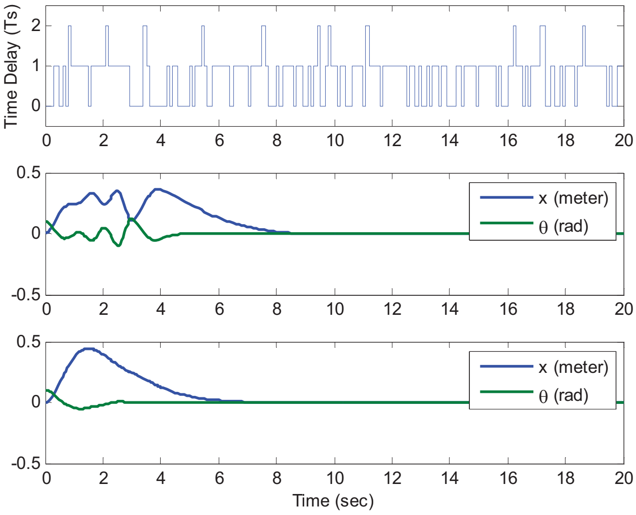


Figure 5. (a) The random time delay, (b) The response with the LQR controller, (c) The response with the controller generated by the improved V-K algorithm

## V. Conclusion

In this paper, the NCS is modeled as discrete-time Markovian linear jump system where the time delay is modeled as Markov chain. Using the mean square stability the system stability as formulated as BMIs. The V-K iteration algorithm is used to solve the BMIs. We used an improved V-K iteration algorithm where the decay rate is improved in both the EVP and the GEVP loops. The method is tested on the cart and the inverted pendulum and we found that the decay rate is improved.

*Abstract*—**Networked control systems (NCS) are in existence for quite some time. The network-induced delays and packet drops; and their effect on control system's performance has been a burning topic for last one decade. Dependability in context of NCS has not got much attention. While it is an important aspect of NCS intended to be used in critical application. The paper reviews the present state of developments in NCS and presents open problems pertaining to dependability of NCS. Solutions to these problems may increase the presence of NCS by many folds and in many fields.**

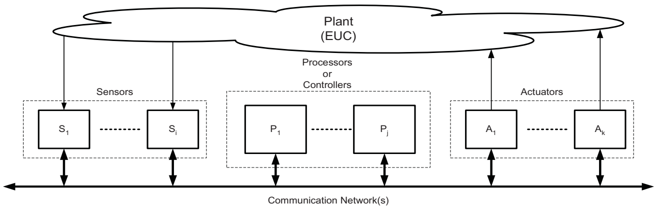

Fig. 1. Schmatic of a typical NCS

## I. Introduction

Networked Control System (NCS) contains a number of interconnected devices that exchange data through shared communication networks. Examples of such systems are found in industrial automation, building automation, office and home automation, intelligent vehicle systems and advanced aircraft and spacecraft. These systems are driven by an important feature, instead of point-to-point connections, all system elements (sensors, actuators and controllers) are connected to the network as nodes. The advantages of this implementation include [1], [2]: reduced system wiring, plug and play devices, increased system agility, ease of system diagnosis and maintenance. These features result in modular and flexible system design, simple and fast implementation and powerful system diagnosis and maintenance utilities [3].

Schematically a typical NCS is shown as in Figure 1. Sensor node samples the process parameters with a given sampling period, convert physical parameters to digital and pack the message to send to controller. The controller node unpacks the message(s) from sensor node and use control algorithm to calculate control signals to be sent to actuator node. Actuator node according to control signal takes the corrective action in process. All these messages are sent over shared network. In NCS, time delay has one more factor in addition to node processing delay, it is network-induced delay, i.e. from sensor to controller and controller to actuator.

Control systems are reactive systems; they need to interact with their environment (i.e. process/plant) constantly in a timely manner. Due to this property, control systems come under the category of real-time systems. They can be hard or soft real-time systems based on the consequences of failure. In NCS, the feedback loop is closed by shared communication network(s) where information is sent by means of packets. These shared communication media are prone to random delay and loss of packets. This leads to two challenging problems in analysis and design of networked control systems (NCS), network induced delays and packet dropouts. Both problems can significantly degrade the NCS's performance and dependability. It has long been realized that network induced communication delay is time-varying and nondeterministic, suggesting that the delay behavior is unpredictable. Packet dropout occurs when communication networks are unreliable or the communication latency is so big that the packet has to be purposely dropped.

Thess inherent issues of NCS - network-induced delay and packet loss - are well acknowledged [1], [2], [4], [5], [6], [7], [8], [9], [3], [10], [11], [12]. The delay and packet loss can degrade the quality of performance (QoP) of control system or even de-stabilize the system, if not properly designed [1], [2], [13], [14], [15], [7], [16], [6], [5], [17], [8], [18]. The two main directions to approach this problem are, i) design a communication protocol that guarantee delays, ii) design control strategies that *a priori* compensate for network-induced delay and packet loss.

When NCS are used for control, then their main objective is

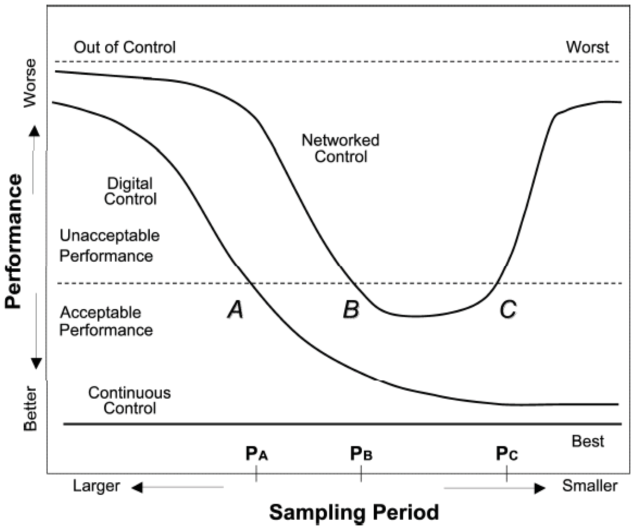

Fig. 2. Performance comparison [2], [9]

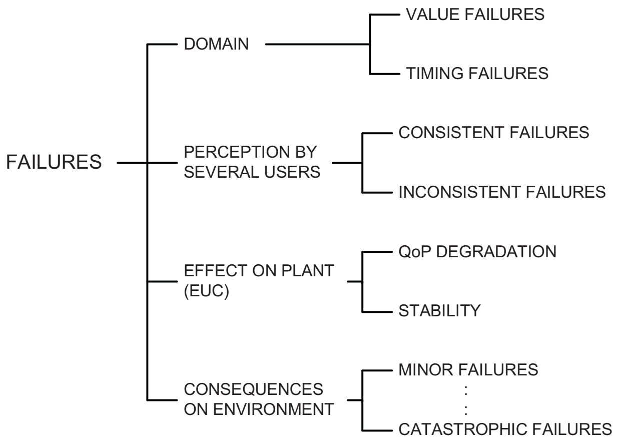

Fig. 3. Failure classification [19], [21]

to guarantee the stability and performance of plant/equipment under control (EUC), i.e. meet the control system specifications. These specifications include phase margin, gain margin, overshoot, steady state error, response-time, and tracking error etc.

The comparison of control performance versus sampling period for continuous control (analog), digital control, and network control is given in Fig. 2. During the NCS design stage, a performance chart can be derived as shown in Fig. 2. This performance chart provides a clear way to choose the proper sampling periods for an NCS. For a fixed control law, the worst, acceptable, and the best regions can be defined based on control specifications. The performance axis in Fig. 2 could be chosen to reflect a subset of the control system specifications. Since the performance of continuous control is not a function of sampling period, the performance index is constant for a fixed control law. For digital control case, the performance only depends on the sampling period assuming no other uncertainties. The performance degradation point A (sampling period $P_A$) in digital control could be estimated based on the relationship between control system bandwidth and sampling rate. For the networked control case, point B can be determined by further investigating the characteristics and statistics of network-induced delays and device processing time delays. As the sampling period gets smaller, the network traffic load becomes heavier, the possibility of more contention time or data loss increases, and longer time delays result. This situation causes the existence of point C in networked control.

With the advances in technologies related to NCS and advantages offered by them over conventional systems, NCS are penetrating into almost every aspect of our life. When these systems are used in critical applications, such as, nuclear power plant, avionics, process plants and automobiles etc., failure of these systems could result in loss of huge investment, effort, life or damage to environment. In such cases, dependability analysis becomes an important tool for decision making at all stages of system life cycle - design, deployment, operation and phase-out. In fact for systems concerning safety of people, demonstration of dependability through testing/analysis is a mandatory requirement before system can be deployed.

The paper reviews the related developments in the area of NCS and introduces dependability. Brief overview of dependability aspects are given in section II. Section III reviews the related developments. Dependability models are discussed in section IV. The open issues pertaining to NCS dependability modeling are outlined in section V, followed by conclusion in section VI.

## II. Dependability: Basic Fundamentals

Dependability of a system is defined by Algirdas Avizienis et al. [19], [20] as “ability to deliver service/function that can justifiably be trusted”. The service delivered by a system is its behavior as it is perceived by its user(s). User could be another system (physical, human) that interacts with the former. Service is delivered when the service implements the system function, where function is the behavior of the system described by its specification.

A system failure is an event that occurs when the delivered service deviates from correct service. A failure is a transition from correct service to incorrect service. Failure is manifestation of error, which in turn is caused by fault [19], [20], [21]. An error is that part of system state that may cause a subsequent failure: a failure occurs when an error reaches the service interface and alters the service. A fault is the adjudged or hypothesized cause of an error. A fault is active when it produces an error, otherwise it is dormant. Fig. 3, shows the modes characterizing incorrect service. Effect on plant (EUC) has been added considering NCS.

Fig. 4 shows the dependability tree consisting of attributes, means and threats.

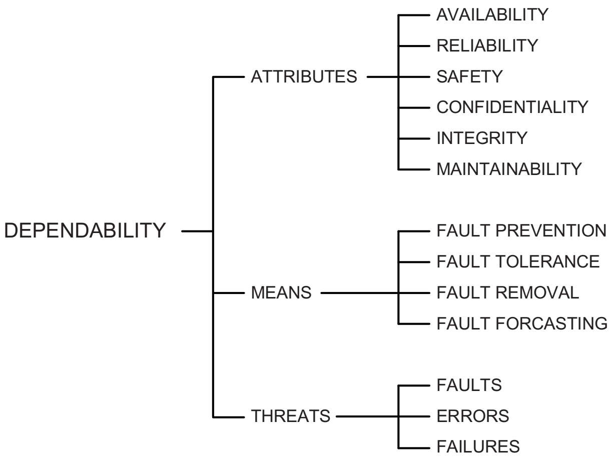

Fig. 4. Dependability tree [19], [21]

The means to attain dependability are a set of four techniques [19], [21]:

1) **Fault prevention:** to prevent the occurrence or introduction of faults
2) **Fault tolerance:** capability to deliver correct service in the presence of faults
3) **Fault removal:** to reduce the number and severity of faults
4) **Fault forecasting:** to estimate the present number, the future incidence, and the likely consequence of faults

The dependability attributes for electronic systems depend on their application or function. An electronic system when used in critical applications can be categorized as safety-critical, mission-critical and economically critical. The definitions of these are given below:

**Safety-critical systems:** systems required to ensure safety of equipment under control (EUC), people and environment.

**Mission-critical systems:** systems whose failure result in failure/loss of mission.

**Economically-critical systems:** systems whose failure result in availability of EUC, causing massive loss of revenue.

Dependability attributes applicable to these systems are safety, reliability and availability, respectively. Fig. 5 shows the applicable dependability attributes pictorially.

## III. Review of NCS related research

NCS related research developments can be categorized as, i) network related, ii) control related, and iii) dependability related. Some of the work is reviewed below.

Network related research is in development and performance evaluation of Fieldbus technology. Ethernet related technologies have also been an area of research because of the market share and cost benefit of Ethernet. For Ethernet new development includes traffic smoothing and switched Ethernet.

The real-time industrial network, often referred to as fieldbus, is an important element for building automated manufacturing systems. Thus, in order to satisfy the real-time requirements of field devices such as sensors, actuators and controllers, a number of fieldbus protocols have been developed. These fieldbus protocols have an important advantage over the widely used Ethernet in terms of their deterministic behavior. However, the application of fieldbuses has been limited because of the high cost of hardware and the difficulty in interfacing them with multi-vendor products. In order to solve these problems, computer network technology, especially Ethernet, is being adopted in industrial automation field. The key technical obstacle for Ethernet for industrial applications is that of its non-deterministic behavior [2], [3]. Non-deterministic behavior makes it inadequate for real-time applications, where packets containing real-time information (control command or sensor/actuator signal) have to be delivered within a certain time limit. To overcome the limitations of standard Ethernet, recent development has lead to switched Ethernet, EtherCAT, EPL and PROFInet [3], [22], [23], [24], [25], [26], [27], [28], [29], [30]. These have been adopted in industrial applications because of the elimination of uncertainties in network operation, which leads to improved performance.

Control system related developments can be classified in three categories: i) dealing with only delay, ii) dealing only with packet drops and iii) dealing with both [31], [32], [33].

For quite a long, it has been realized that conventional reliability models are not sufficient to analyze hard real-time systems, since they do not adequately model the temporal properties of such system [34]. A number of methods and techniques have been proposed since then to model and analyze temporal behavior and correctness [34], [2], [33], [30], [31], [26], [24], [12], [1], [29], [35], [36], [37]. A brief review of these is tabulated in Table 1.

## IV. Dependability models

To address dependability in context of NCS, available literature has the following:

- techniques to design robust controller for a specified bound on time-delay and packet drop rate.
- a number of networks have been characterized for their time delay and packet drop behavior
- a number of control networks have been proposed with guaranteed behavior
- techniques are being developed to characterize a given network to specify its time-delay and packet drop behavior for specified traffic pattern and network load

Conventional dependability models do not incorporate failures due to not meeting timing constraint and dynamic properties. From literature, it is evident that for NCS functional dependability attributes are more appropriate [37]. For programmable electronic systems functional safety has already been standardized and gaining importance [38].

With respect to dependability modeling of NCSs, there seems to be two different categories of systems - i) failure to meet time deadline leads to system failure and, ii) failure due to not keeping the performance objective.

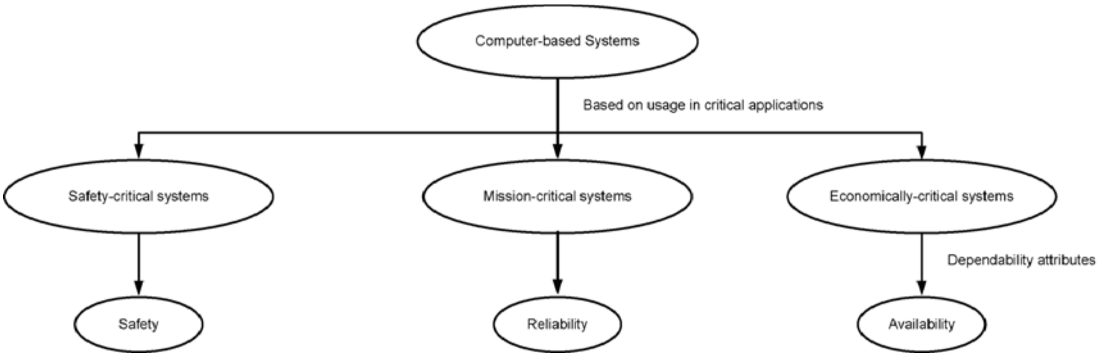

Fig. 5. Failure domains and dependability attributes

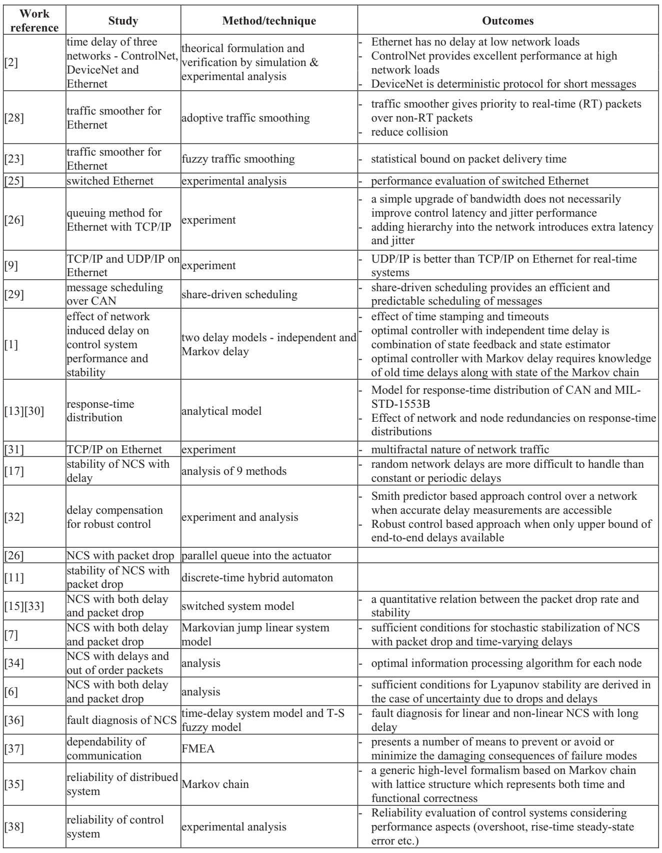
Table 1 Review of related literature



| Work reference | Study | Method/technique | Outcomes |
|---|---|---|---|
| [2] | time delay of three networks - ControlNet, DeviceNet and Ethernet | theorical formulation and verification by simulation & experimental analysis | - Ethernet has no delay at low network loads<br>- ControlNet provides excellent performance at high network loads<br>- DeviceNet is deterministic protocol for short messages |
| [28] | traffic smoother for Ethernet | adoptive traffic smoothing | - traffic smoother gives priority to real-time (RT) packets over non-RT packets<br>- reduce collision |
| [23] | traffic smoother for Ethernet | fuzzy traffic smoothing | - statistical bound on packet delivery time |
| [25] | switched Ethernet | experimental analysis | - performance evaluation of switched Ethernet |
| [26] | queuing method for Ethernet with TCP/IP | experiment | - a simple upgrade of bandwidth does not necessarily improve control latency and jitter performance<br>- adding hierarchy into the network introduces extra latency and jitter |
| [9] | TCP/IP and UDP/IP on Ethernet | experiment | - UDP/IP is better than TCP/IP on Ethernet for real-time systems |
| [29] | message scheduling over CAN | share-driven scheduling | - share-driven scheduling provides an efficient and predictable scheduling of messages |
| [1] | effect of network induced delay on control system performance and stability | two delay models - independent and Markov delay | - effect of time stamping and timeouts<br>- optimal controller with independent time delay is combination of state feedback and state estimator<br>- optimal controller with Markov delay requires knowledge of old time delays along with state of the Markov chain |
| [13][30] | response-time distribution | analytical model | - Model for response-time distribution of CAN and MIL-STD-1553B<br>- Effect of network and node redundancies on response-time distributions |
| [31] | TCP/IP on Ethernet | experiment | - multifractal nature of network traffic |
| [17] | stability of NCS with delay | analysis of 9 methods | - random network delays are more difficult to handle than constant or periodic delays |
| [32] | delay compensation for robust control | experiment and analysis | - Smith predictor based approach control over a network when accurate delay measurements are accessible<br>- Robust control based approach when only upper bound of end-to-end delays available |
| [26] | NCS with packet drop | parallel queue into the actuator | |
| [11] | stability of NCS with packet drop | discrete-time hybrid automaton | |
| [15][33] | NCS with both delay and packet drop | switched system model | - a quantitative relation between the packet drop rate and stability |
| [7] | NCS with both delay and packet drop | Markovian jump linear system model | - sufficient conditions for stochastic stabilization of NCS with packet drop and time-varying delays |
| [34] | NCS with delays and out of order packets | analysis | - optimal information processing algorithm for each node |
| [6] | NCS with both delay and packet drop | analysis | - sufficient conditions for Lyapunov stability are derived in the case of uncertainty due to drops and delays |
| [36] | fault diagnosis of NCS | time-delay system model and T-S fuzzy model | - fault diagnosis for linear and non-linear NCS with long delay |
| [37] | dependability of communication | FMEA | - presents a number of means to prevent or avoid or minimize the damaging consequences of failure modes |
| [35] | reliability of distribued system | Markov chain | - a generic high-level formalism based on Markov chain with lattice structure which represents both time and functional correctness |
| [38] | reliability of control system | experimental analysis | - Reliability evaluation of control systems considering performance aspects (overshoot, rise-time steady-state error etc.) |

The models of these failures which can utilize the available techniques of dependability analysis are the need of the hour. One important failure model is hazard rate. If hazard rate of timing failure and performance-related failure can be obtained, then using available techniques dependability attribute of interest can be estimated.

For systems belonging to first category, response-time distribution can be used to estimate probability of missing the deadline [39], [29], [12].

$$\begin{aligned}
&p = R\left(t > t_d\right)\\
&\text{where:}\\
&p: \text{ probability of timing failure}\\
&t_d: \text{ time deadline}\\
&R\left(\cdot\right): \text{response - time distribution (CDF)}
\end{aligned}\tag{1}$$

Let system failure criteria is $n$ consecutive deadline violation (or timeliness failures). When $n = 1$, number of cycles at which timeliness failure will occur follows geometric distribution [40].

$$\begin{aligned}
&P\left(Z = n\right) = p^{n-1}q\\
&\text{where}\\
&Z: \text{random variable}\\
&q: \text{ probability of occurrence of timeliness failure}\\
&p: 1 - q
\end{aligned}\tag{2}$$

Geometric distribution is a memoryless distribution in discrete time and is counterpart of exponential distribution in continuous time [40]. At gross level (larger time scale), it can be easily converted to exponential distribution. In exponential distribution characterizing parameter is hazard rate, which in this case is referred to as "*timeliness hazard rate*".

$$\begin{aligned}
&\lambda^T = \tfrac{1}{t}\ln\left(\frac{1}{P\left(Z > \left\lceil \frac{t}{t_C}\right\rceil\right)}\right)\\
&where\\
&\lambda^T: \text{Timeliness hazard rate}\\
&t: \text{Operating time}\\
&t_C: \text{Cycle time or period}
\end{aligned}\tag{3}$$

When $n > 1$, number of cycles for timeliness failure will not follow geometric distribution. This process (number of cycles for timeliness failure) is a memory process and directly cannot be modeled as Markov. Using the technique of additional states [41], Markov model can be used to model this process. This is expalined in [29].

For systems belonging to second category, techniques need to be evolved to derive hazard rates of failure due to performance degradation (overshoot, stability, etc.). The other open issues in dependability modeling of NCS are discussed in next section.

## V. Dependability issues in NCS

When systems are used in critical applications, all the means to achieve dependability are employed. Some of them are listed below:

*Fault Prevention:* Methods to avoid the occurrence of failure. For example,

1) selection and use of reliable hardware components,
2) use of fault-free algorithm and software,
3) use of communication network with predictable delay and preferably no drop during transmission

*Fault Tolerance:* Means to tolerate the failure. For example,

1) Redundancy for hardware components, including transmission media,
2) software fault tolerance, recovery and roll-back,
3) control algorithm to cope with random packet delay and drop

*Fault Removal:* Detection and restoration of failed component/unit.

1) diagnosis of hardware component failures,
2) diagnosis of software failures,
3) monitoring of traffic and detection of anomaly

Although some work has been done to improve NCS dependability, but there exist some research gap for dependability modeling and analysis. These are listed as follows:

1) Functional dependability considering *value* as well as *timing* failures
2) Methods to deal with redundancy at node level (mainly actuator node)
3) Methods to deal with redundancy at communication level (mainly controller node)
4) Effect of fault occurrence and removal on system performance
5) Effect of on line repair

The above means try to ensure the uninterrupted operation of system. Like any other critical system, NCS is also expected to have graceful degradation or go a defined state on failure, e.g. *fail-safe* or *fail-silent*. In addition to this, it shall give opportunity for alternate means of control. E.g. in case control system has failed, it shall allow the remote manual control.

Some other issues are:

- Timing of faults: faults affecting the network may have various effects on the control system, depending upon the state of the system, when the failure occurs. E.g. a lost message in transient state does not have the same effect as in steady state.
- Timing model: for safety systems, choice of timing model and indulgent protocol also plays an important role [42].

## VI. Conclusion

NCS have been attracting significant interest in the past few years and will continue to do so for the years to come. With the advent of cheap, small, and low-power processors with communication capabilities, it has become possible to endow sensors and actuators with processing power and the ability to communicate with remote controllers through shared networks. In view of these developments, it is expected that NCS will become the more predominant; replacing the current centralized digital control systems that rely on dedicated connections between system elements.

Along with all advantages that NCS offer, they have some inherent limitations. The main issue being the network induced delays, packet drop, out-of-sequence packet and multiple packets. The network quality of service (QoS) related issues affect the quality of performance (QoP) of control systems and sometime lead to in stability. A lot of work has been done in last decade to address these problems.

Dependability analysis is important when NCS is expected to be used for a critical application. To improve dependability, systems are designed with redundancy, maintenance features and diagnosis. These features make the dependability analysis a complex process. The research gap in this direction has been outlined. As can be seen that scope of dependability of NCS is not limited to 'control algorithms' embedded in the controller node or to the traffic behavior on network. It considers the complete system and analyzes all kind of probable failures.

## Acknowledgment

The authors would like to thank Shri Y.K. Taly for his continual support and guidance. We also thank Shri U. Mahapatra for his kind guidance and critical comments to improve the work. Continual support and encouragement from Shri G.P. Srivastava is highly appreciated.

***Abstract*—The increasing number of Electronic Control Units within the network of a vehicle is increasing the level of complexity of these networks. Thus, fault diagnosis of these sophisticated systems becomes more complex. The aim of this paper is to provide a technique to enable CAN-based fault detection in a premium vehicle network or any other network which uses the Controller Area Network (CAN) protocol for communication. The fault detection technique described here is based on a sequential behaviour of the CAN network of a vehicle and by using signal processing methods commonly used in DNA sequencing analysis, fault detection was achieved and data were classified in clusters of normal scenarios and fault scenario.**

***Keywords-Fault Diagnosis;Electronic Control Unit; Controller Area Network Protocol; DNA Sequencing; Density Power Spectrum; Cross Correlation; Classification; Clustering***

## I. INTRODUCTION

Over the past two decades, numerous mechanical and hydraulic systems have been gradually replaced by electronics due to the development of embedded systems in automotive networks of vehicles [1]. These systems precisely assist driver to take control of the vehicle through the steering, engine control, suspension, braking, stability and traction functions [2]. Each function enabled by these electronic systems has an embedded electronic control unit (ECU) [3], or is distributed among a group of ECUs. The automotive networks of vehicle became more complex as the number of ECUs increased. ECUs need to exchange information among each other. Consequently, for managing data and granting read and write access to ECUs, protocols such as Controller Area Networks (CAN), Local Interconnect Network (LIN), Media Oriented Systems Transport Network (MOST) and more recently the future technology, FlexRay, were defined. One of the most widely used protocols in automotive systems is CAN protocol defined by a Robert Bosch GmbH in early 1990's [4].

In premium vehicles there are over 50 ECUs for both infotainment and control systems which are connected to each other. This increases the level of complexity of the network. Thus, the need of fault diagnosis within these networks becomes more important. To the best of our knowledge system wide diagnostic is not yet available. Fig.1 shows a typical premium vehicle network system architecture that supports both infotainment systems and control systems.

Here the fault diagnosis of the CAN network of a premium vehicle is studied. This vehicle has two different bandwidths: Low speed CAN which takes control of body functions and high speed CAN which takes control of the critical functions of the vehicle which needs real time control. The fault diagnosis within modern vehicle network systems so that faults within the complex network of the vehicle can be identified as belonging to a certain category is investigated here. The introduced method can also be applied in new areas, adopting the real-time fault detection and on-board fault diagnosis, utilising the data rich environment of the CAN network. To verify the system's behaviour fault injection technique is used. This is inserting of an artificial fault into the system and monitoring the response of the whole system [5].

The main purpose was to find a specification in different tests to find a way to distinguish fault scenarios from normal scenarios. After investigating different aspects of the CAN network, based on DNA sequencing approach, a method for distinguishing fault and normal scenarios is presented. Classification and data mining were used to classify scenarios.

It is essential to understand the level of complexity of CAN networks. In the next section different applications of this method is provided and data types and data gathering is discussed in section 3. In section 4, a DNA sequencing based method is proposed as a method to distinguish fault scenarios from normal scenarios. Section 5 provides the results of data analysis. The conclusion of the paper is provided in section 6.

## II. Application

The CAN protocol enables robust serial communication and was introduced by German automotive system supplier Robert Bosch. It was chosen for embedded systems networked applications in various markets such as medical equipment, test equipment, industrial automation and mobile machines. More recently, CAN networks have been popular in automation and control applications too [4, 8]. The techniques used in this paper were developed on the CAN network of a vehicle, but they can also be used in any other applications apart from vehicle industry in which CAN protocols are used.

## III. Data Collection

For the data collection, specific experiments were carried out on a representative vehicle network. The aim of these experiments was to collect data relating to illegal vehicle wake-up. The vehicle network is monitored and saved on computer, utilising a CANcase device to interface to the high speed and low speed networks via USB.

### *A. Message Types*

Two types of messages are published through the CAN network of car, periodic messages and non-periodic messages. Periodic messages are sent regularly through the network for long periods of time. Non-periodic messages are a classification of messages which have an external actuator and are the main focus of this paper. In this network, there are 14 message IDs in the high speed CAN and 47 message IDs in the low speed CAN which are involved in the wake-up process.

### *B. Scenarios and Tests*

The network of the vehicle enters sleep mode when there are no interactions between ECUs to reduce the battery consumption. The sleep mode is a very low-current standby mode with bus wake-up capability [6].

When a non-periodic message is sent through the network, ECUs start to communicate by sending information about their task. After completion of the task, ECUs start to notify that they are ready to enter sleep mode, and upon receiving a confirmation message of “go to sleep mode” ECUs gradually start entering sleep mode [7]. The period of time which network goes from sleep mode to wake-up mode and then again back to sleep mode is called a test. The external action causing data to flow, which classifies the type of the test, is called a scenario.

If the non-periodic message which produced a test is normal function defined by manufacturer, the scenario is considered as a normal scenario. A fault scenario is caused by artificially injecting a non-periodic message into the network.

### *C. Data Visualisation*

Each test is stored as a text file into the computer. As each message passing through the CAN is logged into the computer, it is stored in a new line. Fig.2 shows a small part of data collected from one normal scenario. The first column is time which shows the time that messages were logged in. The second column shows in which CAN the message has been transmitted. If it is 1 it shows that message belongs to the High speed CAN and if it is 2 the message belongs to the Low speed CAN. The third row is the identification number or ID of message in hexadecimal code. Each message has individual number which shows specific data. The rest of 8 columns show data within the message in hexadecimal code. Each message has individual ID which shows specific data. In the analysis stage, each ID is converted into decimal numbers. A normal scenarios occurs when a valid wake-up message is sent, such as pressing the lock button on the car key, and a fault scenario is produced by sending a message not normally involved in wake-up, such as message 1C8, into the data. As all normal scenarios belong to the body functions of the vehicle, analysis will be focused on the low speed CAN.

## IV. Diagnostic Approaches

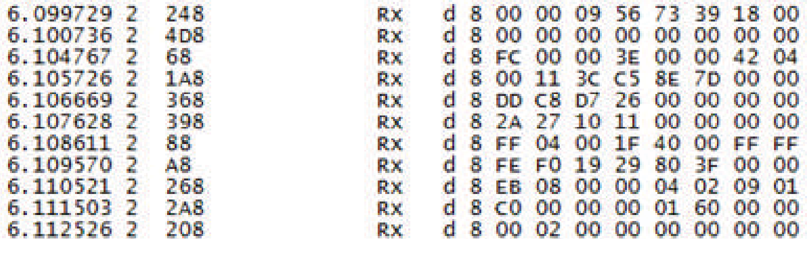
### *A. DNA Sequencing*

The digital genomic information are characterised in a form of sequence of finite numbers of entries coming after each other [9]. There are some similarities between the collected data from the real vehicle’s CAN network and DNA strands. As CAN messages enter the network through competitive arbitration, the sequence of messages becomes a feature of the network, similar to the sequence of bases in a DNA strand. In this section signal processing tools are applied on these sequences. Using classification methods described in section D fault diagnosis in the CAN network of the vehicle is achieved.

### *B. Binary Indicators*

47 different messages passing through the low speed CAN network were identified as significant. Thus 47 numbers are multiplied in its corresponding binary indicator sequences and then all of them are summed in order to build the sequence. Each sequence in the binary indicators ($u_{ID_i}$) is valued “1” if $ID_i$ exists in that sequence or a value of “0” if $ID_i$ is not present in that sequence:

$$x[n]=ID_1.u_{ID_1}[n]+ID_2.u_{ID_2}[n]+\ldots+ID_{47}.u_{ID_{47}}[n]$$
$$n=0, 1, 2, 3, \ldots, N-1 \qquad (1)$$



```

Fig. 2 An example of data collected from vehicle in text file format opened in Windows Notepad.

Frequency domain analysis using DFT is performed, using a sequence of length of N to provide the frequency content, X[k], at a frequency of k.

$$X[k]=ID_1.U_{ID_1}[k]+ID_2.U_{ID_2}[k]+\ldots+ID_{47}.U_{ID_{47}}[k]$$
$$k=0,\ 1,\ 2,\ 3,\ \ldots,\ N\text{-}1 \qquad (2)$$

In which $U_{ID_1}[k]$, $U_{ID_2}[k]$ … $U_{ID_{47}}[k]$ are the DFT of each of the binary indicator sequences x[n], producing a 47 dimensional representation of a frequency spectrum of a sequence of the messages passing through the CAN. The total spectral content, S[k], of a sequence of messages in the CAN at frequency of k is:

$$S[k]=\left|U_{ID_1}[k]\right|^2+\left|U_{ID_2}[k]\right|^2+\ldots+\left|U_{ID_{47}}[k]\right|^2 \qquad (3)$$

Three normal scenarios and two fault scenarios were established to perform fault diagnosis. Fig. 3 illustrates the Density Power Spectrum of the sequence of a test from one of the normal scenarios. The peaks of the power spectrum alter between scenarios, although all scenarios occur in a similar frequency range. In the case of DNA sequences, there are only four binary indicators and as a result there is only one peak that occurs at the frequency of N/3 where N is the length of sequence of x[n]. In the message sequences of the CAN network, there are 47 binary indicators. Hence, there is more than just one peak in the sequence of IDs.

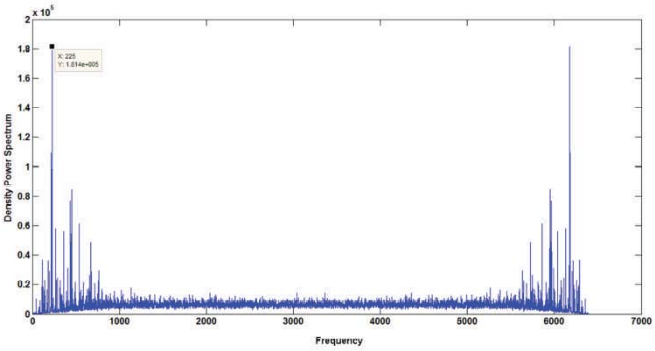

Fig. 3 Density power spectrum of a test from scenario of pressing open boot button on car key.

### C. Clustering Data

Clustering is assigning a set of data into subsets or groups so that data in the same clusters have similarity in some cases [10]. The frequency peaks in the DPS cluster the tests from these five scenarios into 3 different groups: normal scenario 1, normal scenario 2 and faulty scenarios.

### D. Classifier and Classification Method

Classification is a data mining process which aims to accurately assign target classes to data sets. The classifier which is used here is a hybrid system which effectively combines hand-built classifiers and empirical learning methods together [11]. This has the advantage of being able to utilise the characteristics of entire power spectrum in the classification.

One of simplest classification problems is binary classification between two states. This means that target group has only two possible states and classifier predicts state of the data set on a basis of whether they have the property or not. This type of classification is used in this paper.

```
$for\ i,j = 1:5$
$if\ |AXCTS(1,j) - AMVXC(i,j)| \le STD(i,j)$
        $\rightarrow scenario\ group\ of\ i$
$if\ \begin{cases} 1 \le i \le 2 & \rightarrow normal\ scenario\ group\ 1 \\ i = 3 & \rightarrow normal\ scenario\ group\ 2 \\ i > 3 & \rightarrow \qquad fault\ scenario \end{cases}$
```

Fig. 4 Algorithm of comparing a test set with training sets for classification.

#### 1) *Training Set*

Classification methods require training to be effective, which means a training data set is needed. This training set used to establish the relationship between predictors and targets. Different features can be defined in order to extract useful information from training set, and this information can be used to determine classes of future test sets.

Since the length of sequences in different scenarios was different, the test with the longest length, test l, was considered as a basis length of the sequences (length *l*). The length of test l according to the 100 randomly picked tests is 24592 sequences. For the rest of data sets in the test sets, if the length of the sequence of the messages in a test is less than *l,* then sequences of zeros are added to all of the 47 binary indicator sequences of $u_{ID_1}[k]$, $u_{ID_2}[k]$, …, $u_{ID_{47}}[k]$; and if the length of the sequence is greater than *l*, the first *l* sequences were considered, and the rest discarded. This is done because the values produced by this method are dependent on the length of the data sets. By using a standard base length, this effect will be normalised.

Next, the DFT of all the binary indicators are calculated and the density power spectrum of the whole sequence is achieved using equation 3. The density power spectrum of a discrete signal of the messages passing sequentially through the CAN network of the vehicle is a discrete signal. For classifying different scenarios, these discrete signals need to be compared to each other and form the basis of the classification scheme.

#### 2) *Comparison Tool*

The method chosen to compare these discrete signals is the cross correlation. It is a common method for estimating the correlation rate between two series. For a discrete signal, cross correlation is:

$$R_{xy}(d)=\begin{cases}\sum_{n=0}^{l\text{-}d\text{-}1} x[n+d]y^*[n] & d\geq 0 \\ R_{xy}^{\ *}(d) & d<0\end{cases} \qquad (4)$$

In which, *l* is the base length of the data sets and d is the signal delay. With the delay of d in x[n], the degree of correlation between x[n] and y[n] is calculated by dot-product of these two signals. The signals are considered to be periodic, so the cross correlation has twice of the length of its original signals. This operation was performed in MATLAB using the cross correlation command, which by default, computes the raw correlation between two signals without normalising it. The lengths of all data sets are converted to *l* so the normalised cross correlation which is the cross correlation divided by the length of the signals is achieved in advance (biased normalisation).

$$R_{xy,\ \mathrm{biased}}(\mathrm{d})=\frac{1}{l}R_{xy}(\mathrm{d}) \tag{5}$$

20 tests are chosen from each of the five scenarios, giving a total of 100 tests. The density power spectrum of all the 100 tests is calculated. Hence, there are 100 discrete time signals available. The cross correlation of each of the two of these power spectrums are calculated. The result of these calculations are stored in a massive cell with a dimension of 100×100 and in each of these cells, the cross correlation results with the length of 2×*l* is stored.

The peak of these cross correlations shows the maximum correlation of the two tests. The cross correlation of the density power spectrum of each test set and each test in the training sets are calculated and stored in a massive cell. For the calculated cell of the cross correlation with the dimension of 100×100 maximum values of the cross correlation is stored in a matrix with the same dimensionality to create the training sets.

Next, the matrix is divided into 5 matrices with dimension of 20×20 which are the maximum values of cross correlation between the scenario 1 and all the 5 scenarios (including auto-correlation with scenario 1). This is the procedure of making the training set for the first scenario. This should be completed for the second scenario, the third scenario and so on.

The maximum value of the cross correlation, shows rate of correlation between two scenarios. Average of maximum values of the cross correlation (AMVXC) of the 20 tests of each matrix are calculated and saved for each scenarios (Table 1). Also the Standard Deviation (STD) of these maximum values of the cross correlation of these 20 tests are calculated and stored for each scenario (Table 2).

The average value and the standard deviation of each matrix create the training sets for the classification. Fig. 5 shows the steps and the procedure of creating the training sets for the classification of first scenario. So the result of all these calculation will be a 5×5 matrix of average of the maximum values of the cross correlation between the scenarios and another 5×5 matrix is the standard deviation of the maximum values of the cross correlation between the scenarios.

### 3) *Classifying a Test Set*

For each given test set the cross correlation between the density power spectrum of that test set and the density power spectrum of the 100 tests used to build the training set is calculated. This results in 100 cross correlations.

The maximum value of the cross correlation between the test set and the 20 tests of the scenario 1 will be stored in a separate matrix; the maximum value of the cross correlation between the test set and the 20 tests of the second scenario will also be stored in another matrix and so on. Eventually, there will be 5 matrices with dimension of 1×20. The average of these values in each matrix will be calculated and stored in a matrix called Average of XCorrelation of Test Set or AXCTS (i ,j) (Table 3).

The AXCTS is then subtracted from each of the scenario's AMVXC (Table 4). Comparing each row with its counterpart in Table 2, it can be seen that this example test belongs to scenario 2 (normal scenario group 1) as the values in this row are less than those in Table 2. This algorithm is illustrated in Fig.4.

## V. RESULTS

Six test sets from each of the 5 scenarios (total of 30 tests) are randomly picked and considered as the test sets. The classification procedure is carried out on each test set. The confusion matrix in Table 5 shows 100% accuracy for assigning scenarios to the 3 classification groups. Fig.6 shows these 30 test sets in AXCTS matrix classified in the three clusters. In this plot each row of the AXCTS matrix is shown with 5 markers representing AXCTS value for its corresponding scenario. As it can be seen for all tests, the clusters are distinguished.

TABLE I. THE AVERAGE OF THE MAXIMUM VALUES OF THE CROSS CORRELATION FOR THE TRAINING SET

| AMVXC | Scenario1 | Scenario2 | Scenario3 | Scenario4 | Scenario5 |
|---|---|---|---|---|---|
| **Scenario 1** | 68.5296E+11 | 64.8896E+11 | 90.7273E+11 | 32.8471E+11 | 34.0116E+11 |

## VI. CONCLUSION

In this paper, development and diversity of networks in vehicles was studied. The main focus was the Controller Area Network (CAN) protocol as a communication tool. Moreover, it was discussed that fault diagnosis in electronic systems and networks of a vehicle is becoming an increasingly important factor.

For the fault detection, a data mining technique was applied and, from comparison to DNA, the sequencing nature of the data was considered as a feature that could be used as a classifier. The algorithm used here as a diagnosis tool was developed and coded using MathWorks MATLAB R2009a.

Signal processing methods where used to derive the density power spectrum of the binary indicator sequences from the messages sequences in each test. It can be concluded that the place of occurrence of the peaks in the density power spectrum are different among the scenarios and it can be used as the classification feature. According to this feature, three clusters were identified: the normal scenario 1 cluster, the normal scenario 2 cluster and the fault scenario cluster.

Furthermore, instead of just considering the peaks the whole sequence of the power spectrum density was considered. The density power spectrum is a discrete signal in frequency domain and as comparison tool for the classification. The available data was split into training sets and the test sets. The cross correlation of the training sets and the test sets was utilised as a classification feature. This hybrid classifier was able to distinguish the fault scenarios from the normal scenarios in 100% of cases, showing that this method is an effective classifier for these data sets.

This technique was developed on the CAN network of a vehicle, but application of it is not limited to vehicle industry. It can also be used on other backgrounds which use the CAN protocol or even on other networks in a vehicle such as LIN and MOST. Also new methods which adopt real time fault detection and on-board fault diagnosis and use the large amount of information available from the system network to pinpoint the cause of detected faults can use the technique introduced here. The real time fault detection system requires a generic electronic control unit (generic ECU) to monitor data at fast speeds in order to find faults. This requires algorithms with a small numbers of variables in order to respond quickly to faults. This extracted feature may be a useful variable for this purpose.

This method is most effective when a sequence of messages is expected in response to an event (such as network wake-up and shutdown), with the advantage of not needing to understand the underlying network functions. However, other types of faults may not be as clearly defined as this. Network fault detection and diagnosis is a complex issue with no single answer, requiring multiple approaches to categorise faults. This method can provide an additional tool to further research in this area.

chenzhixin@bucea.edu.cn

***Abstract*—As an extensible lightweight message processing framework, SOAP has become the lightweight communication protocol for large scale data exchange in the distributed environment. However, one of the most important problems of SOAP is its relatively poor performance which leads to its limit in high performance applications. The paper proposes a SOAP message transmission mechanism based on variable sliding window, which can improve the performance of SOAP and support transferring data of large, flexible or unknown size via SOAP. In addition, data segmentation is designed to transfer large data and variable-size data and variable sliding window is used to control and improve the transmission efficiency of SOAP messages. The algorithm of application level congestion control was proposed and the transmission reliability of SOAP message was discussed with respect to four exception cases. Finally, the two main impact factors for the transmission efficiency based on variable sliding window such as the size of the sliding window and the length of data slice are analyzed and tested. Simulation results show that transmission efficiency is effectively improved by a reasonable parameters set of the variable sliding window.**

***Keywords-SOAP;sliding window;congestion control; transmission reliability***

## I. INTRODUCTION

Data exchange is the common, fundamental and critical requirement of distributed application in network environment. Data exchange is mainly used to solve the interoperability of different data resources in the infomationization, i.e. to solve the integration and sharing of different data resources between different heterogeneous systems. The essence of data exchange is the sharing and exchange of data. The data exchange platform is completely based on Web service technology using SOAP [1] as its communication protocol. SOAP is an extensive lightweight message processing framework based on XML [2], and has become a de facto standard for data exchange in the open network environment.

With the development of distributed computing technology, more different systems and networks at different speed are connected to the Internet, which results in more serious network congestion. Therefore, one of the most important part of Internet QoS[3] is how to deploy the peer communications at different speeds in different network to match capacity of the network. Large scale communications require effective transmission efficiency. Though SOAP provides a powerful interoperability, its own characteristics cause its lower transmission efficiency, e.g. when packaging a SOAP message, the transcoding and parsing will consume a large amount of time; generally, after data are package into a SOAP message, the data package will become more times than the original size; In addition, the time consumption of network transmission will result in the transmission of SOAP messages to take a long time. To the applications which require the higher efficiency of data transmission or large scale data transmission, SOAP can’t be effective to meet practical requirements.

According to the lower transmission efficiency of SOAP message, there are many improvements to improve the transmission efficiency as follows: to improve the transmission efficiency through improved SOAP binding [4]; according to different applications, using the appropriate SOAP message encoding rules [5]; to reduce construction and parsing of SOAP messages [6]; using compression technology to compress the SOAP message [7].

Sliding window technology is mainly used for information flow control, to coordinate the work pace of the sender and the receiver, to avoid the loss of data because the sender sends data too fast to the receiver too late to deal with [8]. This technology is not only widely used in the communication between Internet and the other network, but also used in information exchange of the different layers within the network system. In theory, sliding window can be used in anywhere which requires the flow control.

The paper proposes the VSW-SOAP(Variable Sliding Window-SOAP) to effectively improve the efficiency of data transmission. VSW-SOAP uses variable sliding window mechanism in SOAP message transmission and takes data slice as the SOAP message attachments. The basic data unit in the variable sliding window is the SOAP message with slice attachment.

The paper is organized as follows: Section II analyzes the principle of VSW-SOAP, defines the variable sliding window, discusses SOAP attachment segmentation, the structure of SOAP message and the transmission workflow of SOAP messages; Section III proposes an application level congestion control algorithm based on variable sliding window; Section IV

This work was funded by Beijing municipal outstanding talents Fund(Grant No. 2011D005017000002) and Dr. Start Fund of BUCEA (Grant No.101101815).

discusses the reliable transmission mechanism for SOAP message; Section V analyzes the main factors of VSW-SOAP and gives the simulation results; the conclusion and outlook for further work is given in Section VI.

## II. PRINCIPLES OF VSR-SOAP

### A. Variable sliding window

For data transmission, in extreme cases, unbounded input stream requires unbounded memory, which is clearly not applicable. Therefore, a window strategy is used to limit the number of tuples for each input stream stored in the processing of unbounded flow. The sliding window is set an interval on the data stream which only includes part of the new data of the data stream. With the arrival of new data, the window proceeds to replace the old data with new data. Therefore, the sliding window can be seen as a historical snapshot of a limited part of the data stream, while taking advantage of the characteristics of the sliding window to meet the real time and unbounded requirements of data flow.

As a historical snapshot of a limited part of the data stream, sliding window can be divided into time-based sliding window and tuple-based sliding window. The two sliding window usually assume that the window size is unchanged. In previous data transmission algorithms, many algorithms are based on the unchanged sliding window mechanism which achieves considerable results in terms of time and space complexity. However, these technologies have usually ignored the time-varying characteristics of specific issues in data stream. Therefore it is difficult to implement adaptive adjustment of data model when the data distribution characteristics are changeable [9, 10].

Variable sliding window can adaptively adjust the window size according to the change of data stream flow and data distribution in order to achieve a minimum consumption of memory space and processing time. The principle of variable sliding window is as follows: the sender maintains a continuous data set to be sent, called the sending window; at the same time, the receiver also maintains a continuous data set to be received, called the receiving window. The window is used for store data during message transmission. When updating data, the window will slide. In accordance with the principle of the sliding window, the sender has a sending window and the receiver has a receiving window. The sending window is used to implement flow control. The size of sending window represents the maximum number of data sent by the sender when the acknowledgment message is not received. The receiving window is used to control whether data can be received. At the receiving node, only when the serial number of the data is in the receiving window, the data can be accepted. The window size of variable sliding window is determined according to the data flow change. When the flow rate is quickly, reduce the size of the sliding window; otherwise, when the flow rate is very slow, increase the size of the sliding window in real time.

The differences between the SOAP sliding window and the other sliding window lies in: the data stored in SOAP sliding window are the SOAP messages, the function of the sliding window is to control the speed of the SOAP messages, to implement the network congestion control and to ensure a reliable orderly transmission of SOAP message attachment data. After the transmission is finished, the sliding window of the receiver will reassemble the slice data in the received SOAP message attachments into the original data.

### B. SOAP attachment segmentation

If the data of the SOAP message with attachments is large, it is difficult to read the whole data into memory only once. Even if the data can read only once, it will be very difficult and time consuming for large data encryption and decryption operations. Especially when the network quality is poor, if there are transmission data errors, retransmitting the entire data is costly. Thus, for the large scale data attachment in the SOAP message, data can be segmented into multiple slices. The data slices can be encapsulated as a new SOAP message attachment using MIME, DIME or XOP. Each time the sender can send a SOAP message attachment containing one or more data slices.

The process of data segmentation and encapsulation as a SOAP attachment is shown in Figure 1.

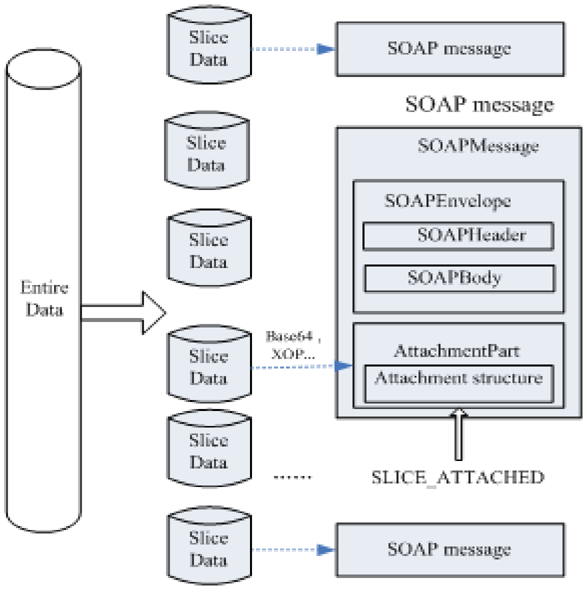

Figure 1. The process of data segmentation and encapsulation as a SOAP attachment

Because the data encapsulated in the SOAP message attachment is not complete data, but one or more data slices, the body of the SOAP message is required to at least include the following information: SOAP message number(SOAPID), the data number to be sent(DataNumber), the slice number (SliceNumber), whether it's the last data (isLastData), whether it is the last slice (isLastSlice). SOAPID is used to uniquely identify the SOAP message number that the data slice belongs to. DataNumber is used to represent the data that the data slice belongs to. SliceNumber is data slice number which represents the current transmission data slice. isLastData represents whether it's the last data. isLastSlice represents whether it's the last data slice. In this way, if there's requirement to transmit large scale attachments data, SOAP message data can be broken down into multiple small SOAP messages with a slice attachment.

By SOAP attachment segmentation, it avoids to read the entire data into memory at one time which is useful to encrypt and decrypt. Besides, the approach also supports flexible or unknown size SOAP attachment.

### *C. The structure of the SOAP message*

In the variable sliding window, the SOAP message is divided into data message and acknowledgment message.

The data message is sent by the sender and each data message contains one or more data slices. The length of slice is determined through consultation between the sender and the receiver. The slices are encapsulated in the SOAP message in accordance with the agreed specification. The basic information of data message is indicated in the body of SOAP message, which mainly includes: SOAPID, DataNumber, SliceNumber, IsLastData, IsLastSlice, the length of each data slice(size), safety information(Encryption). The structure of data message is shown in Figure 2.

```
 <TransportRequest>
      <SOAPID/>
      <DataNumber/>
      <SliceNumber/>
      <IsLastSlice>yes/no</IsLastSlice>
      <IsLastData>yes/no</IsLastData>
      <Encryption/>
       <Data> </Data>
</TransportRequest>
```

Figure 2. The structure of data message

The acknowledgment message is sent by the receiver to confirm the data message issued by the sender. The acknowledgment message of the SOAP message body contains the following information: SOAPID, the type of acknowledgment message(ACKType), the data number confirmed(ACKDataNumber), the slice number confirmed(ACKSliceNumber) , IsLastData, IsLastSlice, Specific response information(ResponseInfo).The structure of acknowledgment message is shown in Figure 3.

```

        <IsLastSlice>yes/no</IsLastSlice>
        <ResponseInfo></ResponseInfo>
</TransportResponse>
```

Figure 3. The structure of acknowledgment message

### *D. The workflow of VSW-SOAP*

Based on variable sliding window, the workflow of the SOAP message transmission mechanism can be described as follows:

1) The connection between the sender and the receiver can be established through the three-way handshake. The three-way handshake can be implemented based on predefined transmission protocols and ports. In the three-way handshake, the following information are required to provide: SOAP attachment package specifications, transport protocols, sliding window size, the length of slice, timeout interval, the maximum number of retransmission once timeout, the data slice number in a single SOAP message;

2) According to the conventions built by three-way handshake, the sender and the receiver are initialized, including initialization of the sliding window, starting the timers of the sender and receiver;

3) The sender reads data in accordance with the agreed length of slice, then packages the data slices into data message, places data message in a sliding window to be sent. After the transmission process is finished, the sender will wait for acknowledgment messages from the receiver;

4) The receiver receives and parses the data message. According to the parsing results, the receiver will determine whether to place the data into the sliding window or to discard the data. Once all data have been received, the sliding window will slide and the receiver will send the acknowledge message to the sender;

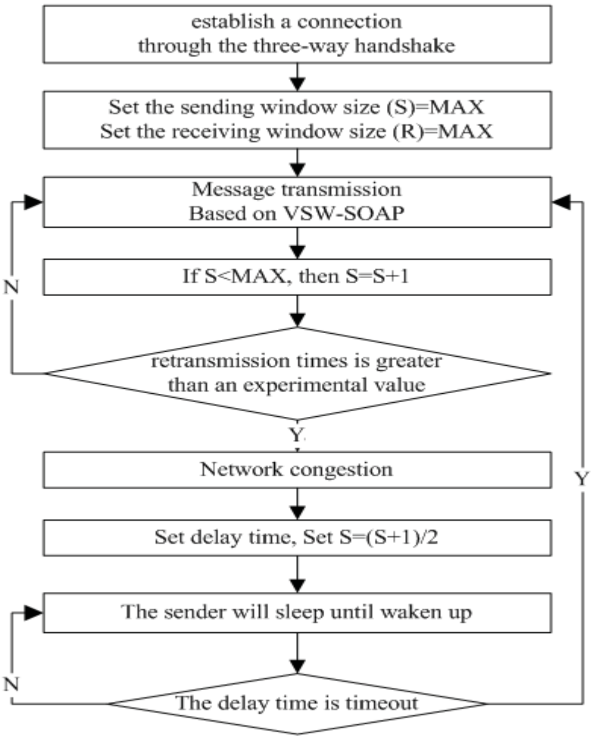
5) Once the sender receives the acknowledgment message, it will parse the SOAP message and determine whether all data have been sent according to the parsing results. If not all data have been sent, the sender will determine whether to retransmit data message or to slide the window in order to read into the follow-up data.

The sender and the receiver will repeat Step 4 and Step 5 until all data are sent.

## III. THE ALGORITHM OF APPLICATION LEVEL CONGESTION CONTROL

Though the SOAP message transmission mechanism based on variable sliding window can effectively improve the transmission efficiency, it also has some disadvantages, e.g. it can cause network congestion when the data are injected into the network too fast. TCP protocol itself has a congestion control mechanism. TCP congestion control usually takes the following three technologies: slowly start, accelerate the decreasing and congestion avoidance [11]. However, because TCP is the transport layer protocol, if the application layer still uses TCP's three congestion control technologies and frequently changes the size of sliding window, it will lead to inefficiency.

This section proposes an application layer congestion control algorithm based on variable sliding window in order to ensure the smooth transmission of the SOAP message. The algorithm of application layer congestion control is shown in Figure 4.



establish a connection
through the three-way handshake

Y
Set delay time, Set S=(S+1)/2
The sender will sleep until waken up
N
The delay time is timeout

Figure 4. The algorithm of application layer congestion control

1) When the sender and the receiver establish a connection through the three-way handshake, set the maximum(MAX) of the sending window size acceptable to both sides, then set the sending window size (S)=MAX and the receiving window size (R)=MAX;

2) In accordance with the sending window size, a sliding window is used to transmit the SOAP message;

3) Once the sender receives an acknowledgment message, it will determine if the sending window size (S) is less than the maximum (MAX) of sending window. If S is less than the maximum of sending window, then S = S +1; Otherwise, keep the sending window size unchanged;

4) During transmission, if the retransmission times of a SOAP message is less than or equal to an experimental value (e.g. 3 times), the system will consider that network transmission is smooth, then will repeat Step2 to Step 4.

If the retransmission times of a SOAP message is greater than an experimental value (e.g. 3 times), the system will consider network congestion, suspend the data transmission for DELAY_T, set S=(S+1)/2. At this time if the receiver did not receive the message for a long time, the receiver will sleep until waken up by the sender.

5) Determine the delay time is timeout. If the delay time is timeout, then continues to suspend data transmission, or proceeds to repeat Step 2 to step 5 until the data transmission is completed.

During the algorithm of congestion control, DELAY_T means data transmission pause time which depends on the congestion time of current network. If the receiver doesn't receive the sender's data for a long time, it will go to sleep state or termination state, and finally will be wakened up by the sender.

## IV. THE TRANSMISSION RELIABILITY OF SOAP MESSAGE

In order to ensure the transmission reliability of the SOAP message based on variable sliding window, the following four cases will be considered during the specific analysis and design: loss of data message, loss of acknowledgment message, duplicate message and data timeout.

Once the data message is lost, if the sender still do not receive the acknowledgment message after waiting for a certain period of time, it will resend the data message. Once the acknowledgment message is lost, if the sender still do not receive the acknowledgment message after waiting for a certain period of time, it will also resend the data message. When the receiver receives the duplicate data message, the receiver will discard the duplicate message, and resend the confirmation of the maximum data slice. Once the receiver waits for data messages timeout, the receiver will resend the confirmation of the maximum data slice, and then wait for the next timeout. If the receiver waits more than timeout maximum value, it can be seen as failure of the transmission.

## V. SIMULATION

In VSW-SOAP, the main factors affecting the transmission efficiency are as follows: sliding window size S (the sending window size Ssender, the receiving window size Sreceiver), the data slice length L and the network transport protocol. The paper won't discuss the network transport protocol for it depends on its realization.

Ssender is negotiated between the sender and the receiver when establishing a connection. Besides, during the transmission, the sender and the receiver can also negotiate to adjust the sliding window size and the length of data slice based on network bandwidth, packet round trip delay, or their own hardware and software environment. Sreceiver is decided by the receiver. If Sreceiver is less than Ssender, the received data is easy to exceed the receiving window range, resulting in data frequently discarded; on the contrary, if Sreceiver is greater than Ssender, it can cause excessive memory overhead although it can cache more data messages. Thus Ssender is best equal or similar to Sreceiver.

A number of test cases are designed to test that S and L how to affect the transmission efficiency. The tests are conducted using the sliding window size from 1 to 50, and the sliding window size is equal to the receiving window size. Because the length of slice is restricted by memory size, the actual test range of length of slice gradually increases from 20K to 10M.

The relationship between the transmitting time and the sliding window size is shown in Figure 5. During the test, HTTP is used as the transport protocol and the length of slice is set 800K.

It can be seen from Figure 5 that the larger the sliding window size, the shorter the transmitting time. When the sliding window size increases to a certain extent, the transmitting time will reach an extreme and almost cease to decrease. The larger the sliding window size, the more the consumption of resources. When the window size increases to a certain extent, the memory and CPU processing speed will become a performance bottleneck. Under the current test environment, when the window size increases from 5 to 10, the transmission efficiency has been increased to a better state. In addition, the sliding window can eliminate the transmitting time difference due to the RTT. When window size increases to a certain extent, the transmitting time is almost the same under the conditions of different RTT.

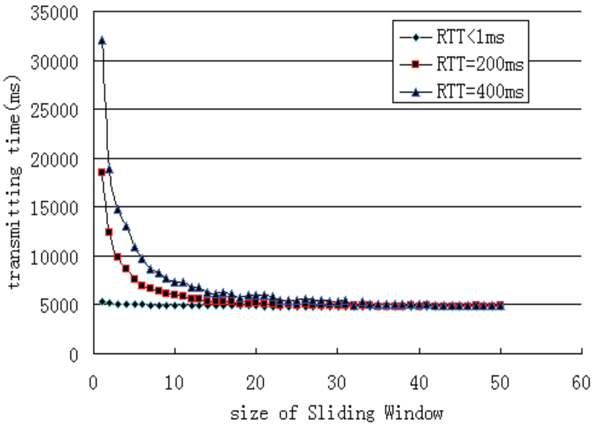

Figure 5. The relationship between the transmitting time and the sliding window size

The relationship between the transmitting time and the length of slice is shown in Figure 6. For the test, RTT is equal to 100ms and the window size is 6. The length of slice gradually increases from 20Kbytes to 10Mbytes.

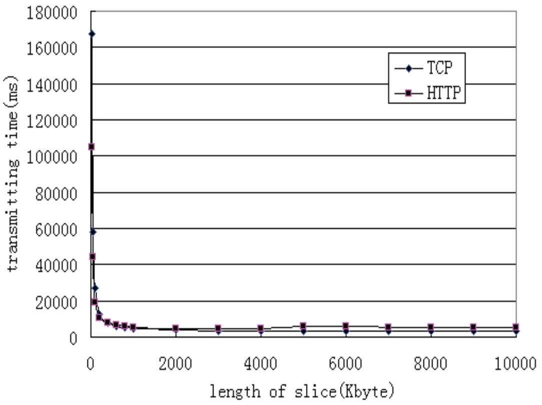

Figure 6. The relationship between the transmitting time and the length of slice

It can be seen from figure 6 that the greater the length of slice, the shorter the transmitting time. When the length of slice increases to a certain extent, the transmitting time will reach an extreme and almost ceases to decrease. Obviously, the length of slice is restricted by the memory, transmission concurrency and CPU processing capacity. Therefore, the length of slice must be set an appropriate value according to practical requirement. Under the current test environment, when the length of slice increases to 400K, the transmission efficiency has been increased to a better state.

## VI. Conclusion

As an extensible lightweight message processing framework, SOAP has become a de facto standard for information exchange in the open network environment. As a SOAP message transmission mechanism based on variable sliding window, VSW-SOAP can effectively improve the transmission efficiency. On the basis of the analysis of the problems faced by data exchange based on SOAP, this paper puts forward the SOAP message transmission mechanism based on variable sliding window, designs an application level congestion control algorithm and discusses the transmission reliability of SOAP message. Simulation results show that transmission efficiency is effectively improved by a reasonable set of parameters of the variable sliding window. With the further development of Web applications such as e-commerce, the VSW-SOAP will also play a greater role.

# Bézier Curve based Trajectory Planning for an Intelligent Wheelchair to Pass a Doorway

Ling Chen, Sen Wang, Huosheng Hu and Klaus McDonald-Maier
School of Computer Science and Electronic Engineering
University of Essex, Colchester CO4 3SQ, United Kingdom
E-mail: {lcheno, swangi, hhu, kdm}@essex.ac.uk

***Abstract*—Door passing is the basic capability of an intelligent wheelchair. This paper presents a novel approach to address the door passing issue using Bézier curve based trajectory planning. The planed path consists of two segments: one from corridor to door and the other from door to the goal position. For each segment, an optimal Bézier curve is generated as a reference trajectory for an intelligent wheelchair to travel smoothly and accurately subject to corridor constraints, curvature limitation and obstacles. The simulation is conducted to verify the feasibility of the proposed approach, and the results show a good performance in terms of tracking accuracy and good maneuverability.**

***Keywords*-Door passing; Bézier curve; optimization; trajectory planning; obstacle avoidance**

## I. Introduction

Door passing is considered as the fundamental capability of intelligent wheelchairs that are operated in an indoor environment. The wheelchair users are normally elderly and disabled, who may suffer some types of disabilities such as Parkinson's disease. They have difficulty in operating wheelchair using a traditional joystick, not to mention to pass through the constrained doorway. Therefore, there is great demand that the intelligent wheelchair could autonomously travel through confined and narrow doorways without user intervention or carer supervision.

In general, this problem can be addressed by two typical methods - obstacle avoidance and trajectory planning. Among all the methodologies solving obstacle avoidance, potential field based method gains the most popularity [1]–[3]. Although it provides an elegant solution to the obstacle avoidance problem, it has the disadvantage of falling into a local minimum as well as being undulating in some singularity point which is unacceptable for the wheelchair, as human being sitting on the wheelchair will feel uncomfortable in this circumstance. Meanwhile, some existing wheelchairs provide the door passage mode, such as the TAO one [4]. However, to the best of our knowledge, they all use the range finder sensor, e.g., infrared, to detect the door frame and avoid it at a low moving speed and the curvature of the traveling trajectory is not smooth and continous [4].

Recently, a trajectory planning based method drives the wheelchair to follow a desired path. Due to the small ratio of the door width to the wheelchair width (only about 300 mm access space for the wheelchair [5], see Fig. 1), it is difficult for the wheelchair to pass through the door at every heading direction. A frontier point method integrated with simultaneous localization and mapping was used for door passing of wheelchair in [6]. However, it needs to continuously generate the mean frontier points, which makes the curves not smooth and time consuming. A Case-Based Reasoning method for door passing was also presented in [7]. But it neither considered the smoothness of the trajectory nor the narrow structure of the doorway.

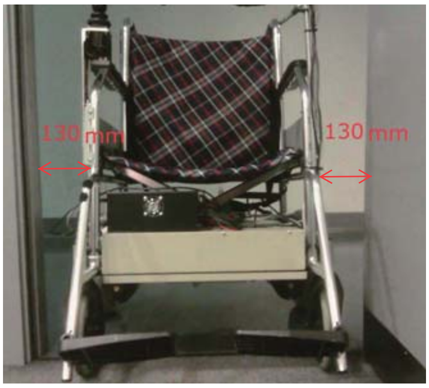

Fig. 1. Wheelchair in the doorway

In order to produce a smooth trajectory, trajectory planning based on circular arc [8], spline [9] and Bézier curves [10], [11] can be adopted. Jolly $et.\ al$ [10] proposed an efficient, Bézier curve based approach for the trajectory planning of a mobile robot, considering the boundary conditions, velocity limitation, etc. Choi $et.\ al$ in [11] presented two trajectory planning algorithms based on Bézier curve for autonomous vehicles with constraints produced by waypoints and corridor width. However, it regards the vehicle as the particle, which is infeasible for the door passing of the wheelchair, in addition the obstacle avoidance has not been taken into account.

This paper intends to propose an efficient strategy for an intelligent wheelchair to pass through the narrow doorway in real time and with the greatest possible success. It introduces the Bézier curve based trajectory planning and the constrained optimization to generate smooth trajectories for the wheelchair to follow without significantly reducing the speed. Moreover, the proposed scheme can avoid the static obstacles while moving to the destination.

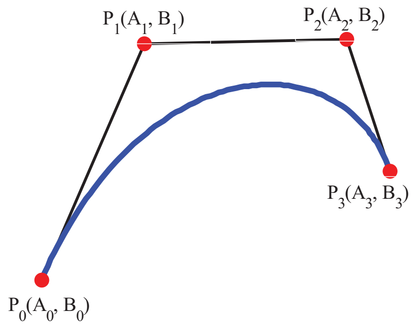

Fig. 2. A cubic Bézier curve defined by four control points

The rest of this paper is organized as follows. Section II gives a brief introduction about the Bézier curve. The door passing strategy is elaborated in Section III, where the problem description, trajectory planning based on Bézier curve as well as the wheelchair control are presented. Section IV presents the simulation results which verify the feasibility of the proposed door passing strategy based on Bézier curves. Finally, a brief conclusion and future work are presented in Section V.

## II. Bézier Curve

Nowadays, Bézier curve as a powerful and efficient tool has been widely used in computer graphics, animation and fonts because of its capacity of smoothing [12]. The Bézier curves can be formulated as

$$B(t) = \sum_{i=0}^{n} b_{i,n}(t)P_i, \quad t \in [0,1] \tag{1}$$

where the polynomials

$$b_{i,n}(t) = \binom{n}{i} t^i (1-t)^{n-i}, \quad i = 0, \ldots n \tag{2}$$

are known as Bernstein basis polynomials of degree $n$, and the binomial coefficient, $\binom{n}{i}$ is expressed as $C_i^n$. The points $P_i$ are called control points for the Bézier curve. The polygon formed by connecting the Bézier points with lines, starting with $P_0$ and finishing with $P_n$, is called the Bézier polygon (or control polygon). The convex hull of the Bézier polygon contains the Bézier curve. The Bézier curves of degree 1, 2 and 3 are called linear, quadratic and cubic Bézier curves respectively, and quadratic and cubic Bézier curves are most common.

The reasons for why Bézier curves can be ideally used for trajectory planning in robotics rest with the following properties of Bézier curve:

- The curve begins at $P_0$ and ends at $P_n$. This is the so called *endpoint interpolation property*.
- The start (end) of the curve is tangent to the first (last) section of the Bézier polygon.

These two properties are exactly the requirements of trajectory planning given two points(start and goal points). The quadratic curve and other curves of higher degree can satisfy with the requirements. However, the quadratic curve is less flexible than cubic curves, and higher degree (more than 3) curves are more computationally expensive to evaluate. Therefore, in this paper, to make a balance between flexibility and computational expense of the proposed curve, cubic curves are chosen as the Bézier curves for trajectory planning for the wheelchair to pass the doorway.

According to (1) and (2), the cubic Bézier curve defined by four control points $P_0(A_0, B_0), P_1(A_1, B_1), P_2(A_2, B_2)$ and $P_3(A_3, B_3)$ in Fig. 2 can be expressed as

$$\begin{aligned} B(t) &= \sum_{i=0}^{3} b_{i,n}(t)P_i \ , \ t \in [0,1] \\ &= (1-t)^3 P_0 + 3(1-t)^2 t P_1 + 3(1-t)t^2 P_2 + t^3 P_3 \end{aligned} \tag{3}$$

As we only consider 2-D environment, the cubic Bézier curve can be specified in the form of $B(t) = (x(t), y(t))$ where

$$x(t) = A_0(1-t)^3 + 3A_1(1-t)^2 t + 3A_2(1-t)t^2 + A_3 t^3 \tag{4a}$$

$$y(t) = B_0(1-t)^3 + 3B_1(1-t)^2 t + 3B_2(1-t)t^2 + B_3 t^3 \tag{4b}$$

## III. Door Passing Strategy

### A. Problem Description

We consider the door passing problem of a wheelchair as a trajectory planning problem. As long as the wheelchair is able to follow the designed path which passes through the doorway without colliding with the door wall as well as other obstacles, then the door passing problem will be well solved. As can be seen in Fig. 3, the wheelchair in the corridor intends to traverse the door on its left side and reach the target in the room. To successfully achieve this goal, the door passing strategy should comply with the following criteria:

- The actual trajectory of the wheelchair has to be graceful and smooth without oscillating or ambiguity, as shown in Fig.3, where the red line represents the desired trajectory in which no obstacles are in the way, and the blue dash line represents the desired trajectory avoiding obstacles.
- Due to the mechanical constraints of the wheelchair, the curvature of the trajectory needs to be limited to certain ranges so that the turning rate will not be too high.
- It is easy for the wheelchair to bump into the door frame if the heading of the wheelchair is not perpendicular to the door plane because of the large volume of the wheelchair. Therefore, it is demanded that the heading of the wheelchair is perpendicular to the door plane when the wheelchair arrives at the $P_d$ point.

We propose the general methods for the wheelchair to pass the doorway as: first, dividing the whole trajectory $\overset{\frown}{P_sP_dP_t}$ into two parts - $\overset{\frown}{P_sP_d}$ and $\overset{\frown}{P_dP_t}$; second, designing the desired trajectory $\overset{\frown}{P_sP_d}$ and $\overset{\frown}{P_dP_t}$ independently based on Bézier curve, to make sure each trajectory meet with the criteria stated above; finally developing an algorithm to control the wheelchair to follow the desired trajectory.

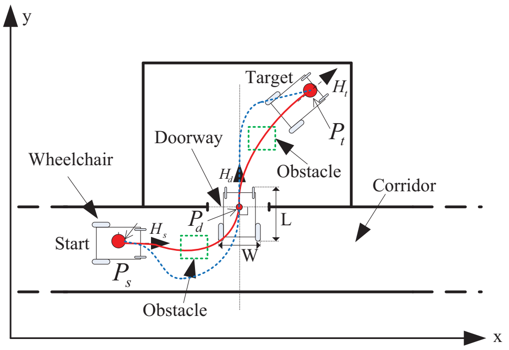

Fig. 3. The schematic description of door passing process of a wheelchair. The red line represents the desired trajectory where no obstacles are in the way, and the blue dash line represents the desired trajectory avoiding obstacles. $P_s$ represents the current position of the wheelchair, $P_d$ is the middle position of the door, and $P_t$ is the target position that the wheelchair is supposed to reach.

### *B. Trajectory Planning based on Bézier Curve*

In this subsection, the trajectory planning for door passing is presented. Its key idea is that the control points which totally define the shape of the Bézier curve are determined using optimization method. The merit of this method lies in the minimum curvature changes of the curve, satisfying the various constraints of the wheelchair and environment and providing the smoothest Bézier curve.

The trajectory planning strategies are divided into two categories depending on whether there is an obstacle. In Fig.3, let $H_s$, $H_d$ and $H_t$ denote the headings at the positions $P_s$, $P_d$ and $P_t$ respectively, and denote the control points of $\widehat{P_sP_d}$ and $\widehat{P_dP_t}$ to be $P_{ci}$ and $P_{ri}$, $i \in 0, 1, 2, 3$, respectively. Then, the trajectory planning is required to generate the cubic Bézier curves which connect the points $P_s$, $P_d$ and $P_t$ with the orientations $H_s$, $H_d$ and $H_t$. Because the target in the room is obstructed by the wall, the wheelchair cannot decide the exact position of the target until it closes to the door. Therefore, the whole trajectory $P_s\widehat{P_d}P_t$ has to be divided into two segments - $\widehat{P_sP_d}$ and $\widehat{P_dP_t}$, for which the Bézier curve based trajectories are independently designed.

*1) Trajectory Planning without Obstacle:* The trajectory planning without obstacle only needs to consider the positions and headings of the beginning and end points of each Bézier curve. There is no demand for obstacle avoidance.

*a) Segment from Corridor to Door:* When the desired door is detected, the wheelchair uses its current position $P_s$, the middle of the door $P_d$ and their corresponding orientations to perform the optimization based control point estimation. The door detection can be achieved by some established techniques, such as computer vision. Since $P_s$ and $P_d$ correspond to the control points $P_{c0}$ and $P_{c3}$ respectively, which are known, the parameter estimation only needs to calculate $P_{c1}$ and $P_{c2}$, which completely determine the shape of the curve once given $P_{c0}$ and $P_{c3}$.

In order to meet the aforementioned requirements, several constraints are devised for the optimization according to the environment and the reality. They are summarized into three types.

i) Corridor structure. In reality, the wheelchair should always be within the corridor while it is turning to the doorway. Therefore, the planned trajectory has to be constrained by the physical structure of the corridor, such as corridor width. Owing to the convex property of Bézier curve, the course can completely lie in the corridor once all the control points are in it. Therefore, the boundary constraint is that $P_{c1}$ and $P_{c2}$ can only be chosen from the corridor area. This can be formulated as

$$P_{c1} \in C \quad P_{c2} \in C \tag{5}$$

where $C$ is the region of the corridor. With this requirement, the produced path can be constrained in the corridor.

ii) Orientations. Since the trajectory planning begins with the heading $H_s$, the slope of tangent line of the designed Bézier curve at position $P_{c0}$ should equal $H_s$. Similarly, the tangent line at $P_{c3}$ should be the normal of the door at the middle in order to overcome the small ratio of door width to the wheelchair's. Therefore, the possible ranges of $P_{c1}$ and $P_{c2}$ can be further reduced to one dimension by the means of this idea. In other words, the $P_{c1}$ and $P_{c2}$ must respectively locate on the tangent lines at positions $P_{c0}$ and $P_{c3}$ due to the aforementioned second property of Bézier curve in Section II. Moreover, $P_{c1}$ has to be searched along the direction of $H_s$, while $P_{c2}$ only can lie on the opposite direction of $H_d$. Hence, the constraints are

$$\theta_0 = \arccos\left(\frac{\overrightarrow{P_{c0}P_{c1}} \cdot H_s}{\|\overrightarrow{P_{c0}P_{c1}}\| \cdot \|H_s\|}\right) = 0 \tag{6a}$$

$$\theta_3 = \arccos\left(\frac{\overrightarrow{P_{c2}P_{c3}} \cdot H_d}{\|\overrightarrow{P_{c2}P_{c3}}\| \cdot \|H_d\|}\right) = 0 \tag{6b}$$

These restrictions ensure that the Bézier curve determined by $P_{c1}$ and $P_{c2}$ can join the starting and end points $P_{c0}$ and $P_{c3}$ with the desired orientations $H_s$ and $H_d$.

iii) Complete convexity. The curvature limitation described in III-A requires that there is no sharp bend or sudden change of curvature in the curve. Thus, the Bézier curve is better to be completely convex. It has been known that a Bézier curve is completely convex if its control polygon is convex. Therefore, $P_{c1}$ and $P_{c2}$ have to be constrained to guarantee the complete convexity of the curve. The cross product method is introduced in this proposed strategy to fulfill this convex requirement. The cross products $\omega_1$ and $\omega_2$ of vectors $\overrightarrow{P_{c0}P_{c1}}$, $\overrightarrow{P_{c1}P_{c2}}$ and $\overrightarrow{P_{c2}P_{c3}}$ are

$$\omega_1 = \overrightarrow{P_{c0}P_{c1}} \times \overrightarrow{P_{c1}P_{c2}} \tag{7a}$$

$$\omega_2 = \overrightarrow{P_{c1}P_{c2}} \times \overrightarrow{P_{c2}P_{c3}} \tag{7b}$$

Therefore, the constraint of the complete convexity is

$$sign(Z_{\omega_1}) \cdot sign(Z_{\omega_2}) > 0 \tag{8}$$

where $sign(Z_{\omega_i})$, $i = 1, 2$, are the rotation direction of the $\omega_i$.

The constrained optimization problem is to find the control points $P_{c1}$ and $P_{c2}$ which make the curve smooth. Then, the curvature and the rate of its change should be as small as possible. According to (4), the curvature of a Bézier curve with respect to $t$ is

$$\kappa(t) = \frac{1}{\rho(t)} = \frac{\dot{x}(t)\ddot{y}(t) - \dot{y}(t)\ddot{x}(t)}{(\dot{x}^2(t) + \dot{y}^2(t))^{3/2}} \tag{9}$$

where $\rho(t)$ is the radius of curve. Therefore, $P_{c1}$ and $P_{c2}$ can be computed by the following constrained optimization problem, which is subjected to (5), (6) and (8):

$$\min_{P_{c1},P_{c2}} \quad \int_0^1 [(\kappa(t))^2 + (\dot{\kappa}(t))^2]dt \tag{10a}$$

$$s.t. \qquad (5) \quad (6) \quad (8) \tag{10b}$$

where $\dot{\kappa}(t)$ is the first derivative of curvature. The interior point method is introduced in this study to solve all the optimization problems. Thus, the calculated $P_{c1}$ and $P_{c2}$ can meet the various requirements and provide an optimal trajectory planning for the first part $\widehat{P_sP_d}$.

*b) Segment from Door to Target:* When the wheelchair arrives in the doorway, it is expected to be at the center of the door with heading being perpendicular to the door. However, because of the disturbances and the control errors, the final position and orientation of last step may not coincide with the desired ones even though the errors may be small under an efficient control strategy. In order to satisfy the third requirement in III-A, the true heading $H_d^a$ needs to be adjusted to the perpendicular direction of the door before addressing the trajectory planning $\widehat{P_dP_t}$.

This trajectory planning from door to target should start from the true position $P_d^T$ with the heading $H_d^a$ in order to maintain the smoothness of the intersection of the two Bézier curves. Moreover, the $P_d^T$ and $P_t$ correspond to the control points $P_{r0}$ and $P_{r3}$ of the Bézier curve respectively. The main idea of this trajectory planning from door to target is similar to the segment from corridor to door except some specified constraints. The constrained optimization problem of this part is

$$\min_{P_{r1},P_{r2}} \quad \int_0^1 [(\kappa(t))^2 + (\dot{\kappa}(t))^2]dt \tag{11a}$$

$$s.t. \qquad P_{r1} \in R \quad P_{r2} \in R \tag{11b}$$

$$\arccos\left(\frac{\overrightarrow{P_{r0}P_{r1}} \cdot H_d^a}{\|\overrightarrow{P_{r0}P_{r1}}\| \cdot \|H_d^a\|}\right) = 0 \tag{11c}$$

$$\arccos\left(\frac{\overrightarrow{P_{r2}P_{r3}} \cdot H_t}{\|\overrightarrow{P_{r2}P_{r3}}\| \cdot \|H_t\|}\right) = 0 \tag{11d}$$

$$sign(Z_{\omega_3}) \cdot sign(Z_{\omega_4}) > 0 \tag{11e}$$

where $R$ is room area, and $Z_{\omega_i}$, $i = 3, 4$, are the cross products of vectors $\overrightarrow{P_{r0}P_{r1}}$, $\overrightarrow{P_{r1}P_{r2}}$ and $\overrightarrow{P_{r2}P_{r3}}$. (11b) is the room boundary constraint, which bounds the planned trajectory by setting the the control points $P_{r1}$ and $P_{r2}$ in the room area. As the orientation and complete convexity constraints, (11c), (11d) and (11e) are respectively very similar to (6a), (6b) and (8) in terms of format and functions. Since the initial value of the optimization problem highly decides if the global minimum can be reached, the beginning point of the period $P_d^T$ is used as the initialization for $P_{r1}$ and $P_{r2}$.

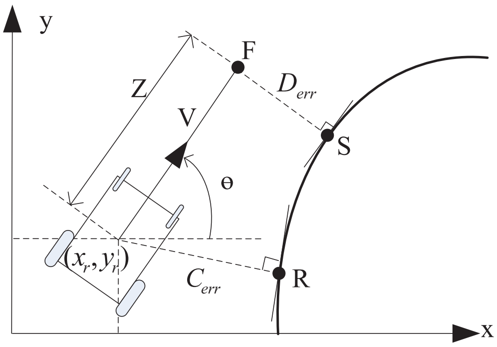

Fig. 4. The position error of the wheelchair is calculated from a point $F$, which is projected in front of the vehicle with a distance of $t$, and unto the desired trajectory to point $S$ [11].

*2) Trajectory Planning with Obstacle:* It is well-known that the door crossing is more difficult for the wheelchair with an obstacle around and this scene is common in practice. In general, the typical techniques divide the door crossing problem into two phases: first, the wheelchair is driven to the area near the door, avoiding the obstacle; then, the door crossing strategy is designed to pass the doorway successfully. However, the special obstacle avoidance step is redundant, especially for the static obstacle, when a one step method is adopted to efficiently address the door passing with obstacle.

This approach also transforms the door crossing with obstacle into the optimization problem, and it is mainly based on the aforementioned trajectory planning. However, the planning of the Bézier curve has to be adjusted according to the obstacle. Assume the static obstacles are distributed as Fig.3. Then, the problem can be addressed by adding an additional constraint to the optimization problem (10) and (11):

$$\begin{aligned} (y(t_k) - y_o)^2 + (x(t_k) - x_o)^2 > d_r^2 \\ t_k \in [0, 1], k \in [1, 1000] \end{aligned} \tag{12}$$

where $x(t_k)$ and $y(t_k)$ are the discrete points sampled from (4), and $d_r$, which depends on the dimensions of the wheelchair and the obstacle, is the allowable minimum distance between the wheelchair and the obstacle. The computed control points $P_{c1}$, $P_{c2}$, $P_{r1}$ and $P_{r2}$ under the above constraint can provide the desired pathes for the wheelchair to pass the door with obstacle avoidance.

### C. Wheelchair Control

In order to drive the wheelchair to track the desired trajectory, a feedback control principle using PID controller is adopted. The position error between the actual position of the wheelchair and the reference trajectory is used as the input of the PID controller. As can be seen in Fig.4, and a point $F$ ahead along the heading of the wheelchair with a distance of $Z$ is used to define the position error, $F$ is projected onto the

TABLE I
THE INPUT PARAMETERS FOR EACH TRAJECTORY

| | $P_s(m)$ | $P_d(m)$ | $P_t(m)$ | $1(H_s, H_d)$ | $2(H_s, H_d)$ | $3(H_d, H_t)$ | $4(H_d, H_t)$ |
|---|---|---|---|---|---|---|---|
| A | (0.1,1.3) | (1.6,1.8) | (0.0,3.5) | (-20,90) | (-40,90) | (90,160) | (90,200) |
| B | (0.1,1.3) | (1.6,1.8) | (3.4,3.5) | (-10,90) | (10,90) | (90,20) | (90,-20) |

reference trajectory at point $S$ such that $\overline{FS}$ is perpendicular to the tangent at $S$. The position error is then represented by the distance $D_{err}$ between point $F$ and $S$. The cross track error $C_{err}$ is defined by the shortest distance between the desired trajectory and the position of the center of the gravity of the wheelchair $(x_r, y_r)$, and $C_{err}$ will be adopted as the indication of the control performance in the simulation analysis in Section IV.The position of the wheelchair $(x_r, y_r)$ is assumed to be estimated by other techniques such as SLAM algorithms.

In this paper, the longitudinal velocity $V$ is considered as constant, and the angular rate $\omega$ as the control output of the PID controller. The discretized PID controller can be expressed as

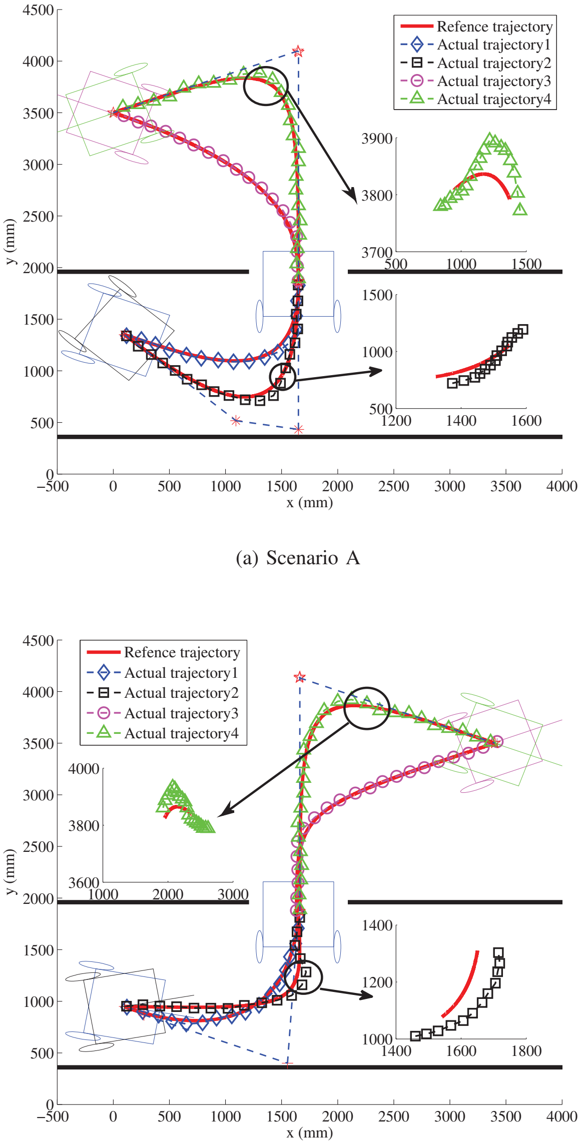
$$\omega = k_p D_{err}^k + k_i T_s \sum_{i=1}^{k} D_{err}^i + \frac{k_d}{T_s}(D_{err}^k - D_{err}^{k-1}) \qquad (13)$$

where $k_p$, $k_i$ and $k_d$ are proportional, integral and derivative gains respectively, $D_{err}^k$ is the current position error, and $D_{err}^{k-1}$ is the position error of last time instance. The reason for why $D_{err}$ rather than $C_{err}$ is used as the input of the PID controller lies in the fact that the required $k_p$ for compensating the same quantity of $C_{err}$ is much larger than that of $D_{err}$, and the larger $k_p$ is more likely to cause system oscillation.

## IV. SIMULATION RESULTS

In order to verify the proposed Bézier curve door passing strategy, simulation work has been conducted. First we carried out two simulation scenarios, namely Scenario A and B, where no obstacles are considered. For each scenario, four different reference trajectories are determined by our Bézier curve based trajectory planning algorithms using optimization technique. The parameters such as the starting position of the wheelchair and its heading, the target position and the heading should be given for determining each reference trajectory.

The required parameters for each reference trajectory are listed in Table I, where $P_s$, $P_d$ and $P_t$ represent the coordinate of starting point in corridor, the coordinate of the middle of the door and the coordinate of the target point in the room respectively. $1(H_s, H_d)$ represents the heading of the starting position and the end position for trajectory 1, and the same meaning goes with other $i(H_s, H_d)$ or $i(H_d, H_t)$ with $i$ being the $i$th trajectory. Using these parameters as the inputs, the Bézier curve based trajectory planning strategy is able to calculate the optimized smooth reference trajectory for the wheelchair to follow gracefully. The PID controller, whose gains are selected to be $k_p = 0.01$, $k_i = 0.001$ and $k_d = 0.001$, is then adopted to drive the wheelchair to track the reference trajectory.

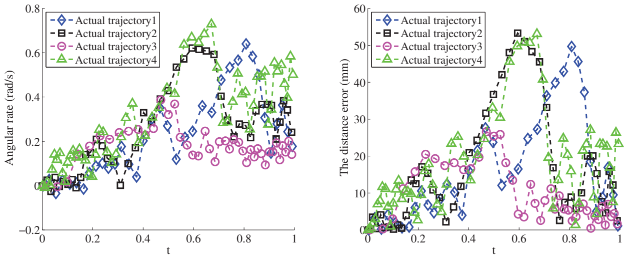


(a) Scenario A

(b) Scenario B

Fig. 5. Reference trajectory and actual trajectory of wheelchair.

Fig. 5 shows the calculated reference trajectories and their corresponding actual trajectories of the wheelchair given the parameters in Table I. As can be seen, several conclusions can be drawn: 1) All the optimized reference trajectories satisfy with the constraints mentioned in Section III-B. That is: first, the wheelchair always is within the corridor; second, the tangent of the Bézier curve at the starting position is equal to the heading of the wheelchair, and the same situation goes with the target position; the control polygon of the designed Bézier curve is convex. 2) The optimized reference trajectories are smooth. 3) The actual trajectories precisely track the reference trajectory, although there are small tracking errors (can be seen from the amplified part of trajectories). With this fact, the basic



(a) Angular rate

(b) Tracking error

Fig. 6. The angular rate and the tracking errors for each trajectory in Scenario A

goal of door passing is successfully achieved.

To analyze the smoothness and the accuracy of the actual trajectories that the wheelchair follows, the angular rate $\omega$ and the distance error $D_{err}$ with respect to the Bézier curve parameter $t$ for each trajectory in Scenario A are shown in Fig. 6a and Fig. 6b respectively. It can be seen that there is no sharp change of the angular rate, which demonstrates the wheelchair is able to move smoothly. The maximum tracking error is about 55 mm, which is both reasonable and acceptable, indicating the relatively high accuracy of the tracking. In order to validate the scheme with obstacle, a scenario where two obstacles are separately distributed in the corridor and room is simulated, see Fig. 7. The blue circles are obstacles, and the widths of wheelchair, corridor and door are assumed to be 75, 160 and 90 centimeters respectively. Compared the trajectory planning without obstacle, which is denoted by the red dash line, with the one affected by the obstacle, which is represented by the diamond and square dash lines, it can be seen that the wheelchair can dynamically adjust its planned trajectories according to the position of the obstacle, avoiding the obstacles and still reaching the destination smoothly.

## V. Conclusions

In this paper, a novel method is proposed to address the tough door crossing problem of the wheelchair. It introduces the Bézier curve based trajectory planning and optimization to produce a smooth and reasonable reference trajectory for the wheelchair to follow. Its merit is that it sufficiently considers the various constraints of the wheelchair and the environment, and can perform the door crossing with graceful and smooth trajectories even hindered by the obstacles. The good performance of the proposed approach is also verified by the means of simulation. It is not limited to the wheelchair, but also can be used for the various mobile robots which intend to pass the narrow door. Our future work will focus on implementing the proposed approach on a real wheelchair.

## I. Introduction

Research in cooperative flight control of multi-aircraft systems has attracted growing interest in recent years. After NASA launched the Autonomous Formation Flight (AFF) program, extensive research and development work has been carried out. One of the experiments was conducted by Dryden Flight Research Center, which demonstrated that an F/A-18 flying in the wingtip vortex behind another F/A-18 exhibited a 14% fuel savings [1]. In addition, in [2], the authors presented the benefits that birds "V" shape formation flying brings to energy saving compared to isolated flying, because of the reduction in induced flying drag. Further, its implications are very significant, not just for fuel and energy saving but for other future applications in civilian and military domains. For instance, formation flight can be used to handle increase in air traffic around airports through civil aeroplane formation taking-off and landing to increase use efficiency of airport runway, and applications in military field include aerial refuelling, aircraft logistics, air formation patrol, and carrier landing systems.

Successful formation flight requires the solution of the formation control problem. A number of approaches have been proposed in the literature. For instance, in [3] and [4], the decentralised behaviour-based approach which was inspired by the study of animal behaviour was applied to a group of mobile vehicles. In [5], the leader-following strategy was employed, which has been widely used to deal with the aircraft formation flight control. Virtual structure approach for synchronising UAV position tracking control and for maintaining formation geometry was presented in [6]. Further, the authors have introduced the extension-decomposition-aggregation (EDA) formation control strategy in [7] to translate the complex formation control problem into a group of sub-problems which are simpler to solve. There, the EDA scheme was applied to the formation control of a point mass robot in the horizontal plane.

In this paper, the EDA strategy is further extended and applied to the complex cooperative flight control of UAVs. A nonlinear *Aerosonde* UAV model is linearised about specific trim conditions, and the multivariable $H_\infty$ control methodology based on linear matrix inequalities (LMI) is then employed to design the longitudinal and lateral formation controllers to maintain the corresponding formation stability. Additionally, proportional-integral (PI) compensators are designed to eliminate steady-state formation errors. Simulation studies showing formation manoeuvres have been performed to demonstrate the effectiveness of the proposed method and the formation stability.

This paper is organised as follows. Section II presents the problem formulation and preliminaries. Section III proposes the EDA formation control methodology, whilst Section IV describes the decentralised longitudinal and lateral formation autopilots design. Section V reports the implementation and simulation results. Finally, concluding remarks and suggestions for future work are provided in Section VI.

## II. Problem formulation and preliminaries

Consider a group of three UAVs flying in a specified formation as depicted in Fig. 1. A reference vehicle (RV) in the group can be selected by a consensus between the UAVs. Note that the RV is different from the leader vehicle in the leader-following approach, since it is mainly used to define the local formation coordinate system (LFCS), which is a convenient way of describing a formation, a simple illustration being shown in Fig. 1.

In contrast to the earth axes frame ($X_E$, $Y_E$, $Z_E$) and the fixed body axes frame ($X_B$, $Y_B$, $Z_B$), the LFCS-axes, $(X_L, Y_L, Z_L)$ are always aligned with the vehicle body axes of the RV. This implies that the LFCS axes always vary with the RV's position and direction. From Fig. 1, the position vector of the $i^{th}$ vehicle in the LFCS is defined as $\mathbf{p}_{Li} = [p_{Lix}, p_{Liy}, p_{Liz}]$, and the desired formation can then be mathematically expressed as $F_d = [\mathbf{p}_{L1}; \mathbf{p}_{L2}; \cdots; \mathbf{p}_{LN}]$, where $L$ represents the LFCS and $N$ is the number of vehicles in the formation.

However, it is not enough to describe a formation by only defining the position in the LFCS, since the motion of UAVs in 3D has six degree-of-freedom (6-DOF) defining the

positions and attitudes. Thus, a complete formation definition in Euclidean space is given by,

$$F_d = [\mathbf{p}_{L1}; \mathbf{p}_{L2}; \cdots; \mathbf{p}_{LN}] \\ \tilde{\mathbf{x}}_i = [\phi_i, \theta_i, \psi_i, \cdots]^T : i = 1, 2, \cdots, N. \tag{1}$$

where $\phi_i$, $\theta_i$ and $\psi_i$ are the roll, pitch and yaw angles respectively constituting the attitude of the $i^{th}$ individual vehicle. Note that the above attitude angles are just partial elements of the state vector $\tilde{\mathbf{x}}_i$ of the $i^{th}$ vehicle. when a formation change is needed, $\tilde{\mathbf{x}}_i$ must generally be regulated by the formation control algorithm. Subsequently, all vehicles within the group will achieve their new desired relative distances. This implies that stabilising relative positions in a formation is a sufficient condition to achieve equal attitude angles. Thus, the primary function of formation control is to maintain the stability of the relative positions by controlling the states of each vehicle (such as the attitude angles above).

## III. Formation Control Methodology

### A. Novel strategy for decentralised formation control

It has been recognised that complex systems can be decomposed into subsystems of lower dimensionality, and those individual subsystem solutions are then combined in some way to provide an overall system response. Motivated by this idea, the EDA scheme proposed in [7] is described in detail here, and Fig. 2 shows the overall process.

Aggregation of indices for stability analysis

Fig. 2. Process of the extension-decomposition-aggregation

For the case of multi-vehicle formation control, each vehicle is a separate entity in the formation space, i.e. there is generally no explicit relationship among the vehicles to represent their formation statuses. The strategy here is to introduce a *virtual* additional system (VAS), which has three main functions: (1) to build a relationship between the isolated vehicles leading to a new overall vehicle formation control system, (2) to involve the desired formation variables or parameters in the overall formation control system, which could be combined with the related individual vehicle model, and (3) to support the subsequent decomposition, and to simplify stability analysis of the overall formation. Note that the VAS is merely an algorithm to act as an "interaction bridge" providing each vehicle with the capability of sensing its local-formation states, which can then be used in the formation control design.

Since the overall formation system involving many variables is difficult to handle as a whole, it is natural to decompose it into several local-formation subsystems. However, it is noted that there is no general systematic procedure for decomposing such a complex dynamical system. Here, using physical insight the overall formation system is decomposed into $N$ individual subsystems, each being called an individual augmented subsystem (IAS) since it combines the individual vehicle model and the local-formation variables. Thus, the initial overall complex formation control problem can now be redefined in terms of stability and set-point tracking for all the decomposed IASs.

In order to analyse the stability of the overall formation, a viable idea is to select a scalar Lyapunov function as an index to represent the stability of each IAS. These indices are then aggregated to mathematically analyse the stability of the overall formation system through the Lyapunov theory. This also brings about a considerable reduction in the dimensionality of the formation stability problem. However, the focus in this paper is on the performance of the proposed formation control system and therefore the stability analysis is not shown here.

### B. A candidate VAS: coupled multiple pendulums

To meet the requirements of the additional system, a virtual multiple-inverted-pendulum system was employed in the original algorithm [7]. However, here a virtual coupled-multiple-pendulum system (CMP) shown in Fig. 3 is used to demonstrate the flexibility of the proposed approach. Here, the CMP consists of $N$ cart-mounted pendulums coupled by $N-1$

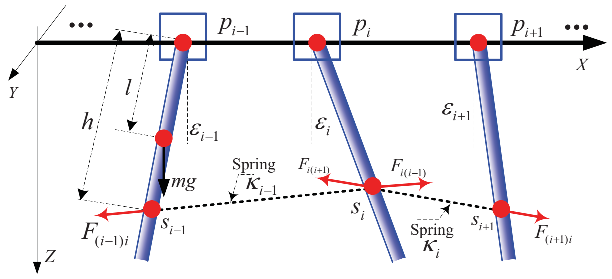

Fig. 3. Coupled multiple pendulums system

springs, and the model of the individual pendulum within the CMP is given by (2),

$$J\ddot{\varepsilon} = -B_c\dot{\varepsilon} - mla\cdot\cos\varepsilon - mgl\sin\varepsilon + W \tag{2}$$

where $J = I + ml^2 = 4ml^2/3$, $I = ml^2/3$ is the inertial moment of pendulum, $\varepsilon$ stands for the deflection angle of each pendulum, $B_c$ is the viscous damping constant at the pivot point, $a$ represents the acceleration, $l$ is the length from the pivot to the gravity centre, $m$ and $g$ represent the mass and the gravitational constant respectively, and $W$ is the resultant torque from the connected springs.

In Fig. 3, each cart of the CMP system can be associated with a vehicle in the formation. The spring connecting two pendulums corresponds to the communication channel between two vehicles, where the magnitude of the torque from the spring force depends on the spring coefficient ($k_s$), the free or natural length ($l_{\kappa_i}$), and the relative distances between the vehicles. Based on these associations, one approach for constructing the relationship is to consider $l_{\kappa_i}$ as the desired formation parameter. Thus, if a formation is disturbed, the force or torque which is caused by the springs must then impact the pendulums, resulting in a change in their deflection angles, $\varepsilon_i$. This implies that the variation of $\varepsilon_i$ is a reflection of the formation error. Thus, the aim of the individual formation control for each IAS is to regulate the deflection angle by manipulating the vehicle states. This will automatically cause the spring to return to its balanced state, i.e. the formation becomes stable. If all the springs return to their natural states or all the deflection angles are equal to zero, this in turn implies that the formation is stable with zero formation error.

Since the CMP is a virtual system, its parameters can be altered by the control algorithm according to the physical dynamics and engineering design requirements of the formation. For example, if the natural length of the springs are dynamically re-defined, the overall vehicle formation will likewise be changed. One of the most interesting aspects of this strategy is that it can be applied to handle vehicle collisions and the desertion problem, both of which are of prime importance in the motion of multiple vehicles. However, this is not discussed here due to lack of space. Recalling the EDA scheme shown in Fig. 2, the overall system is then partitioned or decomposed at the spring positions to obtain the IASs as explained in the next section.

## IV. Decentralised formation autopilot design

### A. Modelling of longitudinal and lateral IASs

Following the standard convention, the 6-DOF aircraft dynamics is approximately decomposed into its longitudinal and lateral components. The longitudinal motion occurs within the plane of symmetry of the aircraft, whereas the lateral-directional motion occurs outside of this plane of symmetry. Based on this separated characteristics and the scheme of EDA, the longitudinal IAS and the lateral IAS can in general be expressed by (3) and (4) respectively.

$$\begin{cases} \dot{\tilde{\mathbf{x}}}_{long} = f(\tilde{\mathbf{x}}_{long}, \delta_{long}) \\ \ddot{\varepsilon}_{long} = -\frac{B_c}{J}\dot{\varepsilon}_{long} - \frac{mgl}{J}\sin\varepsilon_{long} - \frac{ml}{J}a_{long}\cdot\cos\varepsilon_{long} + \frac{1}{J}\cdot W_{long} \end{cases} \tag{3}$$

$$\begin{cases} \dot{\tilde{\mathbf{x}}}_{lat} = g(\tilde{\mathbf{x}}_{lat}, \delta_{lat}) \\ \ddot{\varepsilon}_{lat} = -\frac{B_c}{J}\dot{\varepsilon}_{lat} - \frac{mgl}{J}\sin\varepsilon_{lat} - \frac{ml}{J}a_{lat}\cdot\cos\varepsilon_{lat} + \frac{1}{J}\cdot W_{lat} \end{cases} \tag{4}$$

where $\tilde{\mathbf{x}}_{long}$, $\tilde{\mathbf{x}}_{lat}$ are the state vectors of the longitudinal and lateral dynamics, $\delta_{long}$, $\delta_{lat}$ are their input vectors, $f(\cdot)$ and $g(\cdot)$ are the analytic functions modelling the dynamics of an UAV, $\varepsilon_{long}$ and $\varepsilon_{lat}$ are considered as the variables reflecting their local-formation errors, and $a_{long}$ and $a_{lat}$ are referred to as the longitudinal and lateral accelerations respectively in the inertial reference system.

The designed control framework of an individual aircraft formation system is illustrated in Fig. 4. Here, each plant or so-called longitudinal IAS is generated by combining the longitudinal model with a virtual pendulum (VP) system, and the lateral IAS is obtained likewise. The exogenous inputs $W_{long}$ and $W_{lat}$ are derived from the longitudinal and lateral formation change or error, and are assumed to be *bounded disturbances* to the IASs.

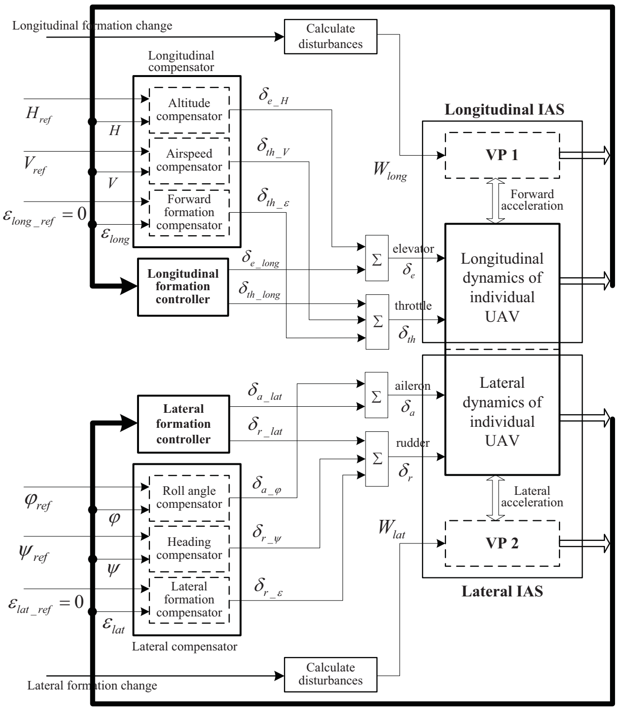

Fig. 4. Longitudinal and lateral autopilots framework

The nonlinear models of the longitudinal and lateral IASs in (3) and (4) can be generally linearised about some specific trim conditions of the aircraft, into corresponding reduced-order state-space equations as shown in (5),

$$\begin{aligned} \dot{\mathbf{x}}_{long} &= A_{long}\mathbf{x}_{long} + B_{1\_long}\mathbf{W}_{long} + B_{2\_long}\mathbf{u}_{long} \\ \dot{\mathbf{x}}_{lat} &= A_{lat}\mathbf{x}_{lat} + B_{1\_lat}\mathbf{W}_{lat} + B_{2\_lat}\mathbf{u}_{lat} \end{aligned} \tag{5}$$

where $\mathbf{x}_{long} = [\tilde{\mathbf{x}}_{long}, \varepsilon_{long}, \dot{\varepsilon}_{long}]^T$ and $\mathbf{x}_{lat} = [\tilde{\mathbf{x}}_{lat}, \varepsilon_{lat}, \dot{\varepsilon}_{lat}]^T$ are the states of the longitudinal and lateral IASs respectively, which are the augmented vectors from the vehicle states $\tilde{\mathbf{x}}_{long}$ and $\tilde{\mathbf{x}}_{lat}$. Similarly, $\mathbf{W}_{long}$ and $\mathbf{W}_{lat}$ are augmented vectors from $W_{long}$ and $W_{lat}$ respectively, whereas $\mathbf{u}_{long}$ and $\mathbf{u}_{lat}$ correspond to the control input vectors in the longitudinal and lateral directions.

### B. Lateral formation autopilot design

For the lateral formation autopilot, the lateral formation motion in the $(X_L,Y_L)$ plane is considered. As shown in Fig. 4, the proposed lateral formation autopilot consists of two components: the multivariable *lateral formation controller* and the *lateral compensators*. Here, the former is designed by using the LMI-based $H_\infty$ robust control methodology [8], [9], [10], to compute the control signals ($\delta_{a\_lat}$ and $\delta_{r\_lat}$), maintain the stability of the lateral IASs and reject the disturbances ($\mathbf{W}_{lat}$). However, it is noted that although these controllers maintain the stability of the lateral formation, zero steady-state formation error cannot be guarantee because of the system type. This is why PI-based lateral compensator given by (6) is supplemented for eliminating this error,

$$D(s) = K_p(1+K_i/s) \tag{6}$$

where $K_p$ and $K_i$ are the proportional and integral parameters respectively, which are individually tuned for each of the roll, heading and lateral formation compensators.

Since the convergence of the roll and heading angles is a necessary condition for the stability of the overall formation system, the roll and heading compensators guarantee the roll and heading angles to asymptotically converge to $\phi_{ref}$ and $\psi_{ref}$ respectively. The nominal value of $\phi_{ref}$ is usually set to zero during normal operation, whereas $\psi_{ref}$ depends on vehicle's particular role in the formation. For instance, if the current vehicle is RV, $\psi_{ref}$ can be calculated by a guidance algorithm, otherwise it should be the same as the heading angle of RV ($\psi_{RV}$). In addition, since the local-formation variable, $\varepsilon_{lat}$, is a reflection of the lateral formation change, the respective formation compensator is also required to converge $\varepsilon_{lat}$ to $\varepsilon_{lat\_ref}$ which should be regulated to zero to ensure no steady-state formation error.

As shown in Fig. 4, the resultant of the complete inputs, $\delta_a$ and $\delta_r$, for the lateral dynamics can be expressed by (7).

$$\begin{aligned}\delta_a &= \delta_{a\_lat} + \delta_{a\_\varphi} \\ \delta_r &= \delta_{r\_lat} + \delta_{r\_\psi} + \delta_{r\_\varepsilon}\end{aligned} \tag{7}$$

These control signals can then drive the individual UAV to maintain the stability of the lateral formation and compensate the steady-state lateral formation error.

### C. Longitudinal formation autopilot design

The longitudinal formation autopilot deals with the longitudinal formation motion in the $(X_L,Z_L)$ plane. It is generally more complicated than the lateral formation autopilot because the airspeed plays a significant role in different stages of the flight, such as take-off, climb/descend and altitude hold stages. The designed strategy here is that the *formation altitude steady-state error* is regulated by the pitch angle, and the *forward formation steady-state error* is eliminated by regulating the airspeed.

In Fig. 4, the longitudinal formation autopilot consist of two components: the *longitudinal formation controller* and the *longitudinal compensators*. The former can be also developed by using the LMI-based $H_\infty$ control methodology to compute the control signals ($\delta_{e\_long}$ and $\delta_{th\_long}$) to guarantee the stability of the longitudinal formation, and the latter is employed to eliminate the steady-state errors of the altitude ($H$), the airspeed ($V$) and forward formation ($\varepsilon_{long}$). The related compensators have the same structure as (6), where $K_p$ and $K_i$ are separately designed for each variable. The resultant control signals, $\delta_e$ and $\delta_{th}$, of the longitudinal formation autopilot are then calculated by (8).

$$\begin{aligned}\delta_e &= \delta_{e\_long} + \delta_{e\_H} \\ \delta_{th} &= \delta_{th\_long} + \delta_{th\_V} + \delta_{th\_\varepsilon}\end{aligned} \tag{8}$$

These control inputs can then maintain the stability of the longitudinal formation in addition to compensating for the longitudinal steady-state formation error.

## V. Implementation and simulations

### A. Implementation of linear longitudinal and lateral IASs

The performance of the proposed methodology was evaluated by using the 6-DOF *Aerosonde* UAV nonlinear simulink model [11]. The autonomous *Aerosonde* has a length of $1.74m$, a wingspan of $2.87m$, maximum payload capacity of $5kg$ and endurance of up to $30hours$. It was designed for applications including long-range weather data acquisition and reconnaissance over oceanic and remote areas.

In this paper, the IAS models were evaluated by trimming the *Aerosonde* model. The trim condition is chosen as: $V = 26m/s$, initial $H = 800m$, $\phi = 0rad$ and fuel mass is $2kg$. The parameter values of CMP system are heuristically chosen as: $m = 50kg$, $g = 9.81m/s^2$, $l = h = 0.3m$, $J = (4/3)ml^2 = 6kg\cdot m^2$, $B_c = 12N\cdot s/m$, $k_s = 0.1N/s$, but can be related to the dynamics of the physical system to be controlled. Furthermore, the relevant symbols representing the states, inputs and outputs of the longitudinal and lateral IASs are given in Table I.

TABLE I
RELEVANT SYMBOLS OF *Aerosonde* LINEAR MODEL

| Variable | Symbol | Variable | Symbol |
|---|---|---|---|
| Longitudinal velocity | $u$ | Airspeed | $V$ |
| Lateral velocity | $v$ | Sideslip angle | $\beta$ |
| Normal velocity | $w$ | Angle of attack | $\alpha$ |
| Roll angle | $\phi$ | Roll rate | $p$ |
| Pitch angle | $\theta$ | Pitch rate | $q$ |
| Yaw angle | $\psi$ | Yaw rate | $r$ |
| Altitude | $H$ | Engine rotation speed | $\omega$ |
| Longitudinal formation variable | $\varepsilon_{long}$ | Lateral formation variable | $\varepsilon_{lat}$ |
| Elevator deflection | $\delta_e$ | Throttle deflection | $\delta_{th}$ |
| Aileron deflection | $\delta_a$ | Rudder deflection | $\delta_r$ |

Specifically, the resulting dynamic equations of the longitudinal IAS are written as (9), which are obtained from the trimming of (3).

$$\begin{aligned}\dot{\mathbf{x}}_{long} &= A_{long}\mathbf{x}_{long} + B_{1\_long}\mathbf{W}_{long} + B_{2\_long}\mathbf{u}_{long} \\ \mathbf{y}_{long} &= C_{long}\mathbf{x}_{long} + D_{1\_long}\mathbf{W}_{long} + D_{2\_long}\mathbf{u}_{long}\end{aligned} \tag{9}$$

where $\mathbf{x}_{long} = [u, w, q, \theta, H, \omega, \varepsilon_{long}, \dot{\varepsilon}_{long}]^T$, $\mathbf{u}_{long} = [\delta_e, \delta_{th}]^T$, and $\mathbf{y}_{long} = [V, \alpha, q, \theta, H, \varepsilon_{long}, \dot{\varepsilon}_{long}]^T$ represent the state, input, and output vectors respectively. The resulting matrices are given by (10).

$$
\begin{aligned}
A_{long} &= \begin{bmatrix} -0.23 & 0.51 & -1.19 & -9.80 & 0 & 0.01 & 0 & 0 \\ -0.55 & -4.38 & 25.39 & -0.46 & 0 & 0 & 0 & 0 \\ 0.41 & -4.73 & -5.06 & 0 & 0 & 0.01 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0.05 & -1.00 & 0 & 26.00 & 0 & 0 & 0 & 0 \\ 33.97 & 1.58 & 0 & 0 & -0.05 & -3.13 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ -0.65 & 0.76 & -0.02 & -24.53 & 0 & 0.03 & -24.5 & -2 \end{bmatrix} \\
B_{1\_long} &= \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.1667 \end{bmatrix}^T \\
B_{2\_long} &= \begin{bmatrix} 0.35 & -2.60 & -35.90 & 0 & 0 & 0 & 0 & 0.59 \\ 0 & 0 & 0 & 0 & 0 & 346.5 & 0 & 0 \end{bmatrix}^T \\
C_{long} &= \begin{bmatrix} 0.9989 & 0.0466 & 0 & 0 & 0 & 0 & 0 & 0 \\ -0.0018 & 0.0384 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} \\
D_{1\_long} &= [0]_{8\times1}, D_{2\_long} = [0]_{8\times2}
\end{aligned} \tag{10}
$$

Similarly, the state-space equations of the lateral IAS are expressed as (11), which were achieved by trimming of (4),

$$
\begin{aligned}
\dot{\mathbf{x}}_{lat} &= A_{long}\mathbf{x}_{lat} + B_{1\_lat}\mathbf{W}_{lat} + B_{2\_lat}\mathbf{u}_{lat} \\
\mathbf{y}_{lat} &= C_{lat}\mathbf{x}_{lat} + D_{1\_lat}\mathbf{W}_{lat} + D_{2\_lat}\mathbf{u}_{lat}
\end{aligned} \tag{11}
$$

where $\mathbf{x}_{lat} = [v, p, r, \phi, \psi, \varepsilon_{lat}, \dot{\varepsilon}_{lat}]^T$, $\mathbf{u}_{lat} = [\delta_a, \delta_r]^T$, and $\mathbf{y}_{lat} = [\beta, p, r, \phi, \psi, \varepsilon_{lat}, \dot{\varepsilon}_{lat}]^T$. Their resulting matrices are given by (12).

$$
\begin{aligned}
A_{lat} &= \begin{bmatrix} -0.68 & 1.21 & -25.97 & 9.80 & 0 & 0 & 0 \\ -4.47 & -21.99 & 10.58 & 0 & 0 & 0 & 0 \\ 0.72 & -2.85 & -1.11 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0.05 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1.00 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ -1.69 & 0 & 0 & 0 & 0 & -24.53 & -2 \end{bmatrix} \\
B_{1\_lat} &= \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0.1667 \end{bmatrix}^T \\
B_{2\_lat} &= \begin{bmatrix} -1.51 & -132.34 & -5.22 & 0 & 0 & 0 & -3.77 \\ 3.85 & 2.38 & -24.31 & 0 & 0 & 0 & 9.62 \end{bmatrix}^T \\
C_{lat} &= diag(0.0385, 1, 1, 1, 1, 1, 1) \\
D_{1\_lat} &= [0]_{7\times1}, D_{2\_lat} = [0]_{7\times2}
\end{aligned} \tag{12}
$$

Using the LMI-based $H_\infty$ control methodology [10], the calculated state-feedback gain matrices of the longitudinal and lateral formation controllers are given by (13).

$$
\begin{aligned}
K_{long} &= \begin{bmatrix} 0.0455 & -0.1056 & 0.0890 & 4.7866 & 0.4322 & -0.0002 & -0.0055 & -0.1031 \\ -0.1487 & -0.0114 & 0.0094 & 0.2249 & -0.0716 & -0.0008 & 0.3373 & -0.0131 \end{bmatrix} \\
K_{lat} &= \begin{bmatrix} 0.0157 & 0.0119 & -0.0746 & 0.0970 & 0 & 0.0481 & -0.0146 \\ -0.0131 & -0.0081 & 0.0719 & -0.0166 & 0 & -0.063 & -0.0026 \end{bmatrix}
\end{aligned} \tag{13}
$$

Furthermore, the longitudinal and lateral compensators were designed heuristically to eliminate the corresponding formation error, and are listed in Table II.

TABLE II
PI PARAMETERS OF ALL THE COMPENSATORS

| Lateral compensators | | | Longitudinal compensators | | |
|---|---|---|---|---|---|
| Variables | $K_p$ | $K_i$ | Variables | $K_p$ | $K_i$ |
| $\phi$ | 1.0 | 2.0 | $H$ | 0.13 | 0.7 |
| $\psi$ | 0.5 | 2.0 | $V$ | 0.4 | 0.25 |
| $\varepsilon_{lat}$ | 0.15 | 3.80 | $\varepsilon_{long}$ | 0.5 | 4.0 |

To perform the computer simulations and evaluate the performance of the proposed formation control strategy, the nonlinear *Aerosonde* model was utilised with all the controller gains and parameters as shown previously.

## *B. Formation flight simulation*

In the simulation, the constraints on the pitch and roll angles are given as: $\pm 20 deg$ and $\pm 40 deg$, respectively. The group of UAVs is tasked to navigate the 3D waypoints provided in Table (III) which can be generated from an online or offline path planning algorithm. The *planar projection* of the 3D manoeuvring trajectories are displayed in Fig. 5 to show the formation maintenance and changing when needed, where UAV 2 is the RV and UAV 1 and 3 are its neighbours. The altitudes, airspeeds and attitudes are shown in Fig. 6 and Fig. 7 respectively. Using (1) and Fig. 1, the formation change sequences are mathematically expressed by (14), where $F_{d\_A}$ denotes the initial formation shape, $F_{d\_B}$ illustrates the first formation change about their altitudes at $t = 0s$, and $F_{d\_C}$ indicates the new longitudinal and lateral formation changes at $t = 200s$.

TABLE III
WAYPOINTS OF UAVS FORMATION MANOEUVRE

| *Number* | 1 | 2 | 3 | 4 | 5 |
|---|---|---|---|---|---|
| *East*$(m)$ | 0 | 2500 | 3500 | 500 | $-500$ |
| *North*$(m)$ | 0 | 600 | 3500 | 3500 | 1000 |
| *Altitude*$(m)$ | 800 | 1100 | 1400 | 1400 | 1200 |

$$
\begin{aligned}
F_{d\_A} &= \begin{bmatrix} -150 & -150 & 0 \\ 0 & 0 & 0 \\ -150 & 150 & 0 \end{bmatrix} \Rightarrow F_{d\_B} = \begin{bmatrix} -150 & -150 & \mathbf{100} \\ 0 & 0 & 0 \\ -150 & 150 & \mathbf{-100} \end{bmatrix} \\
\Rightarrow F_{d\_C} &= \begin{bmatrix} \mathbf{-300} & \mathbf{-250} & 100 \\ 0 & 0 & 0 \\ \mathbf{300} & \mathbf{450} & -100 \end{bmatrix}
\end{aligned} \tag{14}
$$

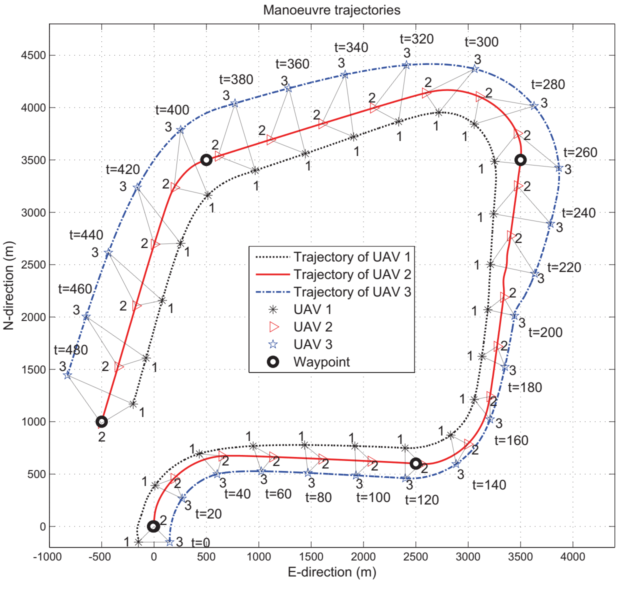

Fig. 5. Planar projection of 3D manoeuvring trajectories

As depicted, the following observations could be made:

1) The group of UAVs completed the desired manoeuvring task of tracking all the required waypoints. Furthermore, the overall formation remained stable, and small formation errors existed only during the formation change and turning manoeuvres.

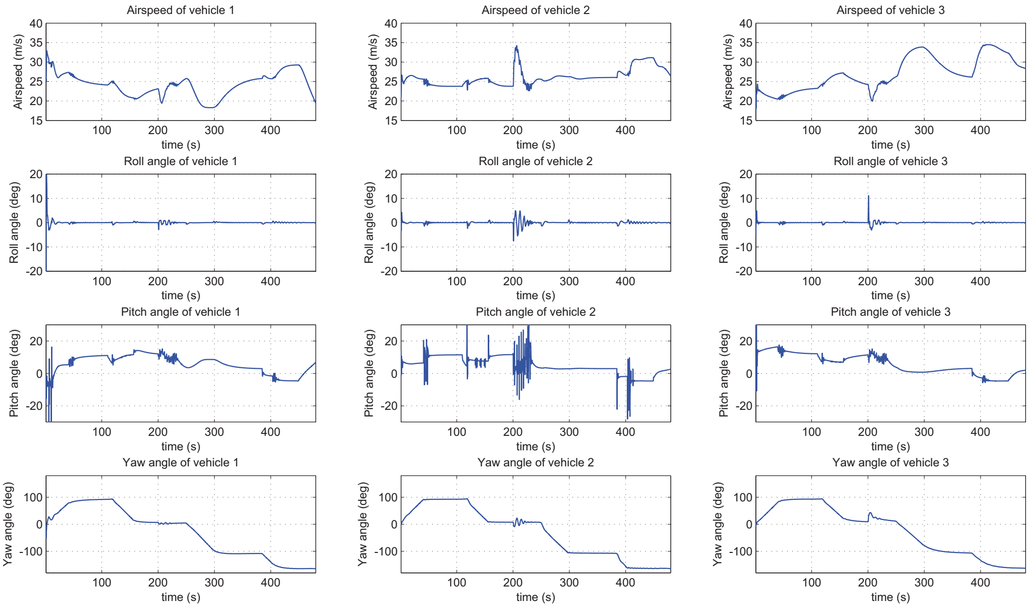

Fig. 7. Dynamics of attitudes while manoeuvring

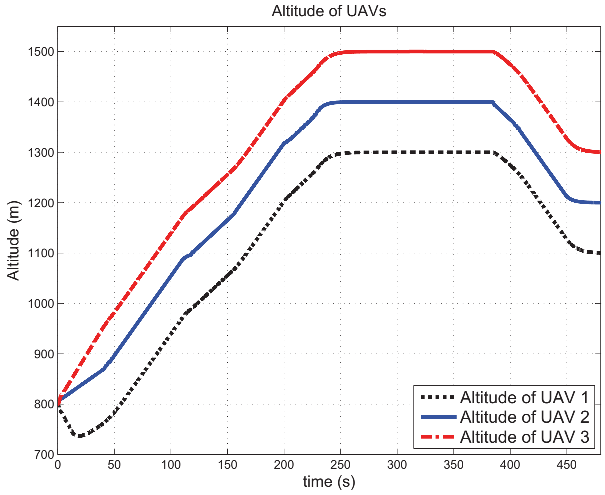

Fig. 6. Dynamics of altitudes while manoeuvring

2) During the turnings, it is clear that the attitude (pitch and roll) of each UAV remains within the specified constraints.
3) The airspeed variation with the formation changing could be observed as it was required to maintain the position of UAVs within the new desired formation as quickly as possible.

## VI. Concluding Remarks

In this paper, the extension-decomposition-aggregation (EDA) scheme was extended to support the design of the decentralised autopilots for the formation flight of UAVs in 3-D. Longitudinal and lateral formation compensators were employed to eliminate the corresponding steady-state formation error. Simulation studies have been performed to verify the feasibility and effectiveness of the EDA-based formation flight strategy. Future work includes mathematical stability analysis of the overall formation and inner/outer collision avoidance.

***Abstract*—In many practical applications, constraints are often present on, for example, the magnitudes of the control inputs. Recently, based on a novel successive projection framework, two constrained iterative learning control (ILC) algorithms were developed with different convergence properties and computational requirements. This paper investigates the effectiveness of these two methods experimentally on a gantry robot facility, which has been extensively used to test a wide range of linear model based ILC algorithms. The results obtained demonstrate the effectiveness of the algorithms in solving one form of the general constrained ILC problem.**

## I. Introduction

Iterative Learning Control (ILC) is a technique for controlling systems operating in a repetitive or trial-to-trial mode with the requirement that a reference trajectory $y_{ref}(p)$ defined over a finite interval $0 \leq p \leq \alpha$ is followed to a high precision, where the constant $\alpha$ denotes the finite trial duration or length. The basic idea in ILC is that information from previous trials is used to update the control input for the next trial in order to sequentially improve performance. Moreover, the next trial input is typically computed during the time taken to reset between successive trials.

Since the original work by [1], ILC has developed into an established area in control systems research and applications. Initial sources for the relevant literature are the survey papers [2] and [3]. These show that a wide range of algorithms have been developed, many of which, particularly those based on a linear plant model, have been experimentally tested.

In many practical applications, constraints are present due, for example, to physical limitations or performance requirements. Hence ILC design must take these constraints into account but most of the currently available ILC results are for unconstrained systems and there are relatively few results for the constrained case. One set of results is due to [4] where a novel nonlinear controller for process systems with input constraints is developed where the learning scheme requires relatively little knowledge of the process model. In [5] an ILC problem with soft constraints is studied where Lagrange multiplier methods are used to develop a solution. [6] uses quadratic optimal design to formulate a constrained ILC problem and suggests that a quadratic optimal design has the capability of dealing with constraints. Also [7] uses a constrained convex optimization technique to solve the constrained ILC problem for linear systems with saturation constraints.

Recently, the ILC design problem with general convex input constraints has been considered in [8]. This work shows that the constrained ILC problem can be formulated in a recently developed successive projection framework, which provides an intuitive but rigorous method for system analysis and design. Based on this, a systematic approach for constraints handling is provided and two algorithms to solve this problem developed. The convergence analysis shows that when perfect tracking is possible, both algorithms can achieve this goal whereas the computation of one algorithm is much less than the other at the cost of slightly slower convergence rate. When perfect tracking is not possible, both algorithms converge to asymptotic values representing a ”best fit” solution. Again the more computationally complex algorithm has the best convergence properties. It was also found that the input and output weighting matrices have an interesting effect on the convergence properties of the algorithms.

The main aim of this paper is to give experimental results to verify the effectiveness of the constrained ILC algorithms using a gantry robot facility previously used to test a wide range of ILC algorithms, including Norm Optimal ILC (NOILC) [9]. The paper is organized as follows. In Section 2, the required results from the derivation of the constrained ILC algorithms are given. Then in Sections 3 and 4, the gantry robot facility and the test parameters are described. The experimental results are given in Section 5 and Section 6 gives conclusions and suggestions for further research.

## II. Iterative Learning Control for Constrained Linear Systems

Consider the following discrete linear time-invariant system

$$\begin{aligned} x_k(t+1) &= Ax_k(t) + Bu_k(t), \\ y_k(t) &= Cx_k(t), \end{aligned} \tag{1}$$

where $t$ is the time index (i.e. sample number), $k \geq 0$ is the trial index and $x_k(0) = x_0, k = 1, 2, \cdots$ is the same for all trials. The control objective is to track a given reference signal $r(t)$ and $u_k(t), x_k(t), y_k(t)$ are input, state and output vectors, respectively, of the system on trial $k$. In operation, a trial is completed, the system is reset and a new trial begins. The ILC design uses information from previous trial(s) to compute the control input for the next trial in a manner that improves tracking performance from trial-to-trial.

Before presenting the main results, the operator form of the dynamics is introduced using the well-known lifted-system representation, which provides a straightforward "$N \times N$ matrix" approach in the analysis of discrete-time ILC [10], [11].

Assume, for simplicity, the relative degree of the system is unity, i.e. the generic condition $CB \neq 0$ is satisfied (the case when the system relative degree is greater than one follows as an obvious generalization), then the system state-space model (1) on trial $k$ can be written in the form

$$y_k = Gu_k + d, \tag{2}$$

where $G$ and $d$ are the $N \times N$ and $N \times 1$ matrices

$$\begin{aligned} G &= \begin{bmatrix} CB & 0 & \cdots & 0 & 0 \\ CAB & CB & \ddots & 0 & 0 \\ CA^2B & CAB & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & CB & 0 \\ CA^{N-1}B & \cdots & \cdots & CAB & CB \end{bmatrix} \\ d &= \begin{bmatrix} CAx_0 & CA^2x_0 & CA^3x_0 & \cdots & CA^Nx_0 \end{bmatrix}^T . \end{aligned} \tag{3}$$

The $N \times 1$ vectors of input, output and reference time series $u_k, y_k$ and $r$ are defined as

$$\begin{aligned} u_k &= \begin{bmatrix} u_k(0) & u_k(1) & \cdots & u_k(N-1) \end{bmatrix}^T, \\ y_k &= \begin{bmatrix} y_k(1) & y_k(2) & \cdots & y_k(N) \end{bmatrix}^T, \\ r &= \begin{bmatrix} r(1) & r(2) & \cdots & r(N) \end{bmatrix}^T. \end{aligned} \tag{4}$$

Also no loss of generality arises from assuming that $d = 0$ (non-zero $d$ can be incorporated into the reference signal by replacing $r$ with $r - d$). Hence (2) becomes

$$y_k = Gu_k, \tag{5}$$

where $G$ is nonsingular and hence invertible.

Tracking error improvements from trial-to-trial are achieved in ILC by the design of a control law of the following general form

$$u_{k+1} = f\left(e_{k+1}, \ldots, e_{k-s}, u_k, \cdots, u_{k-r}\right). \tag{6}$$

When $s > 0$ or $r > 0$, (6) is termed a higher order updating law. This paper only considers algorithms of the form $u_{k+1} = f\left(e_{k+1}, e_k, u_k\right)$. For higher order algorithms, refer to [12], [13] and the references therein. The ILC design problem can now be stated as finding a control updating law (6) such that the system output has the asymptotic property that $e_k \to 0$ as $k \to \infty$.

There are many design methods to solve the ILC problem. The one used in this paper is based on a quadratic (norm) optimal formulation [14] where, on each trial, a performance index is minimized to obtain the system input time series vector to be used on the next trial. The basis of this paper is NOILC that designs the control input to minimize the performance index

$$J_{k+1}(u_{k+1}) = \|e_{k+1}\|_Q^2 + \|u_{k+1} - u_k\|_R^2, \tag{7}$$

subject to the constraint $e_{k+1} = r - Gu_{k+1}$, where $G$ is the operator representation of the system (1) and $Q$ and $R$ are positive definite weighting matrices. Also $\|e\|_Q^2$ denotes the quadratic form $e^TQe$ and similarly for $\|\cdot\|_R^2$. Solving this optimization problem gives the following optimal choice for the time series vector $u_{k+1}$

$$u_{k+1} = u_k + R^{-1}G^TQe_{k+1} \tag{8}$$

which, when $k \to \infty$, asymptotically achieves perfect tracking. This well-known NOILC algorithm has many appealing properties including implementation in terms of Riccati state feedback. More details concerning NOILC can be found in [14]–[17].

In practical applications, system constraints are encountered and of different forms, e.g., input constraints, input rate constraints and state or output constraints. Constraints can be divided into two classes termed hard and soft, respectively. Hard constraints are those on magnitude(s) at each point in time, for example, output limits on actuators. Soft constraints are those that are applied to the whole function rather than its point-wise values e.g. constraints on total energy usage. This paper only considers input constraints.

Suppose the input is constrained to be in a set $\Omega$, which is taken to be a closed convex set in some Hilbert space $H$. In practice, the set $\Omega$ is often of simple structure. For example, the following are often encountered:

- input saturation constraint:

$$\Omega = \{u \in H : |u(t)| \leq M(t)\}$$

- input amplitude constraint:

$$\Omega = \{u \in H : \lambda(t) \leq u(t) \leq \mu(t)\}$$

- input sign constraint:

$$\Omega = \{u \in H : 0 \leq u(t)\}$$

- input energy constraint:

$$\Omega = \{u \in H : \sum_{t=0}^{N-1} u^2(t) \leq M\}$$

If there are no constraints, the ILC design problem is relatively easy to solve and there are many design methods in the literature. However, when constraints are present, the problem becomes more complicated since it is now necessary to decide how to incorporate them into the design process and retain known performance properties. In what follows, two constrained ILC algorithms recently developed in [8] using a novel successive projection framework are summarized.

*Algorithm 1:* Given any initial input $u_0$ satisfying the constraint with associated tracking error $e_0$, the input sequence $u_{k+1}, k = 0, 1, 2, \cdots$ , defined by

$$u_{k+1} = \arg\min_{u\in\Omega} \left\{ \|r - Gu\|_Q^2 + \|u - u_k\|_R^2 \right\}, \tag{9}$$

also satisfies the constraint and iteratively solves the constrained ILC problem.

Constrained Algorithm 1 has the following properties:

*Theorem 1:* Algorithm 1 converges to point $u_s^*$ which is uniquely defined by the following optimization problem

$$u_s^* = \arg\min_{u\in\Omega} \|r - Gu\|_Q^2. \tag{10}$$

Moreover, this convergence is monotonic in the tracking error, that is,

$$\|e_{k+1}\| \leq \|e_k\|, k = 0, 1, \cdots . \tag{11}$$

In the case when perfect tracking is possible, Constrained Algorithm 1 will converge to zero tracking error and has desirable properties of monotonic convergence in tracking error norm. However, it requires the solution of a quadratic programming (QP) problem and can be computationally demanding and in [8] two efficient solution methods were developed but are omitted here for brevity.

Another algorithm that is less computationally demanding is the following.

*Algorithm 2:* Given any initial input $u_0$ satisfying the constraint with associated tracking error $e_0$, the input sequence $u_{k+1}, k = 0, 1, 2, \cdots$ , defined by the solution of the input unconstrained NOILC optimization problem

$$\tilde{u}_k = \arg\min_{u} \left\{ \|r - Gu\|_Q^2 + \|u - u_k\|_R^2 \right\}, \tag{12}$$

followed by the simple input projection

$$u_{k+1} = \arg\min_{u\in\Omega} \|u - \tilde{u}_k\| \in \Omega, \tag{13}$$

also satisfies the constraint and iteratively solves the constrained ILC problem.

*Remark 1:* The first step in Algorithm 2 requires the solution of the input unconstrained NOILC optimization problem (12). Unlike Algorithm 1, which may cause computational problems in solving the large constrained QP problem (9), (12) has a real-time Riccati solution [16]

$$\begin{array}{rcl} u_{k+1}(t) & = & u_k(t) - R^{-1}B^T M(t), \\ M(t) & := & K(t)(I + BR^{-1}B^T K(t))^{-1} \times \\ & & A(x_{k+1}(t) - x_K(t)) - \xi_{k+1}(t), \end{array} \tag{14}$$

where $K(t)$ satisfies the Riccati equation

$$\begin{array}{r} K(t) = A^T K(t+1)A + C^T QC - A^T K(t+1)B \times \\ (B^T K(t+1)B + R)^{-1} B^T K(t+1)A \end{array} \tag{15}$$

with final time condition $K(N) = 0$. Moreover, $\xi_{k+1}(t)$ satisfies the differential equation

$$\begin{array}{r} \xi_{k+1}(t) = (I + K(t)BR^{-1}B^T)^{-1}(A^T \xi_{k+1}(t+1) \\ + C^T Qe_k(t+1)), \end{array} \tag{16}$$

which is computable in reverse time as it is driven by tracking error from the previous trial $k$ [16].

*Remark 2:* The second step in Algorithm 2 requires the solution of the problem (13) and would appear to need the application of optimization methods. However, in practice the input constraint $\Omega$ is often a point-wise constraint and the solution of (13) can be computed easily. For example, when $\Omega = \{u \in H : |u(t)| \leq M(t)\}$, the solution is

$$u_{k+1}(t) = \left\{ \begin{array}{ll} M(t) & : \tilde{u}_k(t) > M(t) \\ \tilde{u}_k(t) & : |\tilde{u}_k(t)| \leq M(t) \\ -M(t) & : \tilde{u}_k(t) < -M(t) \end{array} \right. \tag{17}$$

for $t = 0, \cdots , N - 1$.

Constrained Algorithm 2 requires less computational effort but, unlike Constrained Algorithm 1, it cannot guarantee monotonic convergence of the tracking error norm. Instead, it achieves monotonic convergence of weighted error norm, as shown in the following theorem.

*Theorem 2:* When perfect tracking is not possible, Algorithm 2 converges to a point $u_s^*$ which is uniquely defined by the following optimization problem,

$$u_s^* = \arg\min_{u\in\Omega} \left\{ \|Ee\|_Q^2 + \|Fe\|_R^2 \right\}. \tag{18}$$

Moreover, this convergence is monotonic with respect to the following performance index

$$J_k = \|Ee_k\|_Q^2 + \|Fe_k\|_R^2, \tag{19}$$

where

$$\begin{array}{rcl} e & = & r - Gu \\ E & = & I - G\left(G^T QG + R\right)^{-1} G^T Q \\ F & = & \left(G^T QG + R\right)^{-1} G^T Q \end{array} . \tag{20}$$

It was also shown in [8] that when perfect tracking is not possible, the choice of $Q$ and $R$ in Algorithm 2 has an interesting effect on the convergence properties. In particular, there is a compromise between the convergence rate and the tracking performance: using a smaller $R$ will result in faster convergence, however, with a larger final tracking error.

Simulation studies have demonstrated that the two algorithms considered above can solve the constrained ILC problem efficiently, with different convergence properties and computational requirements. The remainder of this paper examines the performance of the algorithms experimentally on a gantry robot that has been used to tests an extensive range of linear model based ILC algorithms [9], [18].

## III. GANTRY ROBOT TEST FACILITY

This approach has been experimentally implemented on a 3-axis gantry robot. Figure 1 shows this experimental facility where the robot head performs a ‘pick and place’ task and is similar to systems which can be found in many industrial applications. These include food canning, bottle filling or automotive assembly, all of which require accurate tracking control, each time the operation is performed, with a minimum level of error in order to maximize production rates. This is an obvious general area for application of ILC.

Each axis of the gantry robot has been modeled based on frequency response tests where, since the axes are orthogonal, it is assumed that there is minimal interaction between them. Here we first consider the X-axis (the one parallel to the conveyor in Figure 1) and frequency response tests (via Bode approximate gain plots in Figure 2) result in a 7th order continuous-time transfer-function as an adequate model of the dynamics on which to base control systems design.

$$G_X(s) = \frac{13077183.4436(s+113.4)}{s(s^2+61.57s+1.125\times10^4)} \times \cdots$$
$$\frac{(s^2+30.28s+2.13\times10^4)}{(s^2+227.9s+5.647\times10^4)(s^2+466.1s+6.142\times10^5)}. \tag{21}$$

The dynamics have been sampled at $T_s = 0.01$ seconds to yield the discrete state space model which can be used to compute the model matrix $G$ according to (3). The same procedure has been applied to the Y-axis and Z-axis. For the details see [9].

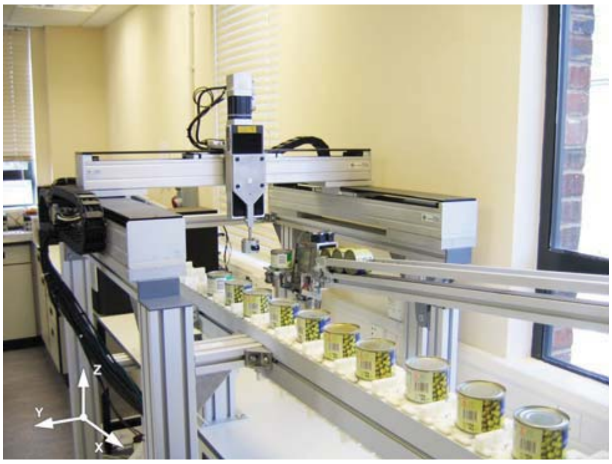

Fig. 1. The multi-axis gantry robot.

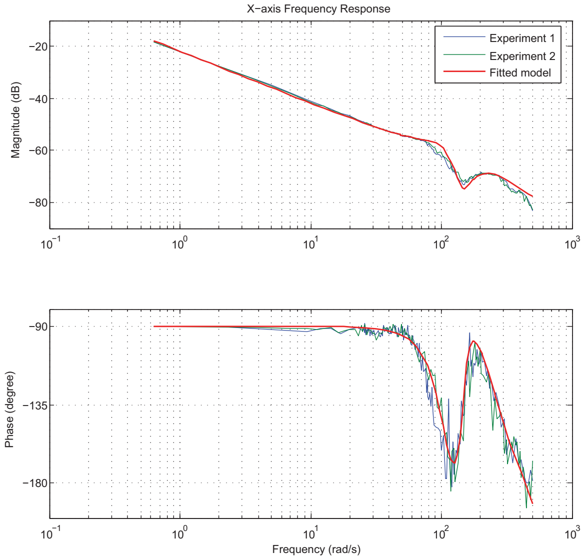

Fig. 2. Frequency response test results and fitted model

$$A_x =$$
$$\begin{bmatrix} 0.035 & 1.000 & 0 & 0 & 0 & 0 & 0 \\ -0.008 & 0.035 & -0.071 & 0.156 & 0 & 0 & 0 \\ 0 & 0 & -0.158 & 1.000 & 0 & 0 & 0 \\ 0 & 0 & -0.078 & -0.158 & 0.569 & 0.698 & 1.319 \\ 0 & 0 & 0 & 0 & 0.388 & 1.000 & 0 \\ 0 & 0 & 0 & 0 & -0.390 & 0.388 & 1.080 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1.000 \end{bmatrix},$$
$$B_x = \begin{bmatrix} 0 & 0 & 0 & 0.0164 & 0 & 0.0134 & 0.0197 \end{bmatrix}^T,$$
$$C_x = \begin{bmatrix} -0.0003 & -0.0054 & -0.0145 & 0.0316 & 0 & 0 & 0 \end{bmatrix}.$$

## IV. TEST PARAMETERS

The gantry robot is designed to repeatedly complete a pick-and-place motion in synchronization with a moving conveyor. A reference trajectory for the gantry movement has been predefined with the purpose of synchronizing its motion with that of the conveyor, which is running at a constant speed. Each axis is controlled individually and has its own reference trajectory and they are combined to form the 3D reference trajectory given in Figure 3 which clearly shows the ‘pick and place’ action. The signal duration is 2 seconds.

## V. EXPERIMENTAL RESULTS

This section gives the results of experimental performance of the two constrained ILC algorithms given in Section 2. Input constraints were imposed such that for each axis, the amplitude of the input voltage was limited to be 90% that of the optimal input $u^*$, which produces performance tracking. Note that under these constraints perfect tracking is not possible, which is more practically relevant than the trivial case where perfect tracking is achievable).

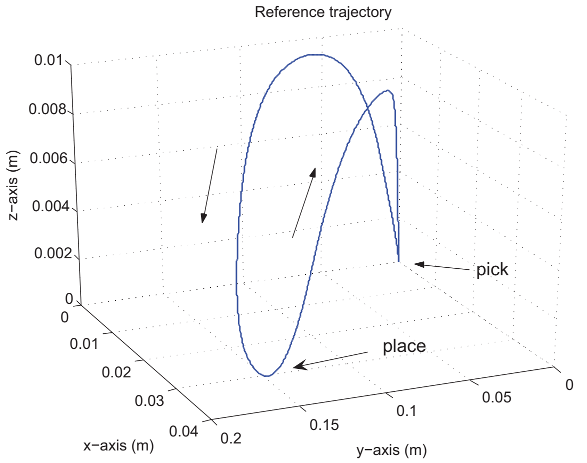

Fig. 3. 3-D combined reference trajectory.

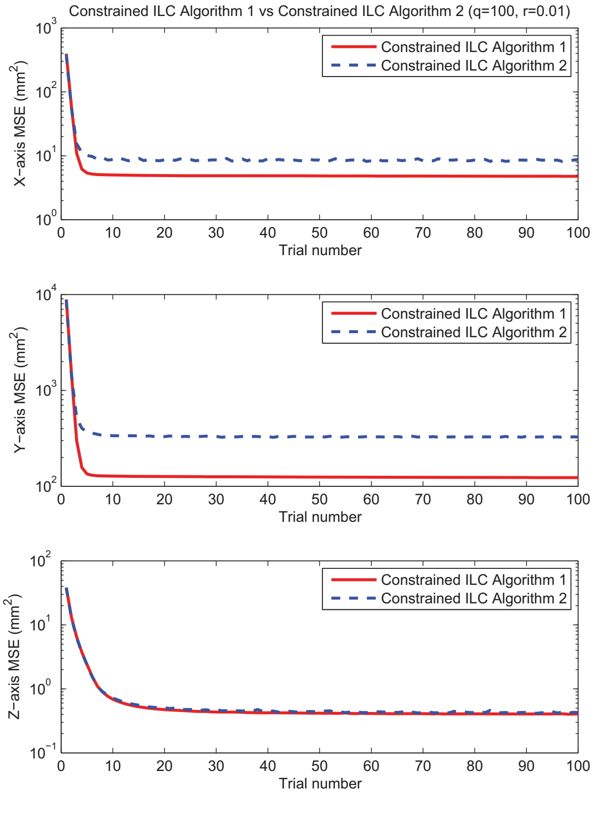

Fig. 4. Comparison of Convergence with $Q = 100I, R = 0.01I$

The cost function weighting matrices are chosen as diagonal matrices with common diagonal entries of 100 and 0.01 for all three axes and the experimentally results are given in Figure 4. These results confirm that both algorithm solve the constrained ILC problem and converge to some final values. The convergence of Constrained ILC Algorithm 1 is monotonic in the tracking error norm, whereas Constrained ILC Algorithm 2 is not. Moreover, the final tracking error norm of Constrained ILC Algorithm 1 is smaller than that of Algorithm 2, which is consistent with the theoretical predictions.

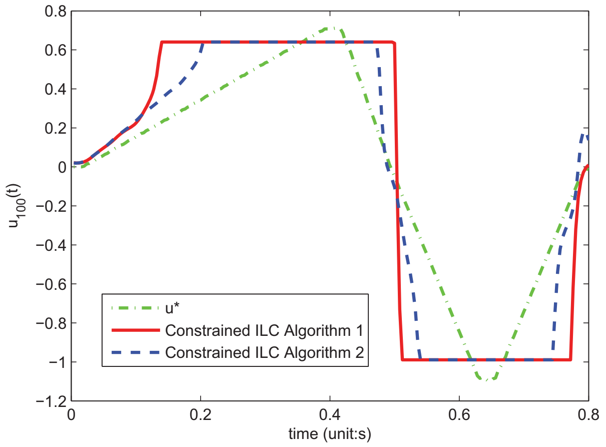

Fig. 5. Input on the $100^{th}$ trial for the X-axis

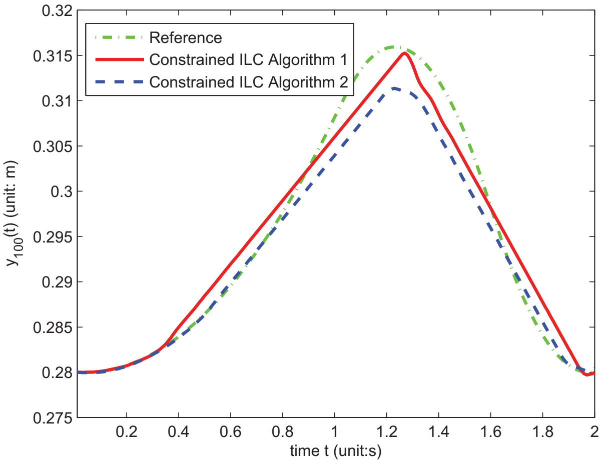

Fig. 6. Output on the $100^{th}$ trial for the X-axis

To expand the discussion of these results , the input, output and tracking error on $100^{th}$ trial for X-axis are given in Figures 5-7. Using Constrained ILC Algorithm 1, a smaller tracking error (on average) is obtained, compared to Constrained ILC Algorithm 2. Note also that the input computed by Algorithm 2 does not just enforce saturation on the original input but adds some compensation (Figure 5).

Figures 8 shows the effects of varying the selection of the weighting matrices keeping the diagonal structure but changing the control input weighting to 0.1. Compared to the results in Figure 4, this new choice puts larger weighting on the input change, leading to slower convergence. Varying this weighting value has no effect on the final tracking error for Algorithm 1

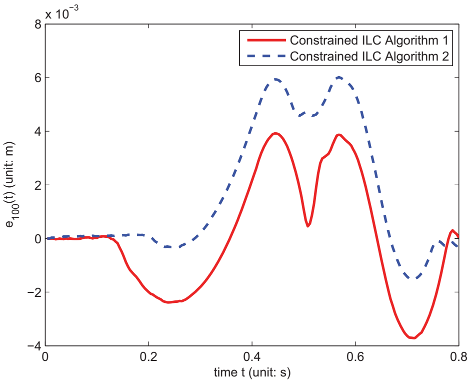

Fig. 7. Tracking error on the $100^{th}$ trial for the X-axis

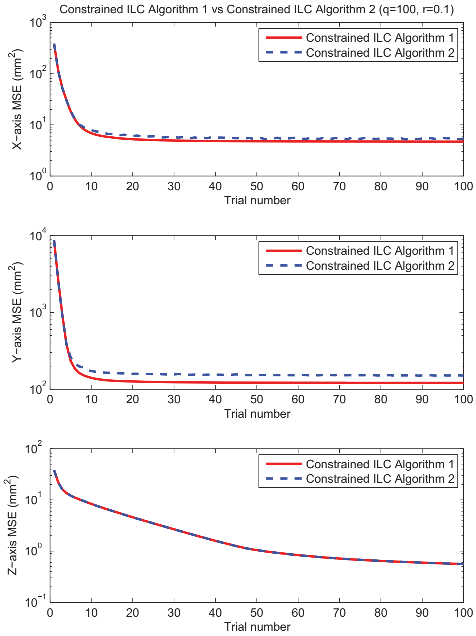

Fig. 8. Comparison of Convergence with control weighting increased to 0.1.

but in Algorithm 2 it results in a better (almost optimal) tracking accuracy, which verifies the theoretical results of Section 2.

Using these results, it can be concluded that Constrained ILC Algorithm 1 performs better than Algorithm 2. However, this is achieved at the expense of higher computational load, which may be not acceptable in some applications but Algorithm 2 achieves nearly optimal performance using a quite simple computation, which is equally (if not more) important in many cases.

## VI. Conclusions

In this paper, two constrained ILC algorithms developed based a successive project framework in [19] have been tested on a gantry robot facility. The results confirm that both algorithms can solve the constrained ILC problem efficiently, while the computation of one algorithm is much less than the other at the cost of slightly sacrificed convergence performance. This requires a compromise between the performance/accuracy and the computational cost.

The experimental results in this paper are based on a linear model of the gantry robot, where nonlinearities are neglected and can be treated as model uncertainty. The results clearly demonstrate certain robustness of the algorithms used. However, further theoretical robustness analysis still needs to be done and constitutes part of planned future research.

*Abstract*—**For the fault tolerant control of an eight-rotor VTOL Unmanned Air Vehicle (UAV), a control allocation scheme is proposed. The eight-rotor configuration provides actuator redundancy to ensure safe operation under rotor/motor failures. A PD controller is used to generate total thrust and moment demands. A cascade inverse method of control allocation is proposed to allocate the controller commands to the actuators whilst ensuring that actuator saturation does not occur. If the vehicle is subjected to rotor failures, the scheme re-allocates the commands to maintain the vehicle stability and performance. Until actuator saturation occurs the response of the vehicle is the same when operating with all motors or fewer. The response of the vehicle to several combinations of complete actuator failures is investigated by simulation and it is shown that the proposed method is able to maintain control after failure of up to four actuators. The controller is invarient and the vehicle response to commands is identical until motor saturation occurs.**

*Index Terms*—**Control Allocation, VTOL UAV, Octorotor, Fault Tolerance**

## I. Introduction

Unmanned Air Vehicles (UAVs) capable of Vertical Take-off and Landing (VTOL) operations can provide many advantages over conventional manned aircraft and UAVs which are not capable of such flight. They give mission flexibility in that a runway is not needed for launch and recovery, give a stable platform for capturing images due to their hover capability, are capable of high agility maneuvers such as vertical drops [1] and allow for operations in harsh and hostile environments since they do not put a human operator at risk. One major drawback with using conventional quadrotor vehicles such as OS4 [2], STARMAC [3], Qball-X4 [4] and tri-rotor vehicles [5] is that there is no effector redundancy. If a rotor fails completely then control is lost and the vehicle may crash. This is an unacceptable scenario when operating over populated urban areas.

It is fairly straightforward to demonstrate that complete loss of a rotor for a quadrotor results in a vehicle that is not fully controllable. However, with a partial failure in one rotor, a quadrotor is still controllable. Fault detection and recovery schemes have been investigated for a 50% thrust reduction in one rotor by [6] and, using a sliding mode method, by [7]. Other methods for partial failures can be found in [4], [8]. Fault tolerant control for a quadrotor subject to sensor failures has been investigated by [9] and by [10]. Even though a total loss of a rotor results in an uncontrollable vehicle, it has been shown that partial control can be maintained [11] with a loss of yaw control.

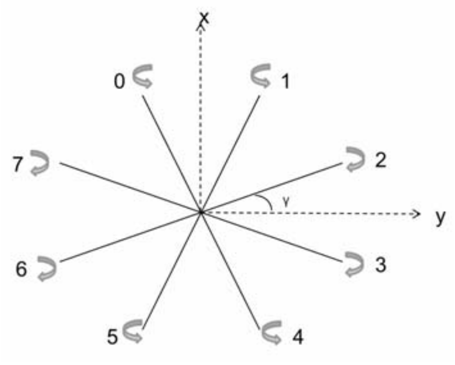

Fig. 1. Octorotor Schematic Layout

TABLE I
Vehicle Parameters

| | |
|---|---|
| Thrust factor, $b$ | $3.13 \times 10^{-5}$ |
| Drag factor, $d$ | $7.5 \times 10^{-7}$ |
| Inertia $I_x, I_y$ | $7.5 \times 10^{-3}$kg m$^2$ |
| Inertia $I_z$ | $1.3 \times 10^{-2}$kg m$^2$ |
| Rotor Inertia, $J$ | $6 \times 10^{-5}$kg m$^2$ |
| Length of arm, $l$ | 0.4m |
| Vehicle mass, $m$ | 1.2kg |
| $\gamma$ | $22.5°$ |

The octorotor has been proposed as a solution to the problem of safe operation of quadrotor-like UAVs [12], [13]. A schematic of the vehicle is shown in Figure 1 with parameters shown in table I. With eight independently controllable rotors the vehicle has in-built hardware redundancy. Combinations of various rotor thrusts will provide moments causing the vehicle to roll around the x axis and pitch around the y axis. Yaw control is achieved by varying the thrust from the clockwise and counter-clockwise rotors whilst keeping a constant overall thrust value. This generates an imbalance in the gyroscopic drag causing the vehicle to yaw around the z axis. Furthermore, if the thrust of any single rotor is changed then it will generate a rolling, pitching and yawing moment. This is a property that can be exploited when fewer than eight rotors are utilized.

It is possible to use various combinations of rotors to generate moments across the body. The allocation and mixing of the thrust demands to achieve a desired objective is the control allocation problem. Various methods for linear control allocation have been proposed including explicit ganging [14], rule based systems [15, pp. 89-106] which have switches in the control laws depending on the failure scenario, daisy chaining [16] which divides the actuators into sets that can perform the same task and are then ranked according to preference for usage and effectiveness until the requirements are met or the maximum performance from the set is reached. Online optimization methods have been proposed, see [17] for a review. The most common approach uses constrained quadratic programming (e.g. [18], [19], [20], [21], [22]) and this results in efficient solutions. A Redistributed Pseudo Inverse (RPI) method [21] is used in this paper. This method can increase the possibility of reaching an optimal solution to an inverse problem and allows for actuator saturation to be considered. A comparison of control allocation methods with control effectiveness uncertainties [23] has shown that the RPI method leads to low errors and high performance.

This paper proposes the use of controller reallocation as a means of obtaining fault tolerant control of the octorotor vehicle subject to failures in one or more rotors. Stability and performance of the vehicle is maintained by means of an RPI control reallocation scheme. The performance of the vehicle subject to multiple rotor failures is shown by simulation. The authors believe this is the first work to show full controllability of all states for a VTOL UAV after rotor failures.

In Section II the dynamics of the octorotor are presented. The essential dynamics are well known [24], [25], [26] but this work focusses on the application to a vehicle with eight rotors rather than the four found in other work [2], [3]. The controller tasked with stabilizing the body angles and global altitude is developed in Section III. A description of rotor saturation and control allocation via the RPI method is given in Section IV. Section V shows results from numerical simulations showing how the control re-allocation can control the vehicle with hardware failures.

## II. Octorotor Dynamics

### A. Dynamics Model

The dynamics of small VTOL UAVs are well developed. Here, the Newton-Euler approach is used [24], [25], [26] with the following assumptions:

- the structure is rigid and symmetric,
- the propellers are rigid,
- the thrust and the drag are proportional to the square of the speed of the rotor,
- ground effect is neglected,
- the inertia matrix is diagonal,
- the rotor Coriolis force and wind forces are not included,
- and the motor dynamics are ignored.

The state variables used in this analysis are:

$$X = [U \; V \; W \; P \; Q \; R \; x \; y \; z \; \phi \; \theta \; \psi]^T \tag{1}$$

where $U, V, W$ are the body-centric velocities of the vehicle, $P, Q, R$ are the rotation rates, $x, y, z$ describe the global position of the vehicle in the inertial frame and $\phi, \theta, \psi$ are the Euler angles. Consider a body-fixed frame with the x,y, and z axes originating at the center of mass of the vehicle. An inertial frame is fixed to the Earth and has axes in the conventional North-East-Down arrangement. The orthogonal rotation matrix $S_b$ converts from a body-fixed coordinate system to the Earth-fixed coordinate system with the assumptions that

- the Earth is flat and stationary and
- the center of gravity lies at the origin of the body axis reference frame

and is given by

$$S_b = \begin{bmatrix} c\theta c\psi & c\theta s\psi & -s\theta \\ s\phi s\theta c\psi - c\phi s\psi & c\phi c\psi + s\phi s\theta s\psi & c\theta s\phi \\ c\phi s\theta c\psi + s\phi s\psi & c\phi s\theta s\psi - s\phi c\psi & c\theta c\phi \end{bmatrix} \tag{2}$$

where $s\phi = \sin\phi$, $c\phi = \cos\phi$ etc. This notation is used throughout the paper.

The total forces and moments in the body axis are given by

$$F_{net} = \frac{d}{dt}[m\mathbf{V}] + \omega' \times [m\mathbf{V}] \tag{3}$$

$$M_{net} = \frac{d}{dt}[I\omega'] + \omega' \times [I\omega'] \tag{4}$$

where $\mathbf{V}$ is the vector of linear velocities, $\omega'$ is the vector of angular velocities, $I$ is the inertia matrix and $m$ is the mass of the vehicle. The gravitational force $F_g$ is

$$F_g = m \; S_b \begin{bmatrix} 0 \\ 0 \\ g \end{bmatrix} = mg \begin{bmatrix} -s\theta \\ c\theta s\phi \\ c\theta c\phi \end{bmatrix} \tag{5}$$

where $g$ is the acceleration due to gravity. The total force $F_{net}$ is the force of gravity and the forces generated through the rotors, $F_p$,

$$F_{net} = F_g + F_p, \tag{6}$$

which from (3) gives

$$\begin{bmatrix} \dot{U} \\ \dot{V} \\ \dot{W} \end{bmatrix} = \frac{1}{m}\begin{bmatrix} F_{px} \\ F_{py} \\ F_{pz} \end{bmatrix} + g \begin{bmatrix} -s\theta \\ c\theta s\phi \\ c\theta c\phi \end{bmatrix} - \begin{bmatrix} QW - RV \\ RU - PW \\ PV - QU \end{bmatrix} \tag{7}$$

From (4), the total moments $M_{net}$ acting on the vehicle are

$$M_{net} = \begin{bmatrix} M_x \\ M_y \\ M_z \end{bmatrix} = \begin{bmatrix} I_x & 0 & 0 \\ 0 & I_y & 0 \\ 0 & 0 & I_z \end{bmatrix} \begin{bmatrix} \dot{P} \\ \dot{Q} \\ \dot{R} \end{bmatrix} + \begin{bmatrix} P \\ Q \\ R \end{bmatrix} \times \begin{bmatrix} I_x & 0 & 0 \\ 0 & I_y & 0 \\ 0 & 0 & I_z \end{bmatrix} \begin{bmatrix} P \\ Q \\ R \end{bmatrix} \tag{8}$$

Rearranging in terms of the state variable derivatives gives

$$\begin{bmatrix}\dot{P}\\ \dot{Q}\\ \dot{R}\end{bmatrix} = \begin{bmatrix}M_x/I_x\\ M_y/I_y\\ M_z/I_z\end{bmatrix} - \begin{bmatrix}((I_z-I_y)/(I_x))\,QR\\ ((I_x-I_z)/(I_y))\,RP\\ ((I_y-I_x)/(I_z))\,PQ\end{bmatrix} \tag{9}$$

The rotation matrix, $S_b$, from (2) is used to express the movement of the vehicle in the global axes once the body-centric velocities are known:

$$\begin{aligned}\begin{bmatrix}\dot{x}\\ \dot{y}\\ \dot{z}\end{bmatrix} &= S_b^T \begin{bmatrix}U\\ V\\ W\end{bmatrix}\\ &= \begin{bmatrix}c\psi c\theta & c\psi s\theta s\phi - s\psi c\phi & c\psi s\theta c\phi + s\psi s\phi\\ s\psi c\theta & s\psi s\theta s\phi + c\psi c\phi & s\psi s\theta c\phi - c\psi s\phi\\ -s\theta & c\theta s\phi & c\theta c\phi\end{bmatrix} \begin{bmatrix}U\\ V\\ W\end{bmatrix}\end{aligned} \tag{10}$$

The flight path is found by integrating (10). It contains the body-centric Euler angles and these are related to the global body angles through

$$\begin{bmatrix}P\\ Q\\ R\end{bmatrix} = \begin{bmatrix}1 & 0 & -s\theta\\ 0 & c\phi & s\phi c\theta\\ 0 & -s\phi & c\theta c\phi\end{bmatrix} \begin{bmatrix}\dot{\phi}\\ \dot{\theta}\\ \dot{\psi}\end{bmatrix} = S_e^{-1} \begin{bmatrix}\dot{\phi}\\ \dot{\theta}\\ \dot{\psi}\end{bmatrix}$$

giving

$$\begin{bmatrix}\dot{\phi}\\ \dot{\theta}\\ \dot{\psi}\end{bmatrix} = S_e \begin{bmatrix}P\\ Q\\ R\end{bmatrix} \tag{11}$$

where

$$S_e = \begin{bmatrix}1 & t\theta s\phi & t\theta c\phi\\ 0 & c\phi & -s\phi\\ 0 & s\phi/c\theta & c\phi/c\theta\end{bmatrix} \tag{12}$$

### B. State Space Model

The general state space model $\dot{X} = f(X, \Gamma)$ is obtained from (7), (9), (10), (11) and (17) with state variables given by (1) and control given by

$$\Gamma = \begin{bmatrix}F_{pz}\\ M_p\end{bmatrix} \tag{13}$$

where $M_p = M_{net}$. This gives the state equation

$$\frac{d}{dt}\begin{bmatrix}U\\ V\\ W\\ P\\ Q\\ R\\ x\\ y\\ z\\ \phi\\ \theta\\ \psi\end{bmatrix} = \begin{bmatrix}-g\ s\theta - (QW - RV)\\ g\ c\theta s\phi - (RU - PW)\\ (-c\theta c\phi F_{pz}/m) + g\ c\theta c\phi - (PV - QU)\\ (M_x/I_x) - ((I_z - I_y)/I_x)\,QR\\ (M_y/I_y) - ((I_x - I_z)/I_y)\,RP\\ (M_z/I_z) - ((I_y - I_x)/I_z)\,PQ\\ (c\psi c\theta)U + (c\psi s\theta s\phi - s\psi c\phi)V + (c\psi s\theta c\phi + s\psi s\phi)W\\ (s\psi c\theta)U + (s\psi s\theta s\phi + c\psi c\phi)V + (s\psi s\theta c\phi - c\psi s\phi)W\\ -s\theta U + (c\theta s\phi)V + (c\theta c\phi)W\\ P + (t\theta s\phi)Q + (t\theta c\phi)R\\ c\phi Q - s\phi R\\ (s\phi/c\psi)Q + (c\phi/c\theta)\,R\end{bmatrix} \tag{14}$$

### C. Actuator Model

The total force provided by the rotors in the body frame is

$$F_{pz} = \sum_{i=0}^{7} b\ \Omega_i^2 \tag{15}$$

where $b$ is the term relating the rotor thrust to the squared rotor speed $\Omega_i^2$. The rotor axes are mounted vertically on the vehicle so

$$F_{px} = F_{py} = 0 \tag{16}$$

The moments, $M_x, M_y, M_z$, are generated by the differences in the thrusts of the eight rotors. The relationship between the control $\Gamma$ and the rotor speeds is given by

$$\Gamma = \Lambda\Sigma \tag{17}$$

where $\Sigma$ is the vector containing the squared rotor speeds

$$\Sigma = \begin{bmatrix}\Omega_0^2 & \Omega_1^2 & \Omega_2^2 & \Omega_3^2 & \Omega_4^2 & \Omega_5^2 & \Omega_6^2 & \Omega_7^2\end{bmatrix}^T, \tag{18}$$

and $\Lambda$ is the control allocation matrix

$$\Lambda = \begin{bmatrix}b & b & b & b & b & b & b & b\\ b_s & -b_s & -b_c & -b_c & -b_s & b_s & b_c & b_c\\ -b_c & -b_c & -b_s & b_s & b_c & b_c & b_s & -b_s\\ d & d & -d & -d & d & d & -d & -d\end{bmatrix}, \tag{19}$$

where $b_s = bl\sin\gamma$, $b_c = bl\cos\gamma$ and where $\gamma$ denotes the angle between the arms of the vehicle and the major axis lines as shown in Figure 1, $l$ denotes the arm length from the center of the vehicle to the rotor axis, the factor $b$ relates the squared rotor speed $\Omega_i^2$ to the thrust and the drag factor $d$ relates the gyroscopic drag to the squared rotor speed.

## III. CONTROLLER

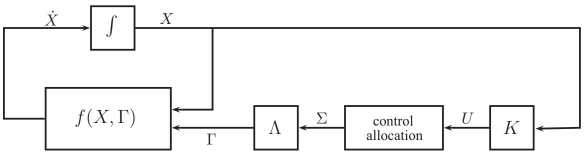

Fig. 2. System Block Diagram

Figure 2 shows the block diagram of the system which is assumed to provide perfect control allocation, that is $\Gamma = U$. The number of rotors and the allocation of the control demands, $\Sigma$, are not considered in the control block where the output, $U$, is simply a moment demand. This means that any maneuvers are completed with the same performance regardless to the number of functional rotors. The operator should not notice any performance change with rotor/motor failures unless all actuators are saturated.

Even though the vehicle has eight physical actuators the system is under actuated in that the actuators can only directly affect four of the six degrees of freedom. For this reason only four control demands can be performed. The control $\Gamma$ (17) contains the total thrust and three moment demands and corresponds to commands $U_i$, $i = 1, 2, 3, 4$.

To design the controller, several further assumptions are made on the model presented in Section II. The vehicle is assumed to operate near hover (non-acrobatic flight), hence the cross coupling terms are ignored in (9) and state derivatives $\dot{P}, \dot{Q}, \dot{R}$ are assumed to be proportional to the controller demands:

$$\begin{bmatrix} \dot{P} \\ \dot{Q} \\ \dot{R} \end{bmatrix} = \text{diag}\left(\frac{1}{I_x}, \frac{1}{I_y}, \frac{1}{I_z}\right) \begin{bmatrix} U_2 \\ U_3 \\ U_4 \end{bmatrix} \tag{20}$$

Similar approximations are made to (10) and (11) to obtain

$$\dot{z} = W \tag{21}$$
$$\dot{\phi} = P \tag{22}$$
$$\dot{\theta} = Q \tag{23}$$
$$\dot{\psi} = R \tag{24}$$

The total thrust is calculated in the Earth-fixed frame meaning the thrust from the rotors $F_{pz}$ must be multiplied by the appropriate factors in the $S_b$ matrix (2). Using (3) and (7) the total thrust demand is known. Based on these approximations, a PD scheme is used for the controller block, $K$, with the individual commands:

$$U_1 = -\frac{m}{c\phi c\theta}(K_{pz}(z_d - z) - K_{dz}(\dot{z}) + g) \tag{25}$$
$$U_2 = (K_{p\phi}(\phi_d - \phi) - K_{d\phi}(\dot{\phi})) \tag{26}$$
$$U_3 = (K_{p\theta}(\theta_d - \theta) - K_{d\theta}(\dot{\theta})) \tag{27}$$
$$U_4 = (K_{p\psi}(\psi_d - \psi) - K_{d\psi}(\dot{\psi})) \tag{28}$$

The gain values were tuned by trial and error and are identical for the roll and pitch controllers (26) and (27) since the vehicle has planes of symmetry along the x and y body axes and so it is possible to equate the pitch and roll responses to a rotor thrust. The gain values for the yaw controller, (28), are set lower than for the roll and pitch since the gyroscopic drag generated by the rotor turning is lower than the moment created when a rotor speed is increased. This means that the yaw response is more sluggish than the roll and pitch response.

## IV. Rotor Saturation and Linear Control Allocation

### A. Rotor Saturation

The allowable values of the rotor speeds $\Omega_i(t)$ are limited between absolute lower and upper bounds $\underline{\Omega}_i$, $\overline{\Omega}_i$ such that

$$\underline{\Omega}_i \leq \Omega_i(t) \leq \overline{\Omega}_i \tag{29}$$

holds for all $t$. There is a maximum thrust that can be generated by each motor-propeller combination due to the constraint on the maximum rotational speed, as well as a minimum thrust due to the lowest rotation speed of the rotor. Furthermore, it is assumed that the motors cannot turn backwards so a negative thrust cannot be generated. Hence, for the octorotor, $\underline{\Omega}_i \geq 0$. Test bed modeling can reveal the limit to the rate at which the motors can respond but in this paper no motor dynamics are modeled and it is assumed that the rotors respond instantaneously. Hence no constraint on the control rates is imposed. From (18), (29) can be rewritten as

$$\underline{\Sigma}_i \leq \Sigma_i(t) \leq \overline{\Sigma}_i \tag{30}$$

Repeating (17), the mapping of the generation of moments to the thrusts from the rotors is

$$\Gamma = \Lambda\Sigma \tag{31}$$

where for the octorotor, with all rotors operational, the dimension of $\Lambda$ is $4 \times 8$ and the full control allocation matrix is given by (19). It should be noted that this differs from the control mapping of a quadrotor where the dimension of $\Lambda$ is $4 \times 4$ [27] and a simple matrix inversion is used to determine the individual rotor thrust values based on the control demands.

For the octorotor a pseudo-inverse method is used. Ideally the thrust demands are shared between all eight rotors. This ensures that no single rotor is close to its maximum threshold which for these simulations was set at 700 rad/s. If an unattainable command is demanded by the controller then the allocation block will not pass it forward to the dynamics block. This is achieved using the redistributed pseudo inverse (RPI) method which is outlined in Section IV-B. This method allows for a control reallocation following a rotor failure. The dimension of the matrix $\Lambda$ is reduced to $4 \times (8 - q)$ where $q$ is the number of failed rotors. The outputs of the individual rotors are then capable of providing the required thrust until their maximum is reached. At this point they are saturated and no more thrust can be generated. In such a state the vehicle may not be controllable.

### B. Redistributed Pseudo Inverse (RPI) Method

The redistributed pseudo inverse method extends the pseudo inverse method by explicitly accounting for actuator saturations. The method is originally attributable to [21], the method we use here is based on the description in [14]. A similar approach, called the Cascaded Generalized Inverse method is proposed by [28]. The process is iterative in that a succession of pseudo inverse solutions are calculated with position saturated control effectors removed from subsequent pseudo inverse solutions. The algorithm is

Step 1. Set $\tilde{\Lambda} = \Lambda$ and $c_i = 0$ for all $i$.

Step 2. Solve the modified pseudo inverse control allocation problem:

$$\Sigma = -c + \tilde{\Lambda}^{+}[\Gamma + \Lambda c] \tag{32}$$

where $\cdot^{+}$ denotes the Moore-Penrose pseudo inverse.

Step 3. If $\underline{\Sigma}_i < \Sigma_i < \overline{\Sigma}_i$ for all $i$, then end. Otherwise,

- for all $i$ such that $\Sigma_i \leq \underline{\Sigma}_i$, set $c_i = -\underline{\Sigma}_i$ and remove the $i$th column of $\tilde{\Lambda}$ and
- for all $i$ such that $\Sigma_i \geq \overline{\Sigma}_i$, set $c_i = -\overline{\Sigma}_i$ and remove the $i$th column of $\tilde{\Lambda}$

and return to Step 2.

The scheme is simply adapted for a control reallocation scheme in the event of an actuator failure by augmenting Step 1. Following a total failure in the $j$th actuator, remove the $j$th column of $\tilde{\Lambda}$ and remove $c_j$. Then proceed as above.

## V. Simulations

In order to test the performance of the redistributed pseudo inverse reallocation method combined with the PD controller, simulations of a number of scenarios were carried out using MATLAB/Simulink. All scenarios began with the vehicle in a hover with all of the state derivatives equal to zero, and the aim is to maintain hover despite multiple rotor failures. The failure condition was initiated at a time of $t = 3$s via a switch in the simulation. It is assumed that the time taken for rotor fault detection and controller reallocation is 0.5s.

Four scenarios were investigated:

1) Failure in rotor 7.
2) Failure in rotor 0 and 7.
3) Failure in rotor 1, 5 and 7.
4) Failure in rotor 1, 3, 5 and 7.

The flight path of the vehicle is described by its altitude $(z)$ and three Euler angles $(\phi, \theta, \psi)$. After the failure the vehicle should recover level flight and regain any lost altitude.

### A. Altitude Recovery

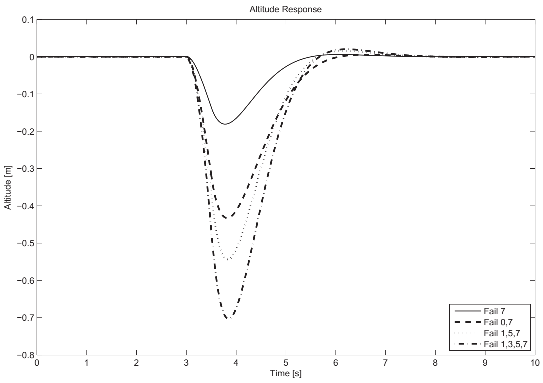

Fig. 3. Altitude Response

Figure 3 shows that as the number of failed rotors increases the altitude drop increases. This is as expected since the total thrust available drops. The vehicle recovers after the reconfiguration to regain the initial altitude with a similar performance after all rotor failures.

### B. Roll Recovery

Figure 4 shows that failure in the rotor caused the vehicle to roll towards the failed rotors. The largest variation from level attitude was with two failed rotors that were next to each other. This generated a large adverse rolling moment before the vehicle recovered to level hover. When four rotors failed, because of the symmetry, no adverse rolling moment was generated and the failed-rotor vehicle acted like a quadrotor with only altitude disturbance.

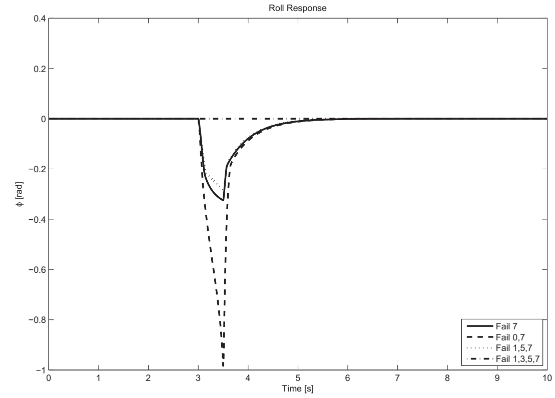

Fig. 4. Roll Response

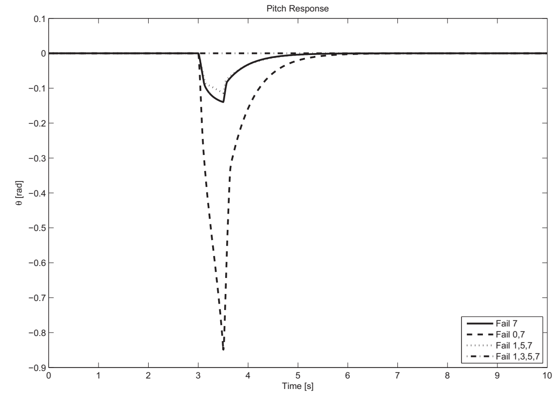

Fig. 5. Pitch Response

### C. Pitch Recovery

Figure 5 shows that the pitch responses are similar to the roll response due to the symmetry over the x and y body axes. The differences in response after the failures were due to the physical location of the failed rotors. The response after reconfiguration is similar to the roll recovery and the vehicle regains hover. Again, with four rotor failures the vehicle only deviates in altitude.

### D. Yaw Recovery

Figure 6 shows that the yaw moment generated from a failed rotor caused the vehicle to yaw slightly. But due to the highly coupled nature of the octorotor dynamics (9) the roll and pitch lead to a large adverse yaw disturbance.

The large roll and pitch generated with a failure in rotors 0 and 7 leads to a large divergence in yaw. The response of the vehicle once reconfigured is not the same as the roll and pitch responses due to the different gains chosen for this controller as described in Section III

## VI. Conclusion

The paper proposes the use of a redistributed pseudo inverse method of control reallocation for the fault tolerant control of

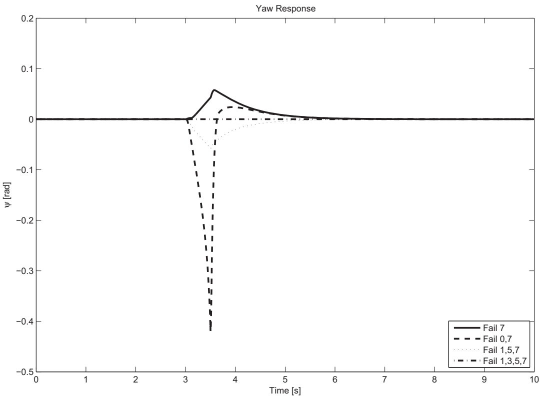

Fig. 6. Yaw Response

an octorotor VTOL aircraft. Unlike the quadrotor, the vehicle stability and performance is resilient to single rotor failure. Furthermore multiple rotor failures can be tolerated; control can be maintained for up to four rotor failures. Four scenarios were investigated by simulation and in all of them the vehicle retained enough control authority to recover from upset angles up to 60°. Note that the proposed method depends on the availability of a fault detection system, this aspect has not been addressed in this paper.

Ongoing theoretical work is investigating the effect of redistributing the rotors so they turn clockwise, counter-clockwise alternating around the vehicle and finding an optimum configuration which will maximize the resilience of the system to multiple rotor failure. In future work, the method will be flight tested.

# Attitude Control of VTOL-UAVs

Maryam Heidarian[†] and Attaullah Y. Memon[‡]

*Abstract*— **This paper presents a novel control approach to obtain asymptotic attitude stability of a quadrotor as a representative of Planar Vertical Take Off and Landing (PVTOL) Unmanned Aerial Vehicles (UAVs). The considered quadrotor is a symmetric VTOL-UAV with four rigid mono-directional propellers, which has been modeled based on quaternion representation with taking Coriolis and gyroscopic torques into account. In the proposed approach, two nearly equivalent control laws (model independent as well as model dependent) have been used to obtain exponential stability of attitude angles and asymptotic stability of attitude angular velocity of the quadrotor UAV. The proposed approach also presents how the attitude parameters i.e. attitude angles and attitude angular velocity can be quickly regulated to their desired values as required.**

*Index Terms*— **Attitude Control, Velocity Control, VTOL, UAV, Quadrotor.**

## I. INTRODUCTION

It is more than two decades since the first VTOL-UAVs were fully demonstrated in practical research works. VTOL-UAVs constitute the class of Unmanned Aerial Vehicles which have the ability of Vertical Take Off and Landing and thus have the capability of fast target acquisition. Due to this, their applications have found a growing interest in performing certain tasks which require high maneuverability and robustness with respect to unknown external disturbances. These UAVs can be used both as individual vehicles and in a team formation of multiple vehicles [1]. Furthermore, use of VTOL-UAVs has been envisaged in a variety of applications, e.g. in environmental protection, intervention in hostile sites, natural risk management, remote inspections, rescue missions, agriculture and, commercial video production. More recently, small quadrotor UAVs have attracted considerable attention by researchers, due to its less complicated mechanical design and maintenance aspects in comparison to helicopters. A quadrotor is essentially a helicopter which has four propellers in cross configuration.

In order to effectively control a VTOL-UAV, a composite control scheme comprising of two different controllers is required, namely: the attitude controller and the position controller. Design of these two controllers constitutes challenging tasks and the same have been addressed separately in the literature. In [2], a dynamical model of quadrotor based on quaternion representation has been derived from Newton-Euler equations. Hamel et al., in [3], identify dynamics of the vehicle beyond the basic nonlinear equations of motion, with gyroscopic torque and Coriolis terms. Based on this model, Tayebi and McGilvray [4], have represented a model independent $PD$ controller with asymptotic stability and a model dependent $PD^2$ controller with exponential stability. A method to obtain attitude control stabilization of a quadrotor through using backstepping technique and adding saturation functions has been analyzed in [5]. Precise measurement of the angular velocity and the initial orientation are required for attitude stabilization of these vehicles. Due to various uncertainties (related to gyroscope and other effects), there may be some errors in these measurements. Using inertial measurements units (IMU's) information to estimate these required values is one of the possible ways to reduce the errors [6]. In their more recent work [7], Tayebi et al., have considered control designs that do not necessarily require exact knowledge of the angular velocity of the aerial vehicle.

In this paper, we consider two nearly equivalent control laws (model independent as well as model dependent) to obtain exponential stability of attitude angles and asymptotic stability of attitude angular velocity of the quadrotor UAV. The rest of the paper is organized as follows. Section II states the problem formulation and presents the necessary mathematical foundation. Section III presents the control design and main results. The simulation results are presented in Section IV, and finally Section V draws the conclusions.

## II. PROBLEM FORMULATION

A quadrotor simply consists of four lift generating propellers mounted on motors. These motors are located at the lateral sides of a cross shaped frame with an angle of 90 degrees between the arms. Center of mass is placed at the intersection of the line joining rotors 1 and 3 and the line joining rotors 2 and 4, which is middle of the connecting links. Furthermore, the quadrotor is assumed to be symmetric and a basic schematic is depicted in Fig. 1.

Flight control of this vehicle is achieved by varying the angular speed of rotors, $w_i, \imath \in 1, 2, 3, 4$. For example, pitching is possible with increasing (reducing) the speed of the rear motor while reducing (increasing) the speed of the front motor. This means, the pitch torque is a function of the difference $w_1 - w_3$. Similarly, roll movement is obtained by using the lateral motors. Thus, the roll torque will be a function of $w_2 - w_4$. Similarly, the yaw motion is obtained by increasing (reducing) the speed of the front and rear motors together while reducing (increasing) the speed of the lateral motors together. These movements can be accomplished while keeping the total thrust, $T$, constant. Also the vertical movement is generated by increasing the total thrust. The

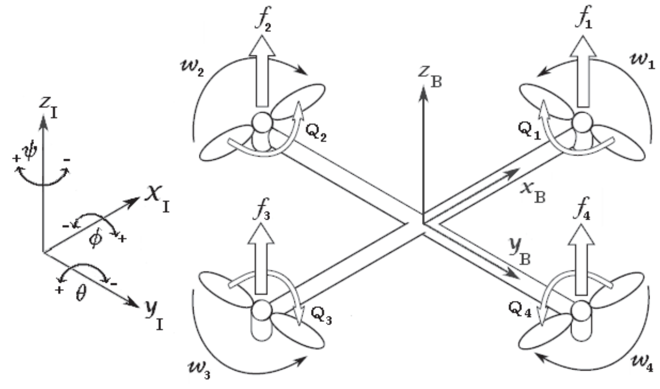

Fig. 1. **Illustration of frames**

main thrust is expressed as:

$$T = \sum_{i=1}^{4} |f_i| \tag{1}$$

$$f_i = b\ w_i^2 z_B \tag{2}$$

Where $f_i$ is the vertically upward lifting force produced by $i$th motor. As we can see in Fig. 1, the rotation direction of two of the rotors is clockwise while the same for the other two is counterclockwise. This is so to balance the movement of the quad rotor and to prevent any yaw drift caused by the unbalanced reactive torques. The reactive torque of $i$th rotor is given by

$$Q_i = l\ w_i^2 \tag{3}$$

Since, each motor turns in a fixed direction, the produced force $f_i$ is always positive. Thus,

$$T = b \sum_{i=1}^{4}\ w_i^2 \tag{4}$$

The constants $l > 0$ and $b > 0$ in the above two equations are dependent on different aerodynamical parameters [8]. The generalized torques (e.g. roll torque $\tau_\phi$, pitch torque $\tau_\theta$, and yaw torque $\tau_\psi$) according to [3] can be represented by

$$\begin{aligned}
\tau_\phi &= b\ d\ (\ w_2^2 -\ w_4^2) &(5)\\
\tau_\theta &= b\ d\ (\ w_1^2 -\ w_3^2) &(6)\\
\tau_\psi &= l(\ w_1^2 +\ w_3^2 -\ w_2^2 -\ w_4^2) &(7)
\end{aligned}$$

in which $d$ is the length of arms between the motors and the center of gravity.

It is noteworthy to mention here that a good working knowledge of the quadrotor dynamical model is essential to improve the performance of the aircraft. Simple vector algebraic laws (e.g. commutativity) cannot be applied to finite rotation vectors of rigid bodies. Due to this, we cannot find the attitude of the aircraft from integrating the angular velocities. Dynamical modeling of the quadrotor requires us to define two reference frames: an inertial frame $I$ defined by set of unit vectors $\{x_I, y_I, z_I\}$ and a body fixed-frame $B$ with orthogonal axes defined by set of unit vectors $\{x_B, y_B, z_B\}$. In order to define the orientation of the aircraft between these two reference frames, one can use Euler angle description, in which a 3 × 3 direction matrix will represent rotation of the aircraft with respect to the body fixed-frame. Euler angle description has an inherent geometric singularity problem. In order to overcome this problem, one can use quaternion representation which defines the rotation of the aircraft with four parameters. The quaternion description is essentially based on Euler's theorem which states that any rotation of an aircraft can be described by a single rotation about a fixed axis.

In what follows, the dynamical model of the quadrotor is obtained via Newton-Euler approach as given in [4]. The basic assumption is that the quadrotor and its propellers are rigid and the external aerodynamic effects (air friction, wind pressure etc.) can be neglected. A simplified model with consideration of Coriolis and gyroscopic torques is given by

$$\begin{aligned}
\dot{q} &= \frac{1}{2}\begin{pmatrix} -(\bar{q})^T \\ s(\bar{q}) + q_0 I \end{pmatrix}\Omega &(8)\\
I_f\dot{\Omega} &= -s(\Omega)I_f\Omega - G_a + \tau_a &(9)\\
I_r\dot{w}_i &= \tau_i - Q_i \qquad i \in 1,2,3,4 &(10)
\end{aligned}$$

where $q$ represents the quaternion equations as given by

$$\begin{aligned}
q &= \begin{pmatrix} q_0 \\ \bar{q} \end{pmatrix}\\
&= \begin{pmatrix}
\cos\frac{\phi}{2}\cos\frac{\theta}{2}\cos\frac{\psi}{2} + \sin\frac{\phi}{2}\sin\frac{\theta}{2}\sin\frac{\psi}{2}\\
\sin\frac{\phi}{2}\cos\frac{\theta}{2}\cos\frac{\psi}{2} - \cos\frac{\phi}{2}\sin\frac{\theta}{2}\sin\frac{\psi}{2}\\
\cos\frac{\phi}{2}\sin\frac{\theta}{2}\cos\frac{\psi}{2} + \sin\frac{\phi}{2}\cos\frac{\theta}{2}\sin\frac{\psi}{2}\\
\cos\frac{\phi}{2}\cos\frac{\theta}{2}\sin\frac{\psi}{2} - \sin\frac{\phi}{2}\sin\frac{\theta}{2}\cos\frac{\psi}{2}
\end{pmatrix} &(11)
\end{aligned}$$

The parameters $\phi$, $\theta$ and $\psi$ respectively represent the roll, pitch and yaw angular displacements about their related axes, and are defined by the following relations [9];

$$\begin{aligned}
\dot{\phi} &= \Omega_\phi + (\Omega_\theta \sin\phi + \Omega_\psi \cos\phi)\tan\theta &(12)\\
\dot{\theta} &= \Omega_\theta \cos\phi - \Omega_\psi \sin\phi &(13)\\
\dot{\psi} &= (\Omega_\theta \sin\phi + \Omega_\psi \cos\phi)\sec\theta &(14)
\end{aligned}$$

in which $\Omega = (\Omega_\phi, \Omega_\theta, \Omega_\psi)^T$ describes the angular velocity of the quadrotor. Furthermore, $I_f \in \mathbb{R}^{3\times3}$ is a symmetric positive-definite constant inertia matrix of the airframe with respect to this frame, and $\tau_a = (\tau_\phi, \tau_\theta, \tau_\varphi)^T$ denotes the control torque. The notation $I_r$ represents the constant moment of inertia of the rotor, and $\tau_i$ , $i \in 1,2,3,4$ represents the rotor torques. The function $s(x)$ in (9) represents a skew-symmetric matrix defined as

$$s(x) = \begin{pmatrix} 0 & -x_3 & x_2 \\ x_3 & 0 & -x_1 \\ -x_2 & x_1 & 0 \end{pmatrix}$$

and is used to define the term $-s(x)I_f\Omega$ in (9), which is due to Coriolis torque. Finally, the term $G_a$ denotes the gyroscopic torque and is defined as

$$G_a = I_r s(\Omega) z_I(-w_1 + w_2 - w_3 + w_4)$$

in which $z_I = (0, 0, 1)^T$.

## III. Control Design and Analysis

The proposed control algorithm to stabilize the attitude of quadrotor follows closely the approach presented in [4], with some technical differences incorporated to seek for an improvement in overall transient performance. We first design the control torque $(\tau_a)$ that stabilizes the attitude of quadrotor dynamically and then, we synthesize a rotor torque $(\tau_i)$ to obtain the control torque $(\tau_a)$ designed earlier, while considering that the real dynamical input to the quadrotor is angular speed of rotors.

### A. Designing the Control Torque $\tau_a$

The dynamical model of the quadrotor, as described in the last section, possesses a cascade structure, in which $\tau_a$ controls $\Omega$ and $\Omega$ controls $q$, i.e. $(\tau_a \to \Omega \to q)$. This means:

$$\dot{\Omega} = g(\Omega, \tau_a)$$

$$\dot{q} = f(q, \Omega)$$

From (8), we have

$$\dot{q} = f(q, \Omega) = F(\Omega)q \tag{15}$$

$$F(\Omega) = \frac{1}{2}\begin{pmatrix} 0 & -\Omega_\phi & -\Omega_\theta & -\Omega_\psi \\ \Omega_\phi & 0 & -\Omega_\psi & \Omega_\theta \\ \Omega_\theta & \Omega_\psi & 0 & -\Omega_\phi \\ \Omega_\psi & -\Omega_\theta & \Omega_\phi & 0 \end{pmatrix} \tag{16}$$

Similarly from (9), we have

$$\dot{\Omega} = g(\Omega, \tau_a) = I_f^{-1}(-s(\Omega)I_f\Omega - G_a + \tau_a) \tag{17}$$

With this in mind, our goal is to find a suitable control law $\tau_a = H(q, \Omega)$. We achieve this objective through the following two steps:

- By finding desired angular velocity $\Omega_d = h(q)$ such that when $\Omega_d$ is given as input to (9), the solution to the nonlinear equation $\dot{q} = f(q, h(q))$ is asymptotically stable.
- By ensuring that the angular velocity $\Omega$ asymptotically tracks the desired angular velocity $\Omega_d$, i.e. $\lim_{t\to\infty}(sup|\Omega - \Omega_d|) = 0$.

*1) Desired Angular Velocity:* The desired angular velocity $\Omega_d$, has to be chosen in such a way that the solution of the nonlinear differential equation $\dot{q} = f(q, \Omega_d)$ converges to its equilibrium point. The equilibrium point, with assuming $0 \leq q_0 \leq 1$ is $q_e = (1, 0, 0, 0)^T$. The quaternion regulation error can be described by

$$\widetilde{q} = q - q_e = (q_0 - 1, q_1, q_2, q_3)^T$$

Comparing $\tilde{q}$ with $\dot{q}$ will give us:

$$\begin{aligned} \dot{\tilde{q}} &= \frac{1}{2}\begin{pmatrix} -(\bar{q})^T \\ s(\bar{q}) + (q_0 - 1)I \end{pmatrix}\Omega \\ &= \frac{1}{2}\begin{pmatrix} -q_1 & -q_2 & -q_3 \\ q_0 - 1 & -q_3 & q_2 \\ q_3 & q_0 - 1 & -q_1 \\ -q_2 & q_1 & q_0 - 1 \end{pmatrix}\Omega \\ &= B(q)\Omega \end{aligned} \tag{18}$$

**Theorem 1.** *Let $\alpha$ be a positive constant and $Q$ is any positive definite symmetric matrix. If the desired angular velocity is given by*

$$\Omega_d = \alpha I B(q)^T Q q \tag{19}$$

*Then, under the stated assumptions and conditions, the overall quaternion system will be exponentially stable. Furthermore, the desired quaternion regulation settling time can be obtained by choosing a suitable value of $\alpha$.*

*Proof:* For simplicity, we will consider $Q = 2I$ in Equation (19) so that

$$\Omega_d = -\alpha\bar{q} \tag{20}$$

Consider the stable unforced system

$$\begin{aligned} \dot{\tilde{q}} &= N(\tilde{q}, \Omega) \\ &= N(\tilde{q}, 0) = 0 \end{aligned}$$

Substituting the value of $\Omega_d$ from (20) we have

$$\dot{\tilde{q}} = -B(q)\alpha\bar{q}$$

Defining

$$V = \tfrac{1}{2}(\tilde{q})^T\tilde{q} = 1 - q_0$$

With substitutions from (8) and (20), we have

$$\dot{V} = -\dot{q_0} = -\tfrac{1}{2}\bar{q}^T\alpha_i(\bar{q})$$

Using the property of quaternion representation [12] that $\bar{q}^T\bar{q} + {q_0}^2 = 1$, and since $0 \leq q_0 \leq 1$, we get

$$\begin{aligned} \dot{V} &= -\frac{1}{2}\alpha(1 + q_0)V \\ &< 0 \end{aligned}$$

which shows that for the desired input the system is input-to-state stable. This means $\lim_{t\to\infty}\tilde{q} = 0$ and from definition of $\tilde{q}$ we can conclude $\lim_{t\to\infty} q = q_e$.

According to the treatment given in [10], it can be shown that the system is asymptotically stable. For exponential stability; substituting (20) into (8) we have

$$\dot{q_0} = \frac{1}{2}\alpha(1 - q_0^2)$$

$$\dot{\bar{q}} = -\frac{1}{2}\alpha q_0\bar{q}$$

The time response of $q(t)$, by solving these differential equations can be found as

$$q_0(t) = 1 - 2c_1\frac{e^{-\alpha t}}{1 + c_1 e^{-\alpha t}} \tag{21}$$

$$\bar{q}(t) = \frac{1 + c_1}{1 + c_1 e^{-\alpha t}}e^{-0.5\alpha t}q(0) \tag{22}$$

where $c_1$ can be defined as $c_1 = \frac{1 - q_0(0)}{1 + q_0(0)}$. From (21) and (22) we can conclude that the quaternion system (8) is exponentially stable [10]. Also from (21) and (22), it can be seen that the parameter $\alpha$ is related to the settling time of the quaternion regulation and according to definition of the regulation settling time $t_q$ in [11], this relationship is given as

$$t_q = \frac{4.6}{0.5\alpha} = \frac{9.2}{\alpha} \tag{23}$$

*2) Desired Angular Velocity Tracking:* In the next step, we design $\tau_a$ such that it makes the angular velocity $\Omega$, asymptotically follows the desired angular velocity (20). The angular velocity tracking error can be described as $\tilde{\Omega} = \Omega - \Omega_d$. Assume that

$$\dot{\tilde{\Omega}} = -\lambda f(\tilde{\Omega}) \tag{24}$$

in which $\lambda$ is a positive constant and $f(\tilde{\Omega})$ is any function of $\tilde{\Omega}$ which satisfies

$$\tilde{\Omega} f(\tilde{\Omega}) > 0 \qquad \tilde{\Omega} \neq 0 \tag{25}$$

$$f(\tilde{\Omega}) = 0 \qquad \tilde{\Omega} = 0 \tag{26}$$

Defining the Lyapunov function candidate as

$$V = \tfrac{1}{2}(\tilde{\Omega})^T \tilde{\Omega}$$

The time derivative of $V$ while considering (24) is

$$\begin{aligned} \dot{V} &= -\lambda \tilde{\Omega} f(\tilde{\Omega}) \\ &< 0 \end{aligned}$$

which shows that $\lim_{t\to\infty} \tilde{\Omega} = 0$ and subsequently, we have $\lim_{t\to\infty} \Omega = \Omega_d$.

A model-dependent control law, $\tau_a$ can now be designed as

$$\tau_a = s(\Omega) I_f \Omega + G_a + I_f \dot{\Omega} \tag{27}$$

Using the definition of $\tilde{\Omega}$, we have that $\dot{\Omega} = \dot{\tilde{\Omega}} + \dot{\Omega}_d$, which with respect to (24) gives

$$\tau_a = s(\Omega) I_f \Omega + G_a - \lambda I_f f(\tilde{\Omega}) + I_f \dot{\Omega}_d \tag{28}$$

From (20), we have $\dot{\Omega}_d = J(q)\dot{q}$, where $J(q)$ is Jacobian matrix of $\Omega_d$ as given by

$$J(q) = \begin{pmatrix} 0 & -\alpha_1 & 0 & 0 \\ 0 & 0 & -\alpha_2 & 0 \\ 0 & 0 & 0 & -\alpha_3 \end{pmatrix}$$

Finally from (15) we get

$$\dot{\Omega}_d = J(q) F(\Omega) q$$

which yields

$$\tau_a = s(\Omega) I_f \Omega + G_a - \lambda I_f f(\tilde{\Omega}) + I_f J(q) F(\Omega) q \tag{29}$$

**Remark 1.** *As an example, one of the functions that can satisfy Equations (25) and (26) is*

$$f(\tilde{\Omega}) = sat(\tilde{\Omega}) = \begin{cases} \tilde{\Omega} & |\tilde{\Omega}| < a \\ sgn(\tilde{\Omega}) & |\tilde{\Omega}| \geq a \end{cases}$$

*Where the positive constant $a$ is the width of the boundary layer of the saturation function.*

**Remark 2.** *The control law (29) will ensure the asymptotic stability of the quadrotor if and only if the regulation of $\Omega$ to its equilibrium point (zero) is faster than regulation of $q$ to $q_e$ which means that*

$$t_\Omega < t_q \tag{30}$$

*Here, the angular velocity tracking error settling time $t_\Omega$ approximately is:*

$$t_\Omega = \frac{a + \alpha}{\lambda \alpha} \tag{31}$$

*Notice that the boundary layer width $a$, has to be sufficiently small such that it is in the angular velocity settling range. Also the control law (29) with respect to the airframe inertia uncertainties $\Delta I_f$ is robustly stable if the angular velocity tracking parameter $\lambda$ is*

$$\lambda > \lambda_0 = a(a + \frac{1}{2}\|J\|_\infty)\frac{\delta}{\sigma_{min}(I_{f0})}$$

*where $I_{f0}$ is nominal value of airframe's inertia matrix and $\Delta I_f \in \{y|\ \|y\|_\infty \leq \delta\}$.*

It is important to point out here that one can simply design a model-independent control law as

$$\begin{aligned} \tau_a &= \dot{\Omega} \\ &= -\lambda f(\tilde{\Omega}) + J(q) F(\Omega) q \end{aligned} \tag{32}$$

Further, with both the control laws of (29) and (32), the regulation problem of attitude angles to their desired values (i.e. at zero as in hovering case) results in an exponentially stable system, and the regulation settling time is a function of $\alpha$.

### *B. Designing the Rotor Torque $\tau_i$*

Having achieved the task of designing control torque (model dependent or model independent), we now proceed to designing $\tau_i$ such that the angular speed of the rotors ($w_i$'s), follow the desired angular speeds generated by our designed control torque $\tau_a = (\tau_\phi, \tau_\theta, \tau_\psi)^T$. From Equations (1)-(3) and (7), we find the desired angular speeds as

$$\begin{aligned} \begin{pmatrix} w_{d_1}^2 \\ w_{d_2}^2 \\ w_{d_3}^2 \\ w_{d_4}^2 \end{pmatrix} &= \begin{pmatrix} 0 & bd & 0 & -bd \\ bd & 0 & -bd & 0 \\ l & -l & l & -l \\ b & b & b & b \end{pmatrix}^{-1} \begin{pmatrix} \tau_\phi \\ \tau_\theta \\ \tau_\psi \\ T \end{pmatrix} \\ &= A^{-1} \begin{pmatrix} \tau_\phi \\ \tau_\theta \\ \tau_\psi \\ T \end{pmatrix} \end{aligned} \tag{33}$$

in which the parameters $b$, $d$ and $l > 0$ are assumed to be positive, in order to ascertain that the matrix $A$ remains nonsingular.

Tracking error of angular speed of rotor's can be described as $\tilde{w_i} = w_i - w_{d_i}$. For making the angular speeds of rotors asymptotically approach their respective $w_{d_i}$'s, assume that

$$\dot{\tilde{w_i}} = -h f(\tilde{w_i}) \tag{34}$$

in which $h$ is a positive constant and $f(\tilde{w_i})$ is any function of $\tilde{w_i}$ that satisfies (25) and (26) by replacing $\tilde{\Omega}$ with $\tilde{w_i}$. Defining the Lyapunov function candidate as

$$V = \frac{1}{2}(\tilde{w_i})^T\tilde{w_i}$$

The time derivative of $V$ while considering (34) is

$$\begin{aligned}\dot{V} &= -h\tilde{w_i}f(\tilde{w_i}) \\ &< 0\end{aligned}$$

which shows that $\lim_{t\to\infty}\tilde{w_i} = 0$ and subsequently, we have $\lim_{t\to\infty} w_i = w_{d_i}$.

We can simply define $\tau_i$ with respect to (10), as

$$\tau_i = Q_i + I_r\dot{w_i}$$

which can be written as

$$\tau_i = Q_i + I_r\dot{w_{d_i}} - hI_rf(\tilde{w_i}) \qquad (35)$$

One of the functions that can satisfy the conditions is

$$f(\tilde{w_i}) = sat(\tilde{w_i}) = \begin{cases} \tilde{w_i} & |\tilde{w_i}| < a \\ sgn(\tilde{w_i}) & |\tilde{w_i}| \geq a \end{cases} \qquad (36)$$

Notice that in Equation (35), one of the possible means of finding $\dot{w_{d_i}}$ can be by using the dirty derivative filter [4];

$$\dot{w_{d_i}} = \frac{s}{1+T_fs}w_{d_i}$$

## IV. Simulation Results

In order to ascertaining the performance of the quadrotor using the proposed control algorithm, we consider a quadrotor with dynamical parameters as listed in Table 1. Using Equation (23), the desired regulation settling time (attitude angles settling time) can give us the required parameters for our control law. Notice that, there is a compromise between choosing a small value of $t_q$ and having large peak value for the angular velocity $\Omega$, since with replacing the control law (29) or (32) in (9), we will find that peak value of the angular velocity $\Omega$ would be a function of $\alpha$, $\lambda$ and $a$. In other words, if we decrease $t_q$, we have increased $\alpha$ and decreased $\lambda$, which will increase the peak value. Furthermore, choosing $a$ as small as possible will cause to smaller peak values. In this paper we have considered the value of $a$ as:

$$a = 0.02\alpha \qquad (37)$$

Simulation 1 (Fig. 2 and Fig. 3) shows the performance of the control law (29) for desired regulation settling time ($t_q$) $0.2s$. From (23) and (37) respectively we will get $\alpha = 46$ and $a = 0.92$. One can choose $t_\Omega = 0.1$ and then from (31), $\lambda = 510$. Simulation 2 (Fig. 4 and Fig. 5) shows the performance of the control law (32) for the previous values.

Consider the initial angles as $\phi = -25°, \theta = 30°, \psi = -10°$, gain $h_i$ , $i\epsilon\{1,2,3,4\}$ as 0.002, $T = 1.5N$ and $T_f = 0.008$ (cutoff frequency of 20 Hz). In Simulations 1 and 2, the desired situation of quad rotor is in hovering. Notice that, performance of both the control laws is nearly equivalent. Trajectories of angular speed of rotors for the system described in Simulation 1 have been depicted in Fig. 6. In Simulation 3 (Fig. 7 and Fig. 8) the system is to be regulated to $\phi_r = 10°, \theta_r = -15°, \psi_r = 5°$. As before, performance of model-independent control law (32) is same as model-dependent control law (29). Trajectories of angular speed of rotors are shown in Fig. 9.

TABLE I

Considered dynamical values

| Dynamical Parameter | Considered Value |
|---|---|
| d | 0.225 m |
| $I_r$ | $3.4 \times 10^{-5}\ kg.m^2$ |
| $I_{f_\phi}$ | $4.9 \times 10^{-3}\ kg.m^2$ |

## V. CONCLUSIONS

We presented a novel control approach to obtain asymptotic attitude stability of a quadrotor as a representative of VTOL-UAVs. Based upon the quaternion representation, we defined a robust control law for attitude control of the quadrotor in which the regulation of attitude angles to their desired values is shown to be exponentially stable, and that the desired settling values can be adjusted by the operator. In the proposed methodology, the tracking of desired angular velocity is shown to be asymptotically stable. The performance of the proposed control design has been ascertained using Simulation.

***Abstract*—A systematic geometric design methodology to generate a stable controller for simultaneous local and remote attenuation that was previously proposed is experimentally validated on a structure. The local control path transfer function for this experimental system is non-minimum phase due to which the original broadband controller design would yield an unstable controller. Here a modified procedure for systems with local non-minimum phase dynamics is used to generate a stable controller. According to this method, reduction in vibration at local and remote points on a structure can be parameterised in terms of the available design freedom and a controller is realised in terms of the optimal selection of this using the minimum phase counterpart of the local control path transfer function. The modified method results in a controller that is both stable and stabilizing and which achieves the desired vibration attenuation at the local and remote points on the structure. An experimental facility that replicates the vibration transmission through the shaft of a propeller blade rig system is used to demonstrate the method. Vibration for excitation near the first bending mode frequency of the resonating part of this structure is attenuated at the non-resonating part of the system without deteriorating vibration at the resonating end.**

## I. Introduction

Active control for reduction of vibration at a specific point on a complex interconnected structure can potentially enhance vibration at other points on the structure [1]. A controller design technique to address the vibration attenuation problem at local and remote points on a structure simultaneously using only a single locally placed sensor actuator pair was presented for a discrete frequency excitation case in [2] and later extended for the broadband case [3]. For vibration attenuation over an arbitrary frequency band, controller implementation involves inversion of the local control path transfer function. When the local control path transfer function is non minimum phase, then the controller itself would be unstable. This problem can be solved using a new design freedom [4] to parameterise reduction in vibration at local and remote points whereby the controller is implemented in terms of the minimum phase counterpart of the local control path transfer function. Additionally, to improve robustness to unmodelled high frequency dynamics, a filter is incorporated into the design freedom selection [5] such that the gain of the closed loop system rolls off at high frequency without deteriorating controller performance in the excitation frequency bandwidth. The aim of this paper is to present experimental verification of this design technique for attenuation of vibration at both local and remote points on a blade rig simultaneously. Trade-offs between stability robustness and disturbance attenuation are also highlighted in terms of the values of the design freedom parameter.

## II. Experimental set-up

A schematic diagram of the blade rig is shown in figure 1. The primary excitation signal $f_p(t)$ is a common signal fed to the two smaller shakers attached at both ends of the bar which acts as the transient loading force due to rotation of the propeller blades. The vibration at the blade end of the shaft $q_p(t)$ is the summation of outputs measured by two accelerometers connected near each of the disturbance shakers. The control input $f_c(t)$ is applied to the control shaker attached at the other end of propeller shaft on the thrust block and a local accelerometer on the thrust block measures local vibration levels $q_c(t)$. Vibration is transmitted from the blade end along the shaft to the thrust block end and is particularly detrimental at the blade resonant frequency. Due to difficulties in measuring and actuating at the blade end for most applications, it is desired to control both blade vibration and its transmission using sensors and actuators placed at the thrust block only[1]. This blade system can be considered as a two input two output system with the transfer function matrix relating the disturbance and control inputs to the remote and local vibration outputs as

$$\begin{bmatrix} q_c(j\omega) \\ q_p(j\omega) \end{bmatrix} = \begin{bmatrix} g_{cc}(j\omega) & g_{cp}(j\omega) \\ g_{pc}(j\omega) & g_{pp}(j\omega) \end{bmatrix} \begin{bmatrix} f_c(j\omega) \\ f_p(j\omega) \end{bmatrix} \quad (1)$$

In the next section, a design freedom parameter is introduced which parameterizes reduction in vibration at the thrust block and blade end. A controller implemented in terms of the optimally selected values of this design freedom would achieve the targeted vibration reduction.

## III. General algorithm

The detailed synthesis of a stable controller using the geometric approach is given in [4], [5]. For the system described in (1), the aim is to design a feedback controller $k(j\omega)$ using as feedback signal only from the thrust block to achieve vibration

[1] Note that this general concept is the subject of several BAE Systems patents

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

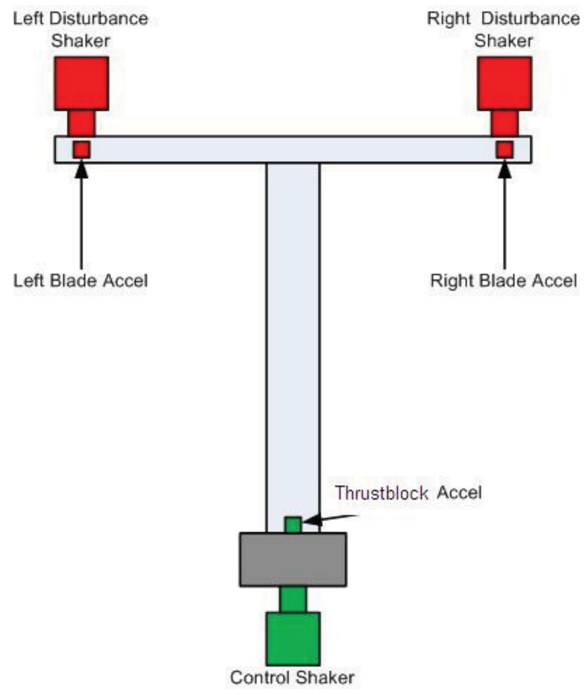

Figure 1. Schematic of blade rig

reduction at both the thrust block and blade end simultaneously. Using control action, $f_c(j\omega) = -k(j\omega)q_c(j\omega)$, the closed loop output respectively at the local and remote points is then given as

$$q_c(j\omega) = \left[1 + \frac{-g_{cc}(j\omega)k(j\omega)}{1 + g_{cc}(j\omega)k(j\omega)}\right] g_{cp}(j\omega)f_p(j\omega) \tag{2}$$

and

$$q_p(j\omega) = \left[1 + \frac{-g_{cc}(j\omega)k(j\omega)}{1 + g_{cc}(j\omega)k(j\omega)} \frac{g_{cp}(j\omega)g_{pc}(j\omega)}{g_{cc}(j\omega)g_{pp}(j\omega)}\right] g_{pp}(j\omega)f_p(j\omega) \tag{3}$$

Denote a design freedom parameter $\gamma$ which is related to the sensitivity function $S(j\omega)$ as

$$\gamma(j\omega) = \frac{1}{g_{AP}(j\omega)f_{LP}(j\omega)}\left[S(j\omega) - 1\right] \tag{4}$$

where $g_{AP}(j\omega)$ is the all pass transfer function formed from the right half plane zeros of $g_{cc}(j\omega)$ and $f_{LP}(j\omega)$ is a low pass or a bandpass filter which improves robustness at out-of-band frequencies. The closed loop local and remote outputs in (2) and (3) can be represented in terms of this parameter variable as

$$q_c(j\omega) = \left[1 + \gamma(j\omega)g_{AP}(j\omega)f_{LP}(j\omega)\right] g_{cp}(j\omega)f_p(j\omega) \tag{5}$$

and

$$q_p(j\omega) = \left[1 + \gamma(j\omega)g_{AP}(j\omega)f_{LP}(j\omega)\frac{g_{cp}(j\omega)g_{pc}(j\omega)}{g_{cc}(j\omega)g_{pp}(j\omega)}\right] g_{pp}(j\omega)f_p(j\omega) \tag{6}$$

The magnitude of the expression inside brackets in RHS of (5) and (6) determines reduction in closed loop local and remote output. The magnitude of these terms can be represented as a circle at each discrete frequency in a $\gamma-$plane. A value for $\gamma$ from inside the circle corresponds to reduction in vibration. If values for $\gamma$ at discrete frequencies in the disturbance frequency bandwidth $[\omega_L, \omega_H]$ is selected from inside the circles given by inequalities (7) and (8), then reduction in vibration at the local and remote points is possible.

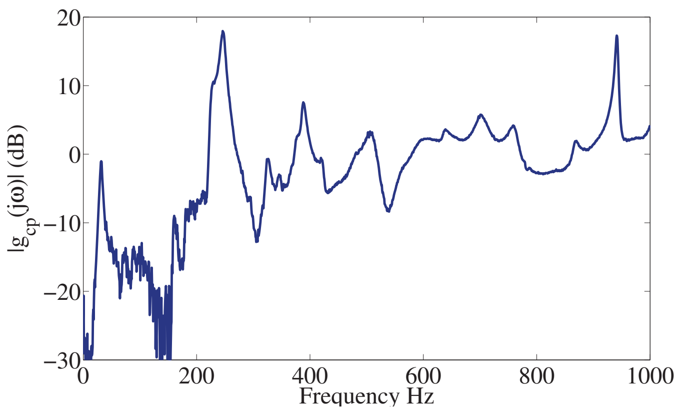

Figure 2. Measured frequency response of primary excitation input to thrust block vibration output

$$\left|\gamma(j\omega_i) + \frac{1}{g_{AP}(j\omega_i)f_{LP}(j\omega_i)}\right| < \left|\frac{1}{g_{AP}(j\omega_i)f_{LP}(j\omega_i)}\right| \tag{7}$$

$$\left|\gamma(j\omega_i) + \frac{1}{g_{AP}(j\omega_i)f_{LP}(j\omega_i)}\frac{g_{cc}(j\omega)g_{pp}(j\omega)}{g_{cp}(j\omega)g_{pc}(j\omega)}\right| < \left|\frac{1}{g_{AP}(j\omega_i)f_{LP}(j\omega_i)}\frac{g_{cc}(j\omega)g_{pp}(j\omega)}{g_{cp}(j\omega)g_{pc}(j\omega)}\right| \tag{8}$$

These optimal $\gamma$ points are interpolated by a stable transfer function and the controller is implemented as

$$k(j\omega) = -\frac{\gamma(j\omega)f_{LP}(j\omega)}{\left[1 + \gamma(j\omega)g_{AP}(j\omega)f_{LP}(j\omega)\right]g_{MP}(j\omega)} \tag{9}$$

where $g_{MP}(j\omega)$ is the minimum phase counterpart of the local control path transfer function.

The magnitude frequency response of the open loop path from primary excitation input on the blade to the local and remote outputs, denoted as $g_{cp}(j\omega)$ and $g_{pp}(j\omega)$ respectively, is plotted in figures 2 and 3. It shows that near the frequency of the first bending mode of the blade (i.e. the iron bar connected to one end of the shaft), vibration transmission to the thrust block is amplified. A feedback controller to achieve simultaneous reduction in the thrust block and blade vibration outputs will be designed for primary excitation around this frequency range.

The first step in controller design is to determine an LTI model for the open loop control path $g_{cc}(j\omega)$ from the measured FRF. As the controller will target vibration reduction in the low frequency region, the measured FRF of the path from control shakers to acceleration on thrust block at frequencies below 800 Hz is fitted with a $15^{th}$ order transfer function model using least squares. The dynamics neglected at frequencies higher than 800 Hz will not be a problem as they will not be excited by the control action due to low pass

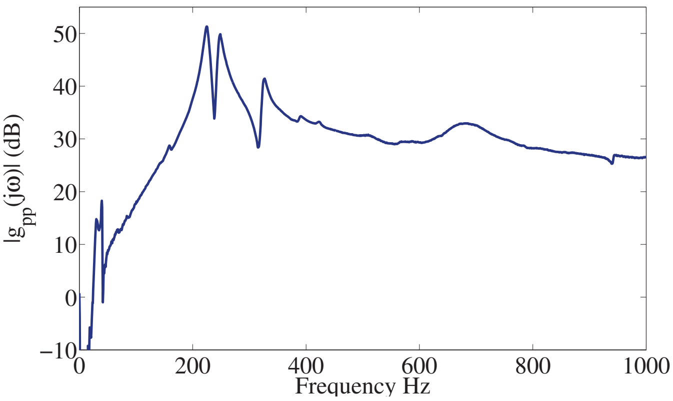

Figure 3. Measured frequency response of primary excitation input to blade vibration output

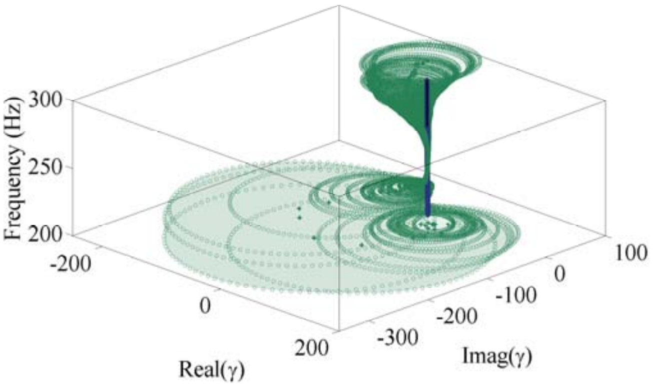

Figure 4. Circles that represent remote vibration attenuation in $\gamma-$ plane at discrete frequencies between 200 Hz and 300 Hz. Unit radius circles corresponding to local vibration attenuation appear as a cylinder that passes through the origin

filter $f_{LP}(j\omega)$. This identified transfer function has 1 right half plane zero so that $g_{AP}(j\omega)$ is of order 1 and $g_{MP}(j\omega)$ has this RHP zero reflected into the LHP.

The circles in the $\gamma-$plane corresponding to reduction in vibration at the local and remote outputs given by (7) and (8) for frequencies around the first bending mode is shown in figure 4. The circles corresponding to reduction in vibration at the blade end are very large in the frequency region from 200 Hz to 220 Hz and above 270 Hz. The distance between the centre of both circles will be large and so it will not be possible to achieve considerable vibration reduction at the blade end without amplifying vibration output at the thrust block end. Optimal $\gamma$ points at these frequencies are selected such that the vibration level at the thrust block is reduced without enhancing the vibration level at the blade end. $f_{LP}(j\omega)$ is chosen as a bandpass filter with lower and higher cut-off frequency as 100 Hz and 600 Hz, respectively.

## IV. Nevanlinna-Pick interpolation

The set of selected optimal $\gamma$ points at discrete frequencies in the disturbance frequency bandwidth is interpolated by a stable transfer function using the Nevanlinna Pick interpolation algorithm [6]. This interpolation problem can be stated as follows: given $n$ distinct points $s_1, \ldots, s_n$ in the right half plane $\Pi^+$ and a collection of complex numbers $H_1, \ldots, H_n$, determine a transfer function $f(s)$ that is analytic in $\Pi^+$ with

$$\sup |f(s)| \leq 1$$

such that $f(s_i) = H_i$, for all $i = 1, \ldots, n$. The solution of this interpolation exists if and only if the associated Pick matrix $P$

$$P = \left[ \frac{1 - H_k \overline{H}_l}{s_k + \overline{s}_l} \right]_{k,l=1}^{n}$$

is positive definite, where $\bar{\bullet}$ denotes complex conjugate. The points $s_i$ according to the above theorem should strictly belong to the Right Half Plane, whereas the set of optimal selected values for the design freedom $\gamma$ have to be interpolated on the imaginary $j\omega$ axis. The frequency points are shifted into the RHP using transformation of Lemma 2 in [8] and is stated as follows: for the optimal $\gamma$ data values at $n$ discrete frequencies $\omega_i$, for $i = 1, \ldots, n$, a stable transfer function $\gamma(j\omega)$ exists if and only if the associated Pick matrix

$$P = \left[ \frac{1 - W_k \overline{W}_l}{s_k + \overline{s}_l} \right]_{k,l=1}^{n} \tag{10}$$

is positive definite, where $W_i = {}^{\gamma_i}/_{M}$ and $s_i = \sigma + j\omega_i$, for $i = 1, \ldots, n$. where $M$ is the maximum modulus of interpolated transfer function and $\sigma$ a positive real number. Increasing $M$ or decreasing $\sigma$ increases the positive definitness of the pick matrix but for a stable controller and good performance at intermediate frequencies, $M$ and $\sigma$ values have to be finely tuned. It should be noted that small values of $\sigma$ will give interpolated transfer function $\gamma(j\omega)$ with poles that are close to the imaginary axis. This would cause oscillations in the frequency response of the identified transfer function $\gamma(j\omega)$ leading to gain and phase crossover at intermediate frequencies. As the non-interpolated points in the disturbance frequency band for small values of $\sigma$ may lie outside (7) and (8) circles in $\gamma-$plane, this would deteriorate controller performance. Although large value of $\sigma$ gives better approximation at intermediate frequencies, $M$ values will have to be increased to get a positive definite pick matrix. A large value of $M$ can result in the nyquist contour of $\gamma(j\omega)g_{AP}(j\omega)f_{LP}(j\omega)$ encircling the critical point which will cause the controller to become unstable as can be seen from (9). If the Pick matrix (10) of optimally selected $\gamma$ points is not positive definite, then an approximate set of sub-optimal points adjusted to lie inside the circles is obtained using Linear Matrix Inequalities that also satisfy the pick condition. This new set of $\gamma$ points is used to obtain the interpolating function using the classical N-P interpolation algorithm.

The first step in iterative classical N-P interpolation algorithm is to compute the elements of Fenyves array $T$.

$$T_{k,l} = \frac{s_l + \bar{s}_{k-1}}{s_l - s_{k-1}} \frac{T_{k-1,l} - T_{k-1,k-1}}{1 - T_{k-1,l}\overline{T}_{k-1,k-1}}$$
$$2 < k < n, \; k < l < n \tag{11}$$

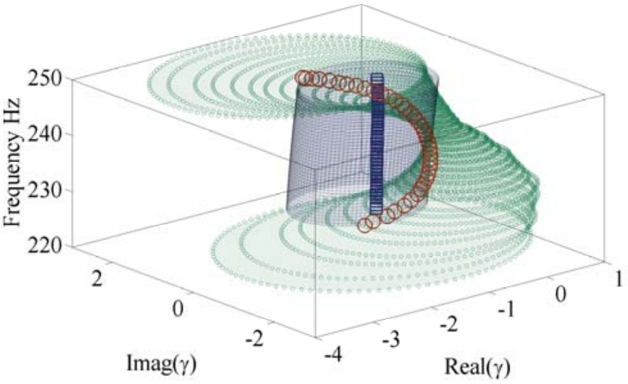

Figure 5. Final operating $\gamma$ points as the frequency response of a stable bounded real interpolated transfer function $\gamma(j\omega)$

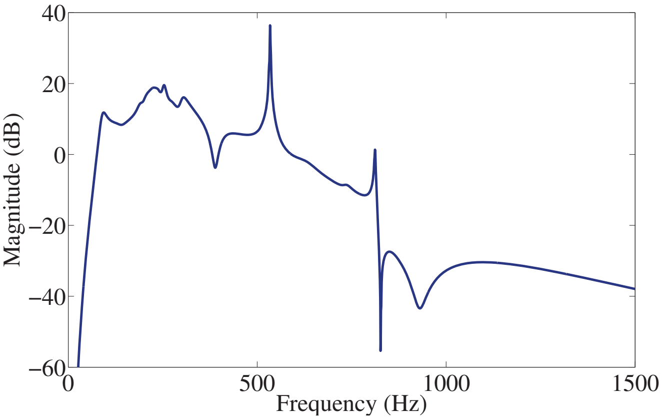

Figure 6. Magnitude plot of the frequency response of controller

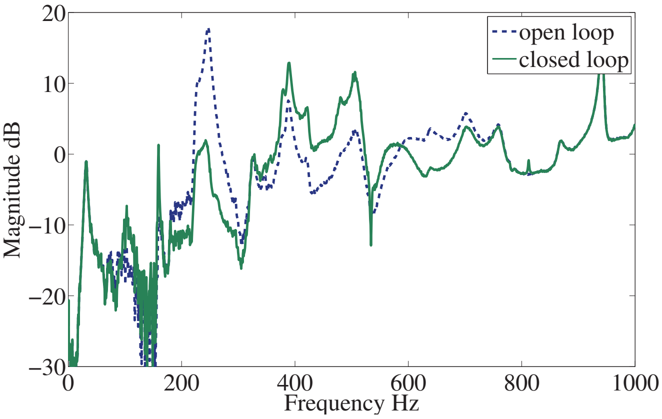

Figure 7. Magnitude plot of the frequency reponse from disturbance to local output with (dashed) and without (solid) feedback controller

where $T_{1,l} = W_l$, for $1 < l < n$. The next step is to recursively estimate $W_1(s)$ from

$$W_k(s) = \frac{T_{k,k} + W_{k+1}(s)\frac{s-s_k}{s+\bar{s}_k}}{1 + \overline{T}_{k,k}W_{k+1}(s)\frac{s-s_k}{s+\bar{s}_k}}, \qquad k = n, n-1, \ldots, 2, 1 \tag{12}$$

If the set of data points $(s_i, W_i)$ for interpolation is augmented with its complex conjugate $(\bar{s}_i, \overline{W}_i)$, then a stable bounded real analytic interpolating function is given by $\gamma(s) = M \times \frac{1}{2}\left[W_1(s+\sigma) + \overline{W}_1(s+\sigma)\right]$ for any arbitrarily selected initial stable bounded analytic function $W_{k+1}(s)$ in (12). There will be at least 4 poles and zeros in $\gamma(j\omega)$ transfer function for every interpolated $\gamma$ point which will affect the order of the final compensator transfer function $k(j\omega)$. In the frequency interval from 200 Hz to 300 Hz there are 164 discrete frequencies at which an optimal $\gamma$ point is selected. Only 6 of the optimal $\gamma$ points are used as interpolation data points in order to get a lower order controller.

The final operating $\gamma$ points obtained from the frequency response of the interpolating function $\gamma(j\omega)$ for frequency 225 Hz to 250 Hz is shown in figure 5. It is seen that in the frequency range 230 Hz to 245 Hz, circles representing remote vibration reduction converge towards the origin and become very small. Due to this several more optimal $\gamma$ points have to be selected in this frequency band alone to get a good transfer function approximation, but this will increase the order of interpolated transfer function considerably. At all other frequencies in the disturbance frequency band, circles representing reduction in vibration at the remote point are considerably larger than the unit circle that corresponds to local vibration attenuation. Hence, final operating $\gamma$ points from inside the unit circle will lie on the boundary of the remote vibration reduction circle. This is predicted to achieve only slight reduction in the blade vibration output using a $58^{th}$ order controller transfer function. This vibration attenuation problem is a case of very extreme magnitude for the dimensionless parameter discussed in [7], which is equivalent to the function formed by the centre of remote vibration reduction circle given as $-g_{cc}(j\omega)g_{pp}(j\omega)\left[g_{cp}(j\omega)g_{pc}(j\omega)g_{AP}(j\omega)f_{LP}(j\omega)\right]^{-1}$. The magnitude of this function is a measure of the severity of the trade-off between disturbance attenuation and stability robustness.

A controller realized in terms of this $\gamma(j\omega)$ transfer function by substituting in (9) has a magnitude frequency spectrum as shown in figure 6. The gain of controller starts to roll-off at 600 Hz due to the filter action thereby improving robustness to unmodelled high frequency dynamics. The theoretical closed loop frequency response of local and remote points with the designed controller is compared with the open loop frequency response as shown in figures 7 and 8.

## V. Experimental Results

The controller obtained in the previous section is a compensator transfer function in continuous time domain. It is integrated with the experimental set-up through Simulink using a dSPACE real time interface prior to which it has to be converted to a discrete time model. A discrete model of compensator using first order hold method with a sampling frequency of 5 kHz is obtained which matches exactly the frequency characteristic of the continuous time domain compensator in the disturbance frequency bandwidth. For different primary excitation inputs $f_p(t)$, the acceleration output at the thrust block $q_c(t)$ and blade end $q_p(t)$ are measured to compare closed loop output against open loop output.

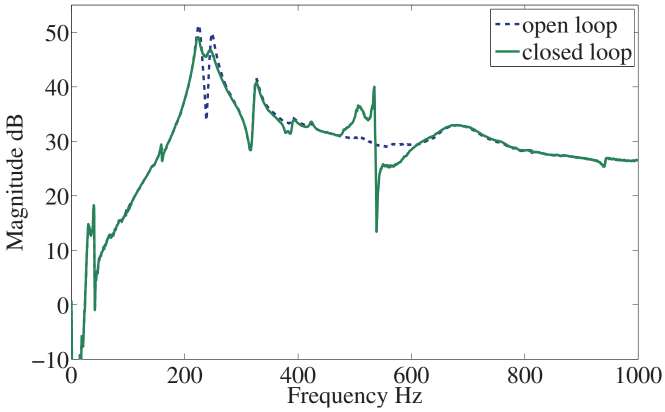

Figure 8. Magnitude spectrum of the frequency reponse from disturbance to remote output with (dashed) and without (solid) feedback controller

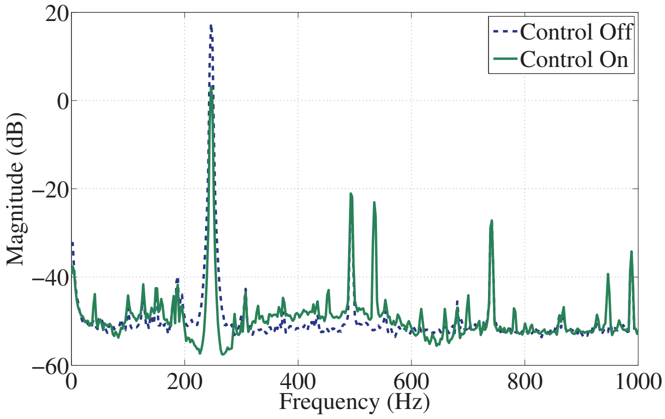

Figure 9. Power spectral density of output from thrust block when primary excitation is discrete frequency excitation at 247 Hz

### A. *Sinusoidal excitation at discrete frequency 247 Hz*

The power spectral density of measured acceleration at the thrust block with and without feedback control for a primary excitation signal at 247 Hz is plotted in figure 9. It shows more than 14 dB reduction in magnitude at 247 Hz using feedback controller and the power spectral density of measured acceleration at the blade end in figure 10 shows around 3 dB reduction in magnitude at 247 Hz. A peak at 534 Hz in the PSD of both closed loop outputs can be noticed which is not present for the open loop case. This is caused by the peak at this frequency in the magnitude of controller frequency response spectrum. In the next section, this peak is reduced without affecting controller performance in the design frequency bandwidth using a notch filter.

## VI. Results after augmenting a notch filter

The controller implementation involves inversion of the minimum phase counterpart of the local control path transfer function so an antiresonance at frequency 534 Hz in the local control path transfer function appears as a peak in the controller FRF. Filter $f_{LP}(j\omega)$ has a high cut-off frequency 600 Hz which is higher than the frequency (534 Hz) at which the peak in controller FRF appears. If the high cut-off frequency of $f_{LP}(j\omega)$ is reduced below 534 Hz and the order of filter is increased in order to take account of the sharp increase in this peak then due to limitations as quantified by Bode's sensitivity integral, amplification at out-of bound frequencies will not be spread over a large frequency range and there will be peaks appearing in the closed loop frequency response. Therefore, the controller is implemented in series with a notch filter which has a notch at 534 Hz in order to reduce the peak at this frequency. The magnitude and phase of the controller is unaffected in the disturbance frequency bandwidth. The acceleration measurements at the thrust block and blade end are taken for different disturbance excitation signals to compare reduction in closed loop output.

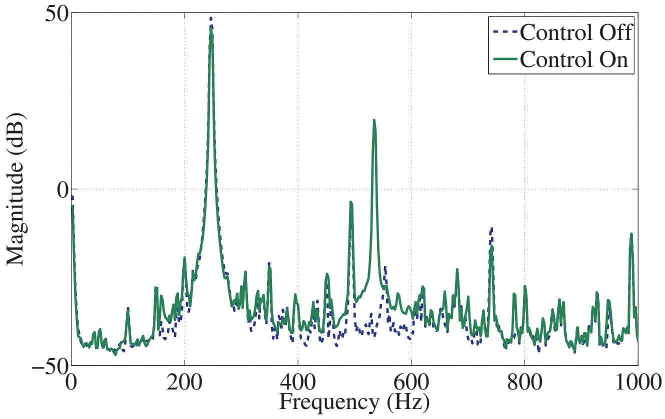

Figure 10. Power spectral density of output from blade end when primary excitation is discrete frequency excitation at 247 Hz

### A. *Sinusoidal excitation at discrete frequency 247 Hz*

The power spectral density of acceleration measured at the thrust block with and without feedback control for a primary excitation signal at 247 Hz shows 16 dB reduction in magnitude as shown figure 11. The power spectral density of acceleration measured at the blade end in figure 12 shows around 3 dB reduction in magnitude at 247 Hz. The peak at 534 Hz is reduced considerably because of the notch filter at this frequency.

### B. *Broad band frequency white noise excitation*

The primary excitation signal input to the disturbance shaker is a random white noise signal and the power spectral density of acceleration outputs from the thrust block $q_c(t)$ and blade end $q_p(t)$ with and without feedback control action is plotted in figures 13 and 14. The PSD of acceleration measured at the thrust block shows around 12 dB attenuation in the disturbance frequency bandwidth while the PSD of measured blade acceleration shows no amplification and a small attenuation as designed.

## VII. Conclusion

A geometric design methodology for vibration control using remotely located stable control systems has been demonstrated

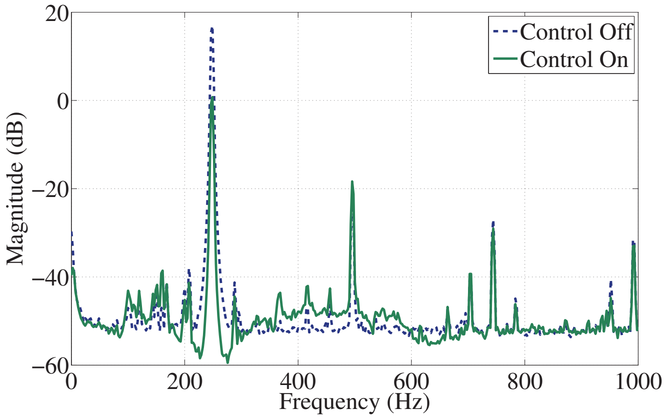

Figure 11. Power spectral density of output from thrust block when primary excitation is discrete frequency excitation at 247 Hz

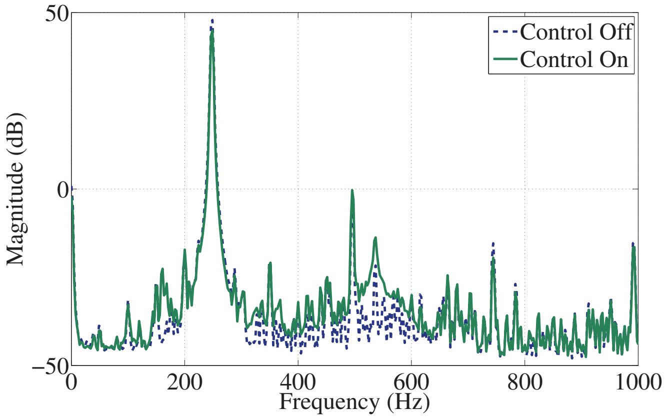

Figure 12. Power spectral density of output from blade end when primary excitation is discrete frequency excitation at 247 Hz

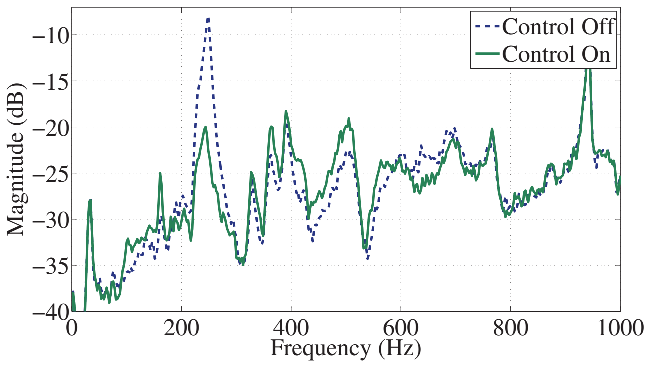

Figure 13. Power spectral density of output at thrust block with primary excitation as random white noise excitation

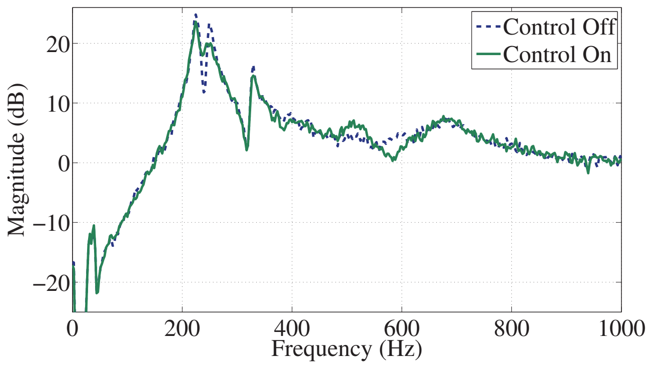

Figure 14. Power spectral density of output at blade end with primary excittion as random white noise excitation

experimentally on a blade rig experimental set-up, which mimicks the vibration transmission problems encountered due to propeller blade excitations encountered in many aerospace and maritime applications. The limitations on actuator and sensor placement can be overcome using this control design approach and shows considerable reduction in closed loop output at the thrust block side near the problematic blade resonant frequency.

***Abstract*—This paper will establish the simulation model and the inverter model of induction motor based on the multi function simulation software AMESim. Considering the influence on the motor from the temperature and other complex factors, and Using Matlab / Simulink software to establish a simulation model of direct torque control system, then we go on combined simulation through the combination of the two aspects. The simulation result shows that the controller make the speed faster and the robustness stronger of the motor control system, but at the same time it exposes the shortcoming that torque pulsing will enlarge at the low speed. Pointing at the shortcoming, this article starts with the principle of extended kalman filtering algorithm, uses of measuring current, voltage on the pattern of stator, deduces from a new motor speed, flux state observer model without speed sensor, and estimates the rotor speed and stator flux. The simulation result shows that this method can solve the problem of flux and torque pulsing effectively.**

***Keywords- Extended Kalman filter; direct torque control; the simulation software AMESim; torque ripple***

## I. INTRODUCTION (HEADING 1)

The full name of AMESim is LMS Imagine.Lab AMESim, that is complex system modeling and simulation platform of the interdisciplinary field. It provides a complete platform of system project design, this makes it possible that the user can build complex model of multidisciplinary field system on a platform. By using of various components provided by system, the user can using the physical model to build the simulation platform, and this improved the difficulties that general modeling software to do it by using of complicated mathematical model. AMESim model is more close to the reality.

Direct torque control is a new type of high performanced AC adjustable-speed transmission control technique. It abandonees the decoupling control theory in vector control. By using of the stator flux orientation and instantaneous space vector theory, and detecting the stator voltages and currents, this control method observes flux and torque of motor in the stator coordinate, then compares the observation value with the given one. By hysteresis controller regulating the error value gets corresponding control signal. To control motor, through synthesizing flux and torque signal to select the corresponding voltage space vector. The advantage of direct torque control is that the torque has faster dynamic response, and the rotor parameters change has certain robustness. The defect of this control method is that torque and flux pulsing is strong especially in the low speed.

The motor speed and flux observer given in this paper check the feasibility of the algorithm, by computer simulation and the comparison between the actual rotor speed and stator flux. The simulation results show that the design of new state observer can reduce the motor flux and torque pulsing effectively, and improve the motor torque performance. And it make high performance motor control possible.

## II. THE INDUCTION MOTOR STATE ESTIMATION BASED ON THE EXTENDED KALMAN FILTER

The object of this paper is the AC induction motor, which is a typical nonlinear system. Under normal circumstances, the Kalman filter is used for state estimation of linear systems, if it is used in the state estimation of nonlinear systems, you must consider to use the extended Kalman filter (Extended Kalman

Filter, EKF). The largest difference between the general Kalman filter and EKF is attempting to make the nonlinear systems linearization [3-7]. After the Jacobian matrix linearization, there is little difference with the general Kalman filter in form.

### *A. The Extended Kalman Filter Design Based On AC Induction Motor*

In two-phase stationary coordinate, in order to use EKF to predict the rotor speed, we need to add to a new state variable [8] [9]. The block diagram of the direct torque control system based on the extended Kalman filter is shown in figure 1. That is where we use voltage and current value which is easy to measure to estimate the value of the stator flux and achieve the speed identification based on the extended Kalman filter algorithm. So as to improve the performance of induction motor direct torque control system [10] [11].

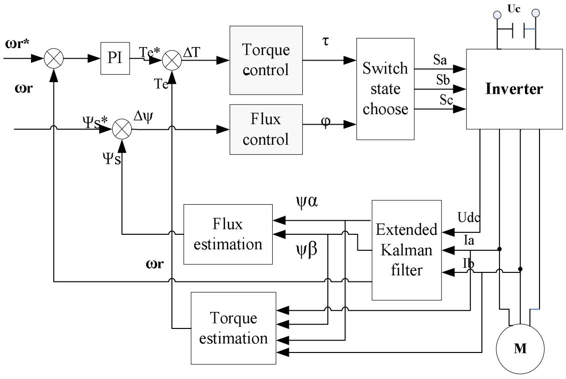

Figure 1 the system block diagram of EKF-DTC

Under the conditions that the sampling period is very short, we can think that the change is zero. Rewriting of the induction motor state-space model:

$$\begin{aligned}\dot{x} &= A\cdot x(t)+B\cdot u(t)\\ y(t) &= C\cdot x(t)\end{aligned} \tag{1}$$

Among the formula:

State variable $x=[i_{\alpha s}\ i_{\beta s}\ \psi_{\alpha r}\ \psi_{\beta r}\ \omega_r]^{\mathrm{T}}$ , measurement variable $y=[i_{\alpha s}\ i_{\beta s}]^{\mathrm{T}}$ , input variable $u=[u_{\alpha s}\ u_{\beta s}]^{\mathrm{T}}$ ,

$$A=\begin{bmatrix} -\dfrac{L_m^2R_r+L_r^2R_s}{\sigma L_sL_r^2} & 0 & \dfrac{L_mR_r}{\sigma L_sL_r^2} & \dfrac{n_pL_m\omega_r}{\sigma L_sL_r^2} & 0\\ 0 & \dfrac{L_m^2R_r+L_r^2R_s}{\sigma L_sL_r^2} & -\dfrac{n_pL_m\omega_r}{\sigma L_sL_r^2} & \dfrac{L_mR_r}{\sigma L_sL_r^2} & 0\\ \dfrac{R_rL_m}{L_r} & 0 & -\dfrac{R_r}{L_r} & -n_p\omega_r & 0\\ 0 & \dfrac{R_rL_m}{L_r} & n_p\omega_r & -\dfrac{R_r}{L_r} & 0\\ 0 & 0 & 0 & 0 & 0 \end{bmatrix}$$

$$B=\begin{bmatrix} \dfrac{1}{\sigma L_s} & 0\\ 0 & \dfrac{1}{\sigma L_s}\\ 0 & 0\\ 0 & 0\\ 0 & 0 \end{bmatrix} \qquad C=\begin{bmatrix} 1 & 0 & 0 & 0 & 0\\ 0 & 1 & 0 & 0 & 0 \end{bmatrix}$$

Where $R_s$ is the stator winding resistance, $R_r$ is the rotor winding resistance, $L_s$ is the stator cyclic inductance, $L_r$ is the rotor cyclic inductances, $L_m$ is mutual cyclic inductance, $\sigma=1-\dfrac{L_m^2}{L_s\tau_r\sigma}$ , $n_p$ is the number of pairs. $\omega_r$ is the rotor speed. It can be seen from the above state equation expression, in addition to the speed, the rest of the amount are all the stator side variables or motor constants, but also it shows the system is a nonlinear system. In other words we can use the extended Kalman filter algorithm. The actual system contains the system and measurement noise inevitably, so we add the noise matrix to the fifth-order model of the AC induction motor. It constitutes the following stochastic nonlinear control system:

$$\begin{aligned}\dot{x}(t) &= f(x(t))+W(t)\\ y(t) &= h(x(t))+V(t)\end{aligned} \tag{2}$$

Among the formula:

$f(x(t))=A\cdot x(t)+B\cdot u(t)$ , $h(x(t))=C\cdot x(t)$ , $W(t)$ is the system noise matrix, $V(t)$ is the process noise matrix. So the space state equation of an AC induction motor conforms the form of general nonlinear systems state equation in 2.1 section. So this paper may be using extended Kalman filter algorithm to research the AC induction motor. Firstly we should linear and discrete the state space model (1) and (2) of the AC induction motor. Specific process is as follows: we can expand the model using of the Taylor series mentioned in the previous section, and then ignore the higher order terms and retain only first order, get the approximation linear model. Assuming that the state equation of the discrete system is as follows:

$$\begin{aligned}\dot{x} &= A_kx(k)+B_ku(k)+W(k)\\ y &= C_kx(k)+V(k)\end{aligned} \tag{3}$$

The dispersion coefficient is :

$$A_k=e^{AT}\approx I+AT\ ,B_k=\int_0^T e^{A\xi}Bd\xi\approx BT\ ,C_k=C\ .$$

We substitute A, B, C into the above equation to get:

$$A_k=\begin{bmatrix} -\frac{L_m^2R_r+L_r^2R_s}{\sigma L_sL_r^2}T_s & 0 & \frac{L_mR_r}{\sigma L_sL_r^2}T_s & \frac{n_pL_m\omega_r}{\sigma L_sL_r^2}T_s & 0 \\ 0 & \frac{L_m^2R_r+L_r^2R_s}{\sigma L_sL_r^2}T_s & -\frac{n_pL_m\omega_r}{\sigma L_sL_r^2}T_s & \frac{L_mR_r}{\sigma L_sL_r^2}T_s & 0 \\ \frac{R_rL_m}{L_r}T_s & 0 & -\frac{R_r}{L_r}T_s & -n_p\omega_rT_s & 0 \\ 0 & \frac{R_rL_m}{L_r}T_s & n_p\omega_rT_s & -\frac{R_r}{L_r}T_s & 0 \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix}$$

$$B_k=\begin{bmatrix} \frac{1}{\sigma L_s} & 0 \\ 0 & \frac{1}{\sigma L_s} \\ 0 & 0 \\ 0 & 0 \\ 0 & 0 \end{bmatrix} \qquad C_k=\begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \end{bmatrix}$$

Known by the five formulas of the extended Kalman filter, we must also know the nonlinear state matrix $f$ , output matrix $h$ and vector partial differential matrix $F$ 、 $H$ . The $F$ is called the Jacobian matrix, and the $H$ is called the transfer matrix.

We can get $f=A_k\cdot x+B_k\cdot u$ from the formula $f(x(t))=A\cdot x(t)+B\cdot u(t)$ , and get $h(x(t))=C\cdot x(t)$ from $h=C_k\cdot x$ . So

$$F(\hat{x}(t))=\frac{\partial f(x(t))}{\partial x(t)}\Big|_{x(t)=\hat{x}(t)}$$

$$=\begin{bmatrix} -R_s/(\sigma L_s)-1/(\sigma T_r) & -\omega_r & R_r/L_r & \omega_r/(\sigma L_s) & -i_{\beta s}+\psi_{\beta r}/(\sigma L_s) \\ \omega_r & -R_s/(\sigma L_s)-1/(\sigma T_r) & -\omega_r/(\sigma L_s) & R_r/L_r & i_{\alpha s}-\psi_{\alpha r}/(\sigma L_s) \\ -R_s & 0 & 0 & 0 & 0 \\ 0 & -R_s & 0 & 0 & 0 \\ (-n_p^2/J)\psi_{\beta r} & (n_p^2/J)\psi_{\alpha r} & (n_p^2/J)i_{\beta s} & (-n_p^2/J)i_{\alpha s} & 0 \end{bmatrix}$$

$$H=\frac{\partial C}{\partial x(t)}\Big|_{x(t)=\hat{x}(t)}=\begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \end{bmatrix}$$

After calculating the above functions and the corresponding matrix, we can apply the five steps of the Extended Kalman Filter. Substituting into the following recursive formula:

$$x(k+1/k)=x(k)+T*f(x(k),u(k)) \tag{4}$$

$$P_{k+1/k}=P_k+(F(x(k))*P_k+P_k*F^T(x(k)))*T+Q \tag{5}$$

$$K(k+1)=P_{k+1/k}*H^T*[HP_{k+1/k}H^T+R]^{-1} \tag{6}$$

$$P_{k+1}=P_{k+1/k}-K(k+1)*H*P_{k+1/k} \tag{7}$$

$$x(k+1)=x(k+1/k)+K(k+1)(y(k+1)-H*x(k+1/k)) \tag{8}$$

Among the formulas, $K$ is the Kalman gain, $P$ is the state error covariance matrix, $Q$ and $R$ are noise covariance matrix whose initial value is artificially given. This article gets each parameter by trial and error method under the premise of ensuring the steady-state tracking and filtering divergence.

### B. System Simulation Model Based On The EKF-DTC System

When the simulation model is set up, the extended Kalman filter is using of the S function. Figure 2 is the Simulink. Simulation diagram with the EKF-DTC.

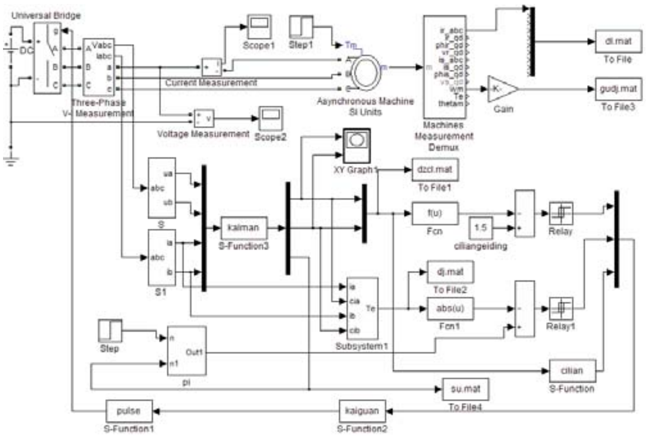

Figure 2. Simulink Simulation model based on EKF-DTC.

Induction motor simulation parameters:

rated power $P_N$ =1.1kw, stator winding resistances $R_s$ =5.793Ω, rotor winding resistances $R_r$ =3.421Ω, stator cyclic inductances $L_s$ =0.368H, rotor cyclic inductances $L_r$ =0.368H,mutual cyclic inductance $L_m$ =0.363H,moment of inertia $J$ =0.0267Kg.m2,the number of pairs $P$ =2.

Based on the EKF-DTC method and the traditional DTC stator flux vector, electromagnetic torque and current simulation waveform, we compare the simulation results.

the given speed is 30 r / s (the rated speed is 150 r/s), and the load torque is 3 N. m.

## III. SIMULINK AND AMESIM SIMULATION REALIZATION AND VALIDATION OF THE ALGORITH

### A. The Structures Of The Joint Simulation Model

We use the motor model in AMESim to instead of the induction motor model of control system in front. At the same time its inverter drive section is also created in the software, to verify the effect of this control algorithm designed. In AMESim, the mathematical model of the induction motor takes the relationship between the temperature and the parameters into account, the system makes it closer to the actual motor system environment, and makes the powerful validation of the effectiveness of the proposed algorithm. In AMESim model, the relationship between the temperature and the motor parameters is as follows:

$$R_s = R_{s_0}(1 + alphaR_s(Temp - T_0))$$

$$tauR = T_{r_0}(1 + alphaT_r(Temp - T_0))$$

Co-simulation electronic control system and Simulink single software simulation model are different. In the co-simulation electronic control system, we introduce the voltage, current sensor signal and speed signal in AMESim into the Simulink model. We can calculate the inverse change switch signal by the computing in the Simulink model and then act on the inverter device of AMESim model. As shown in Figure 4, the S-function in the simulation model is corresponding to the AMESim co-simulation interface in figure 5, to complete the data reception and transmission.

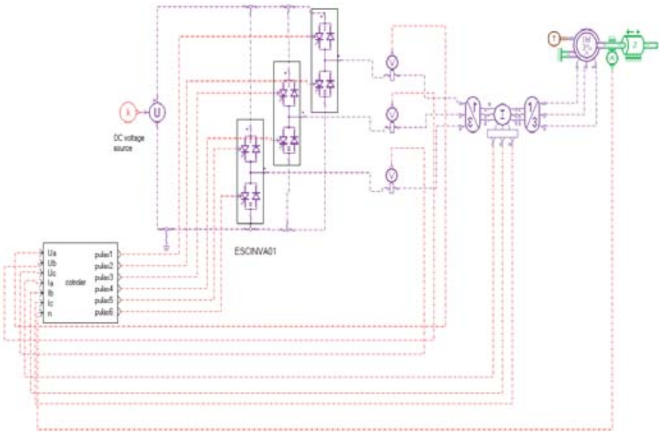

Figure 4 AMESim simulation model of Co-simulation

### B. The Simulation Experiment Of Algorithm Verification

Simulation: the motor parameters still choose the same parameters as the previous ones.

The experimental setup: the reference temperature is 25 degrees Celsius. The given speed is 30rad / s. Observing the stator flux and speed simulation waveform.

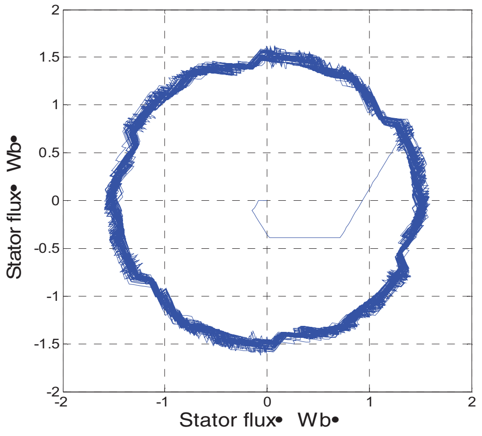

Figure 6. Stator flux waveform of Co-simulation

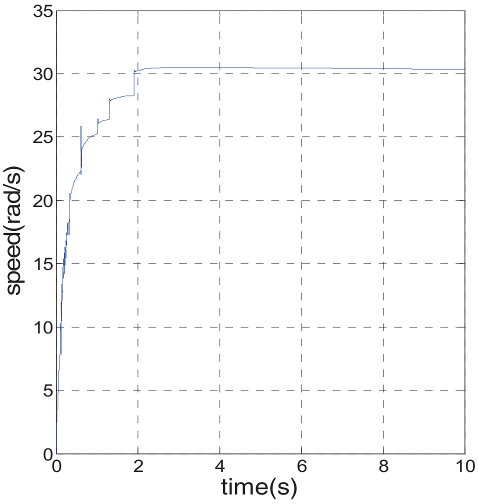

Figure 7. The waveform of the observables under Low-speed

## IV. Conclusion

Analyzing figure 3:

1. It is visible from the comparison between Figure (a1) and Figure (a2). When the motor is running at low speed 30rad / s, the stator flux trajectory is a hexagon in the Traditional DTC method. The control effect is far from ideal. But the stator flux trajectory is approximately circular in EKF-DTC method, and the pulse also significantly reduces.

2. It is visible from the comparison between Figure (b1) and Figure (b2). The electromagnetic torque ripple reduces to a large extent based on the EKF-DTC method.

3. It is visible from the comparison between Figure (c1) and Figure (c2). The current waveform pulse is obvious in traditional DTC method. The current sine wave has been significantly improved based on EKF-DTC method.

4. It is visible from the comparison between Figure (d1) and Figure (d2). The value of a given speed is 30rad / s. The EKF identification value is also about 30rad / s. That is to say that we can achieve the speed recognition based on the EKF-DTC and the no speed sensor technology.

It can clearly be seen that the method reduce the stator flux, electromagnetic torque, the current waveform pulsation to a large extent and improve the steady-state performance of a direct torque control system based on EKF-DTC. Analyzing the reason is that the stator flux observer model is the UI model in the traditional DTC, the accuracy declines seriously at a low speed. However the EKF can remove the error caused by the cumulative integral. The introduction of EFK is equivalent to change the original open-loop stator flux model into a closed-loop control, and eliminate the error in the ring. At the same time EKF achieve speed identification and the speed sensor control, and also maintain the advantages of the DTC fast dynamic response.

Analyzing Figure 6 and Figure 7

The stator flux trajectory is almost circular, but the trajectory is coarse, and it shows that the pulse is large. However, the shape and thickness of the track can still determine that it is limited within an acceptable range. The given speed is 30rad / s. It can be seen from the experimental results that the actual speed can track a given speed. Above all we can conclude that the design algorithm of this paper is effective.

***Abstract*—This paper aims to present an improved adaptive sliding mode control (ASMC) design for rigid spacecraft attitude maneuvers. An adaptive scheme is proposed for the switching gain calculation when the upper bound of the system uncertainty is unknown in advance. Unlike existing ASMC design, which may result in an over-adaptation of the upper bound when the initial system trajectory is located far from the sliding surface, this paper presents a novel ASMC strategy by introducing a decay term in the sliding function to reduce or eliminate the unrelated factor in the adaptation scheme. Consequently, a lower-chattering control signal is achieved. Simulation results are presented to illustrate the effectiveness of the proposed strategy.**

***Index Terms*—attitude maneuver, adaptive sliding mode control, over-adaptation, global sliding mode, chattering suppression.**

## I. Introduction

As a subclass of variable structure control systems, sliding mode control (SMC) is a nonlinear control method that is well known for its robust performance. In the pase decades, SMC has been extensively studied in many practical control systems. SMC can offer many good properties, such as insensitivity to parameter variation, external disturbance rejection, and fast dynamic response, which make it a potential approach for spacecraft attitude control. In [1], the attitude regulation problem was studied and the sliding function was determined by solving an optimal control problem. A smoothing model-reference SMC algorithm was presented in [2], where a desired quaternion error response was predefined for the attitude control system. To reduce the static error, an integral term was added in the sliding function and modified Rodrigues parameters (MRPs) were used instead of quaternion for the non-redundancy in [3]. Moreover, in [4], a nonlinear sliding function was defined according to the properties related to the attitude kinematics.

However, for the SMC design mentioned above, a prior knowledge of the system uncertainty upper bound is required. When such a bound is unavailable in advance, conservative method is generally adopted, where the switching gain is selected sufficiently large. It is well known that the chattering level is directly determined by the switching gain. Hence, such a conservative method may aggravate the chattering problem which could excite the unmodelled dynamics and may lead to instability. Further investigations have proceeded along two lines. On the one hand, technologies are studied for the chattering reduction. Higher-order sliding mode control has been recently proposed to reduce the chattering problem while keeping the main advantages of conventional SMC ( [5]). In [6], the control chattering is reduced by low-pass filtering the control signal. In particular, in [7], three methods were presented for the chattering suppression. Nonetheless, there are no constructive conditions for the switching gain selection in those algorithms and generally a prior knowledge of the bound of the system uncertainty and/or the system states is needed.

On the other hand, attention has also been focused on eliminating the requirement of the prior knowledge of the uncertainty bound. One way is using the disturbance observer (DOB) technique, as suggested in [8] and [9]. However, the DOB based SMC algorithms usually assume that the model uncertainty is generated by a linear exogenous system [10], which is hard to satisfy due to the complexity and unpredictability of the uncertainty. The other effective approach is to integrate adaptive scheme into SMC designs. By updating the switching gain adaptively, the upper bound of model uncertainty is not required to be known in advance. At the first stage, it is generally assumed that the norm of uncertainty was bounded by a linear function of the state-norm. Correspondingly, adaptive laws were designed for the linear function parameters, as suggested in [11], [12], [13]. In particular, in [13], an ASMC algorithm was proposed for the attitude stabilization of a rigid spacecraft, where the lumped uncertainty is assumed to be bounded by a linear function of the norms of angular velocity and quaternion. Afterwards, in [14] the lumped uncertainty was assumed to be bounded by an unknown constant and consequently a simple adaptive law was proposed for the switching gain calculation. Subsequent results can be found in many other applications such as internal combustion engines ( [15]), induction servomotor ( [16]), planetary gear-type inverted-pendulum ( [17]), etc. The major problem of the ASMC algorithms mentioned above is their over-adaptation for the switching gain with respect to the uncertainty bound, which results in the serious chattering phenomena and unnecessary energy consumption.

Considering the shortcomings of the chattering suppression techniques and current ASMC design, it is necessary to put

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

forward a novel ASMC strategy, which does not need a prior knowledge of the upper bound and has the chattering suppression ability. Such a problem was recently investigated in [18], where two new methodologies for the ASMC design were proposed. Unfortunately,those two methods only reduce the switching gain in the sliding phase without considering the reaching phase. Similar to the ASMC design mentioned before, which will be called the ASMC-I algorithm in the following contents, the switching gain is also overestimated in [18] due to its failure in accounting for the initial system error in the adaptation scheme. With this in mind, this paper tries to present an improved ASMC design principle by addressing the attitude control problem for a rigid spacecraft in the presence of inertia matrix uncertainty and external disturbance. The key feature of the proposed ASMC algorithm, referred as the ASMC-II algorithm, is that a decay function is introduced to reduce or eliminate the impact of initial system error in the adaptation scheme. By this modification, the ASMC-II algorithm can give a more accurate estimation of the uncertainty bound and generate a lower-chattering control signal. A large angle attitude reorientation maneuver is employed in the simulation, where the simulation results demonstrate the effectiveness of the proposed strategy.

## II. Preliminary and problem statement

Rigid spacecraft attitude control for large angle maneuvers poses a difficult problem, including nonlinear characteristics in both the dynamics and the kinematics, modelling uncertainty, and persistent external disturbance. In this paper, we will resolve this problem in the ASMC framework. Before moving on, some notations and assumptions are presented here. Three coordinate frames are used in this paper, which are the inertia reference frame $\mathcal{F}_I$, body-fixed frame $\mathcal{F}_B$, and the desired frame $\mathcal{F}_D$. Unless otherwise specified, all the quantities are expressed in their corresponding frames. And it is assumed that the spacecraft attitude and angular velocity are available and the dynamics of actuator is neglected.

### *A. Mathematical Model*

Consider a thruster control rigid spacecraft, whose dynamics is described as follows:

$$J\dot{\omega}_b + \omega_b^\times J\omega_b = T_b + T_d \tag{1}$$

where $J \in \mathbb{R}^{3\times3}$ is the spacecraft inertia matrix, $\omega_b = [\omega_{b1} \quad \omega_{b2} \quad \omega_{b3}]^T \in \mathbb{R}^3$ is the angular velocity vector of $\mathcal{F}_B$ with respect to $\mathcal{F}_I$. The superscript $(\cdot)^\times$ on $\omega_b$ denotes the skew-symmetric matrix operator performing the cross product between two vectors, e.g.,

$$\alpha^\times\beta = \alpha\times\beta \tag{2}$$

where $\alpha$ and $\beta$ are two vectors in $\mathbb{R}^3$. $T_b = [T_{b1} \quad T_{b2} \quad T_{b3}]^T \in \mathbb{R}^3$ is the vector of control torque provided by the thrusters, $T_d = [T_{d1} \quad T_{d2} \quad T_{d3}]^T \in \mathbb{R}^3$ is the external disturbance vector, including gravitational torque, aerodynamic torque, radiation torque, and other environmental and non-environmental torques. Furthermore, the inertia matrix uncertainty is taken into account. Let $J = \hat{J} + \Delta J$ with $\Delta J$ the uncertainty caused by the change in mass properties and $\hat{J} = \mathrm{diag}(J_1, J_2, J_3)$ the nominal inertia matrix. Then the attitude dynamics is given by:

$$\hat{J}\dot{\omega}_b + \omega_b^\times\hat{J}\omega_b = T_b + T_d - \Delta J\dot{\omega}_b - \omega_b^\times\Delta J\omega_b \tag{3}$$

According to the structural feature in (3), one can merge all the elements caused by inertia matrix uncertainty and external disturbance as the lumped uncertainty, i.e., let $d = [d_1 \quad d_2 \quad d_3]^T \in \mathbb{R}^3$ with $d = T_d - \Delta J\dot{\omega}_b - \omega_b^\times\Delta J\omega_b$. Correspondingly, the attitude dynamics is rewritten as:

$$\hat{J}\dot{\omega}_b + \omega_b^\times\hat{J}\omega_b = T_b + d \tag{4}$$

From (4), it is clear that the lumped uncertainty is matched to the system. Without loss of generality, it is assumed that $d$ is bounded by an unknown upper bound, e.g., $\|d\|_\infty < d_{\max}$ with $\|\cdot\|_\infty$ the vector infinite-norm.

By introducing the shadow MRPs, the MRPs set can provide a nonsingular, bounded, minimal attitude description. Hence, MRPs are utilized in this paper instead of quaternion, whose kinematics is:

$$\dot{\sigma}_b = M(\sigma_b)\omega_b \tag{5}$$

where $\sigma_b = [\sigma_{b1} \quad \sigma_{b2} \quad \sigma_{b3}]^T \in \mathbb{R}^3$ denotes the inertial MRPs vector of $\mathcal{F}_B$ with respect to $\mathcal{F}_I$. $M : \mathbb{R}^3 \to \mathbb{R}^{3\times3}$ such that $M(\sigma_b)$ is the Jacobian matrix with $M(\sigma_b) = \dfrac{(1-\|\sigma_b\|^2)I_3 + 2\sigma_b^\times + 2\sigma_b\sigma_b^T}{4}$, $\|\cdot\|$ is the vector 2-norm and $I_3$ is the $3\times3$ identity matrix. Moreover, $M^T(\sigma_b)M(\sigma_b) = m(\sigma_b)I_3$ with $m : \mathbb{R}^3 \to \mathbb{R}$ such that $m(\sigma_b) = (1 + \|\sigma_b\|^2)^2/16$. The transition matrix from $\mathcal{F}_I$ to $\mathcal{F}_B$ in terms of MRPs is given by:

$$R(\sigma_b) = I_3 + \frac{8\sigma_b^\times\sigma_b^\times - 4(1-\|\sigma_b\|^2)\sigma_b^\times}{(1+\|\sigma_b\|^2)^2} \tag{6}$$

A typical Rest-to-Rest attitude maneuver is studied in this paper. The objective is reorienting the spacecraft from an arbitrary stationary attitude to a desired attitude with zero angular velocity. The attitude variables of the desired frame, $\mathcal{F}_D$, are denoted by $\sigma_d \in \mathbb{R}^3$ and $\omega_d \in \mathbb{R}^3$. Then, the error attitude variables are defined as follows:

$$\sigma_e = \sigma_b \oplus \sigma_d^* \tag{7}$$

$$\omega_e = \omega_b - R(\sigma_e)\omega_d \tag{8}$$

where $\sigma_e = [\sigma_{e1} \quad \sigma_{e2} \quad \sigma_{e3}]^T \in \mathbb{R}^3$, $\oplus$ is the MRPs production operator characterizing the successive rotations. For two MRPs expressed in their corresponding frames, e.g., $\sigma_1 \in \mathbb{R}^3$ and $\sigma_2 \in \mathbb{R}^3$, it is operated as follows:

$$\sigma_1 \oplus \sigma_2 = \frac{(1-\|\sigma_2\|^2)\sigma_1 + (1-\|\sigma_1\|^2)\sigma_2 - 2\sigma_1^\times\sigma_2}{1 + \|\sigma_2\|^2\|\sigma_1\|^2 - 2\sigma_2^T\sigma_1} \tag{9}$$

$\sigma_d^*$ is the inverse of $\sigma_d$, which is extracted from the inverse of $R(\sigma_d)$ and $\sigma_d^* = -\sigma_d$. $R(\sigma_e)$ and $R(\sigma_d)$ are the transition matrices from $\mathcal{F}_D$ to $\mathcal{F}_B$ and from $\mathcal{F}_I$ to $\mathcal{F}_D$, their expressions can be obtained by replacing $\sigma_b$ by $\sigma_e$ and $\sigma_d$ in (6). As $\omega_d = 0$, $\omega_e = \omega_b$. Therefore, the error attitude dynamics is expressed same as (4). With respect to the error attitude kinematics, following lemma is introduced.

*Lemma 1:* If the attitude variables pairs $(\sigma_b, \omega_b)$ and $(\sigma_d, \omega_d)$ satisfy the MRPs kinematics formulation described in (5), then the error attitude variables pair $(\sigma_e, \omega_e)$ also satisfies that MRPs kinematics formulation.

*Proof:* The proof is based on the successive rotations in terms of transition matrix. See [20] for further details. ■

Then, the system is governed by the following equations:

$$\begin{cases} \hat{J}\dot{\omega}_b &= T_b + d - \omega_b^{\times}\hat{J}\omega_b \\ \dot{\sigma}_e &= M(\sigma_e)\omega_b \end{cases} \tag{10}$$

### B. Problem Statement

Our aim can be summarized as follows: find a SMC algorithm to steer the attitude variables pair $(\sigma_b, \omega_b)$ from $(\sigma_b(0), 0)$ to $(\sigma_d, 0)$ in the presence of the lumped uncertainty, and find an adaptive law to update the estimation of the unknown $d_{\max}$ for the switching gain calculation which has the chattering suppression ability.

## III. Main Results

### A. AMSC-I Algorithm Design

In this section, we will briefly apply the ASMC-I algorithm for the attitude control problem under consideration. First, the sliding function defined in [4] is given by:

$$S = \omega_b + \lambda \frac{M^T(\sigma_e)}{m(\sigma_e)}\sigma_e \tag{11}$$

where $S = [s_1 \quad s_2 \quad s_3]^T \in \mathbb{R}^3$ and the corresponding sliding surface is determined by $S = 0$, $\lambda > 0$ is the sliding function gain. In the following derivations, $M(\sigma_e)$ and $m(\sigma_e)$ will be denoted by $M$ and $m$ for clarity.

By a left multiplication of (11) with $M$ and using the fact that $M^T M = mI_3$, one has:

$$MS = \dot{\sigma}_e + \lambda\sigma_e \tag{12}$$

When the sliding mode occurs, i.e., $S = 0$ holds, it is easy to conclude that an exponential convergence of the error MRPs, i.e., $\sigma_e(t) = \mathrm{e}^{-\lambda(t-t_r)}\sigma_e(t_r)$, can be obtained if a proper SMC law is designed, where $t_r$ is the time of arrival at the sliding surface. Such a SMC algorithm can be derived by producing a negative definite derivative of the following Lyapunov function:

$$V = \frac{1}{2}S^T\hat{J}S \tag{13}$$

On the basis of [4], one can get the following SMC algorithm:

$$T_b = \omega_b^{\times}\hat{J}\omega_b - \lambda\hat{J}\frac{\left(4M - 2\sigma_e\sigma_e^T\right)\omega_b}{1 + \|\sigma_e\|^2} - \Gamma\mathrm{sgn}(S) \tag{14}$$

where $\Gamma = \mathrm{diag}(\gamma_1, \gamma_2, \gamma_3)$ is the switching gain matrix with its elements $\gamma_i > d_{\max}$ $(i = 1, 2, 3)$ to guarantee the system stability and $\mathrm{sgn}(\cdot)$ is the sign function.

During the above derivations, the sliding function gain $\lambda$ can be determined according the desired system response in the sliding phase. In order to determine the switching gain in the absence of a prior knowledge of $d_{\max}$, the ASMC-I algorithm can be applied.

Consider the modified Lyapunov function:

$$V = \frac{1}{2}S^T\hat{J}S + \frac{1}{2c}\tilde{d}^2 \tag{15}$$

where $c > 0$ is the adaptive gain, $\tilde{d} = \hat{d} - d_{\max}$ is the estimation error with $\hat{d}$ the estimation of $d_{\max}$. According to the ASMC-I design principle in [14], the adaptive switching gain law for the attitude control is:

$$\hat{d} = c\int_0^t \|S\|_1 d\tau \tag{16}$$

where $\|\cdot\|_1$ is the vector 1-norm.

Correspondingly, the ASMC-I algorithm is given by:

$$T_b = \omega_b^{\times}\hat{J}\omega_b - \lambda\hat{J}\frac{\left(4M - 2\sigma_e\sigma_e^T\right)\omega_b}{1 + \|\sigma_e\|^2} - \hat{d}\mathrm{sgn}(S) \tag{17}$$

### B. Over-adaptation in ASMC-I Algorithm

From the ASMC-I algorithm design in Section III-A, one can see that the ASMC-I algorithm is based on conventional SMC algorithm. It is well known that the system trajectory employing the SMC algorithm consists two parts, the reaching phase and the sliding phase, as illustrated in Fig. 1.

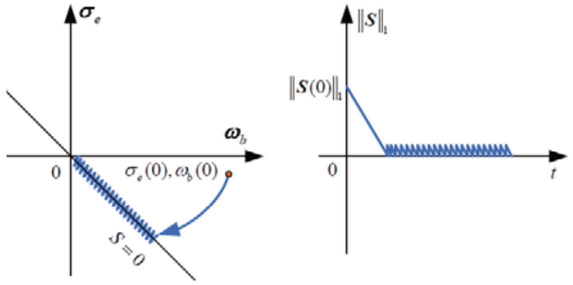

Fig. 1. System trajectory and sliding function response using SMC algorithm in (14)

Recalling the adaptive law in (16), it is obvious that the basic idea of the ASMC-I technique lies in that $d_{\max}$ can be adjusted by the deviation from the sliding surface. From (16), the integral action starts from the very beginning and any departure from the sliding surface, $S = 0$, will result in the increase of the switching gain. In other words, the switching gain adaptation depends on the initial value of the sliding function besides the lumped uncertainty. However, the initial system trajectory is generally located far from the sliding surface as shown in Fig. 1. Hence, $\hat{d}$ would increase quickly at the beginning due to a large $\|S(0)\|_1$ and the resulting $\hat{d}$ is much larger than $d_{\max}$, which leads to an over-adaptation of the switching gain and correspondingly the serious chattering problem in the ASMC-I algorithm.

Moreover, if we divide the adaptive law in (16) into two parts, i.e.,

$$\hat{d} = c\int_{0}^{t_r} \|S\|_1 d\tau + c\int_{t_r}^{t} \|S\|_1 d\tau \tag{18}$$

Then, it is obvious that the first integral term in (18) deals with the deviation in the reaching phase, which is mainly caused by the initial system error; while the second term handles the departure in the sliding phase, which is mainly affected by the lumped disturbance.

### *C. ASMC-II Algorithm Design*

To address the over-adaptation problem in the ASMC-I design, it is natural to reduce or eliminate the proportion of the first integral term in (18). With this in mind, we present the ASMC-II algorithm. First, the sliding function in (11) is modified as

$$S(t) = \omega_b - f(t)\xi + \lambda\frac{M^T}{m}\left[\sigma_e - f(t)\rho\right] \tag{19}$$

where $S(t) = [s_1(t) \quad s_2(t) \quad s_3(t)]^T \in \mathbb{R}^3$, $f(t)$ is a continuous, strictly decreasing function on $t \in [0,\infty)$ with its initial value $f(0) \in [0,1]$ and its final value $f_f = 0$, $\xi = [\xi_1 \quad \xi_2 \quad \xi_3]^T \in \mathbb{R}^3$, $\rho = [\rho_1 \quad \rho_2 \quad \rho_3]^T \in \mathbb{R}^3$ are the coefficients related to the initial system states, and $\rho = \sigma_e(0)$, $\xi = \omega_b(0)$.

According to the above definition, we can find that the initial value of the sliding function is reduced to a small value or even becomes zero by the additional decay function. Therefore, if a proper SMC algorithm is designed to achieve the sliding motion, the sliding surface related to (19) is a new kind of sliding surface, which is illustrated in Fig. 2.

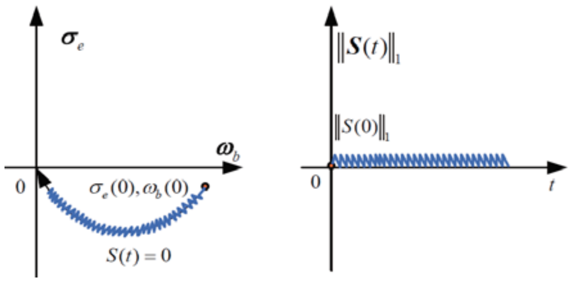

Fig. 2. System trajectory and sliding function response using sliding function in (19)

Therefore, if the sliding function in (19) is used for the switching gain adaptation, the unrelated effect of the initial system error can be reduced or eliminated in the adaptation scheme and the upper bound of the lumped uncertainty can be estimated more precisely, which is the motivation for the ASMC-II algorithm.

*Remark 1:* Actually, the sliding function defined in (19) is an extension of the time-varying sliding function investigated in [21] and [22]. In particular, in [21], it was proved that a *global sliding mode* would be achieved by using the sliding function like (19) with $f(t)$ selected as the exponential decay function $f(t) = \mathrm{e}^{-\kappa t}$ and $\kappa > 0$. However, due to the sensor noise, the initial system error can not be entirely cancelled. Furthermore, if the total time-varying sliding mode case, i.e., $S(0) = 0$, is used for the switching gain adaptation, the system cannot provide enough information for the adaptation due to the fact that there is no departure from the sliding function at the initial time, which will slow down the adaptation procedure. Therefore, in this paper, we introduce a weight in the decay function, e.g., let $f(t) = p\mathrm{e}^{-\kappa t}$ with $p \in [0,1]$ in the following derivations, which will produce an initial departure from the sliding surface purposefully to speed up the adaptive process. When $p = 0$, the sliding function in (19) turns out to be the sliding function in (11); whereas if $p = 1$, it becomes the total time-varying sliding function studied in [21].

For the attitude reorientation control problem, we have $\omega_b(0) = 0$, i.e., $\xi = 0$. For simplicity, the $\kappa$ in the decay function is selected same as the sliding function gain $\lambda$, i.e., let $\kappa = \lambda$. Then the sliding function is specified as:

$$S(t) = \omega_b + \lambda\frac{M^T}{m}\left(\sigma_e - p\mathrm{e}^{-\lambda t}\rho\right) \tag{20}$$

Then, we are ready to present the following theorem:

*Theorem 1:* For the system governed by (10), by adopting the sliding function in (20) and the ASMC-II algorithm in (21), the system trajectory will converge to the sliding function as $t \to \infty$.

$$\begin{cases} T_b = & \lambda p\mathrm{e}^{-\lambda t}\hat{J}\frac{\mathrm{d}}{\mathrm{dt}}\left(\frac{M^T\rho}{m}\right) - \lambda\hat{J}\frac{\left(4M - 2\sigma_e\sigma_e^T\right)\omega_b}{1+\|\sigma_e\|^2} \\ & +\omega_b^\times\hat{J}\omega_b - \lambda^2 p\mathrm{e}^{-\lambda t}\hat{J}\frac{M^T\rho}{m} - \hat{d}\mathrm{sgn}(S(t)) \\ \hat{d} = & c\int_0^t \|S(t)\|_1 d\tau \end{cases} \tag{21}$$

where

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{dt}}\left(\frac{M^T\rho}{m}\right) =& 8\frac{\sigma_e^T\rho M\omega_b - (\rho - \mu + \epsilon)^\times M\omega_b}{(1+\|\sigma_e\|^2)^2} \\ &- \frac{4M^T\rho\sigma_e^T M\omega_b}{(1+\|\sigma_e\|^2)m} \end{aligned}$$

where $\mu = [\sigma_{e3}\rho_2 \quad \sigma_{e1}\rho_3 \quad \sigma_{e2}\rho_1]^T \in \mathbb{R}^3$ and $\epsilon = [\sigma_{e2}\rho_3 \quad \sigma_{e3}\rho_1 \quad \sigma_{e1}\rho_2]^T \in \mathbb{R}^3$.

*Proof 1:* Considering the following Lyapunov function:

$$V = \frac{1}{2}S^T(t)\hat{J}S(t) + \frac{1}{2c}\tilde{d}^2 \tag{22}$$

The time derivative of the above Lyapunov function along the closed-loop system trajectory is:

$$\begin{aligned} \dot{V} =& S^T(t)\hat{J}\dot{S}(t) + \frac{\hat{d} - d_{\max}}{c}\dot{\hat{d}} \\ =& S^T(t)\left(d - \hat{d}\mathrm{sgn}(S(t))\right) + (\hat{d} - d_{\max})\|S(t)\|_1 \\ =& S^T(t)d - \hat{d}\|S(t)\|_1 + \hat{d}\|S(t)\|_1 - d_{\max}\|S(t)\|_1 \\ =& -\sum_{i=1}^{3}\left(d_{\max}|s_i(t)| - d_i s_i(t)\right) \le 0 \end{aligned}$$

Let $\chi = \sum_{i=1}^{3}(d_{\max}|s_i(t)| - d_i s_i(t))$ and it is obvious that $\chi$ is uniformly continuous. By integrating the above equation from zero to $t$, one has:

$$\int_0^t \dot{V} d\tau \leq -\int_0^t \chi d\tau \Rightarrow V(0) \geq \int_0^t \chi d\tau \tag{23}$$

Taking the limits as $t \to \infty$ on both sides of (23) gives:

$$\infty > V(0) \geq \lim_{t\to\infty} \int_0^t \chi d\tau \tag{24}$$

On the basis of Barbalat lemma, one can obtain

$$\lim_{t\to\infty} \chi = 0 \tag{25}$$

which implies that $\lim_{t\to\infty} S(t) = 0$.

*Remark 2:* Above proof implies that the ASMC-II algorithm can only guarantee the asymptotic stability of the sliding function but not the attitude variables, i.e., the system trajectory will converge to the sliding surface in infinite time. However, from the adaptation law in (21), one can see that the switching gain $\hat{d}$ will keep increasing if $S(t) \neq 0$. When $\hat{d}$ increases up to a value large enough to suppress the lumped uncertainty, e.g., $\hat{d} > d_{\max} + \delta$ with $\delta$ a sufficiently small positive scalar, the sliding mode will start in finite time. Similarly, denote the arrival time as $t_r$. By a left multiplication of (20) with $M$, following 3-dimensional first-order vector differential equation can be obtained:

$$\dot{\sigma}_e + \lambda\sigma_e = \lambda p e^{-\lambda t}\rho \tag{26}$$

The analytical solution for $\sigma_e$ is:

$$\sigma_e(t) = \mathrm{e}^{-\lambda(t-t_r)}(\lambda p\rho t + \sigma_e(t_r)) \tag{27}$$

It is obvious $\lim_{t\to\infty} \sigma_e(t) = 0$ and $\lim_{t\to\infty} \omega_b(t) = 0$ from (20). Hence, the attitude control system in (10) with the ASMC-II algorithm in (21) is globally asymptotically stable.

*Remark 3:* Recalling the adaptive law in (21), $\hat{d}$ will become unbounded due to the fact that the sliding function is not identically equal to zero, which may be caused by the finite switching frequency or measurement noise. For implementation in practice, the adaptive law has to be modified to get a bounded switching gain, such as the $\sigma$ modification method in [12]. Here, the approach proposed in [18] will be used, where the adaptive law in (21) is modified as

$$\hat{d} = \begin{cases} c\int_0^t \|S(t)\|_1 \mathrm{sgn}(\|S(t)\|_1 - \eta) d\tau & \text{if} \quad \hat{d} > \varrho \\ \int_0^t \varrho d\tau & \text{if} \quad \hat{d} \leq \varrho \end{cases} \tag{28}$$

where $\varrho > 0$ is a very small scalar to ensure $\hat{d}$ is positive and $\eta > 0$ is carefully chosen to deal with the trade-off in control accuracy and bounded switching gain. Further details on $\eta$ tuning can refer to [18].

## IV. Numerical Simulation

In this section, a comparison of the ASMC-I and ASMC-II algorithms is employed for a large angle attitude maneuver to test the effectiveness of the proposed strategy.

The inertia matrix for the controller design is given by $\hat{J} = \mathrm{diag}(48, 25, 61.8)$ (kg.m) and the uncertainty is 10% of the nominal value. The external disturbance is $T_d = [0.02\sin(0.01t) \quad 0.02\cos(0.01t) \quad 0.04\sin(0.01t)]^T$ (N.m). The initial attitude variables are $\sigma_b(0) = [-0.2 \quad 0.3 \quad 0.1]^T$ and $\omega_b(0) = [0 \quad 0 \quad 0]^T$ (rad/s). The desired attitude is $\sigma_d = [0.1 \quad 0.2 \quad -0.3]^T$ with the desired angular velocity $\omega_d = [0 \quad 0 \quad 0]^T$ (rad/s). For comparison, same control parameters are selected for both the ASMC-I algorithm and the ASMC-II algorithm, where $c = 1$, $\lambda = 0.25$ and the initial value of $\hat{d}$ is zero. The weight $p$ is selected as 0.8. The simulation results are shown in Fig.3–Fig.6.

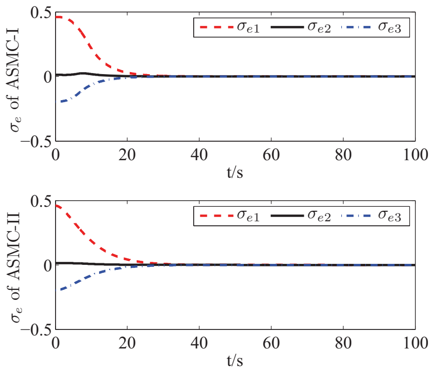

Fig. 3. Error MRPs responses of ASMC-I and ASMC-II

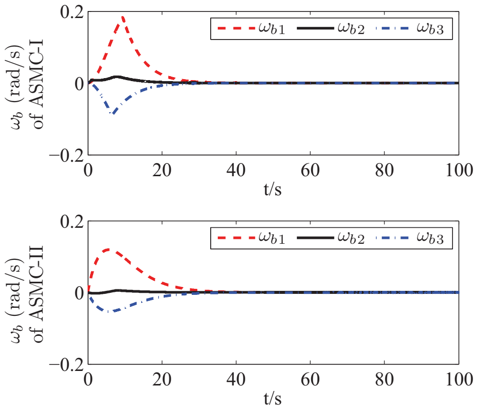

Fig. 4. Angular velocities of ASMC-I and ASMC-II

The maneuver evolutions controlled by ASMC-I and ASMC-II are compared in Fig. 3 and Fig. 4 with the corresponding control torque commands shown in Fig. 5. From Fig. 3, it is clear that both the ASMC-I and the ASMC-II can accomplish the attitude reorientation in the absence of the

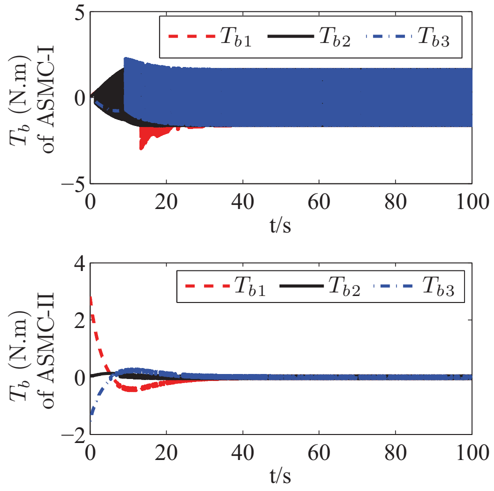

Fig. 5. Control torque commands of ASMC-I and AMSC-II

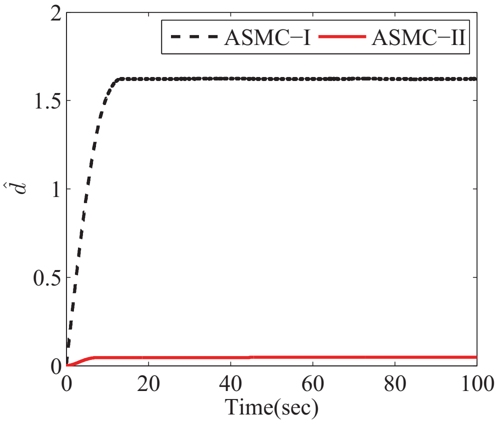

Fig. 6. Adaptive switching gains of ASMC-I and ASMC-II

prior knowledge of $d_{\max}$ and the system responses are similar. Fig. 4 shows the angular velocity response comparison, where the angular velocity controlled by the ASMC-II is smoother than that controlled by the ASMC-I. Nonetheless, there is a significant difference in the control torque commands as shown in Fig. 5. According to Fig. 5, it is obvious that the chattering in ASMC-I is much more serious than that in ASMC-II, which verified the effectiveness of the proposed strategy. Moreover, as shown in Fig. 6, the adaptive switching gain generated by ASMC-II is much smaller than the ASMC-I case, where $\hat{d} \approx 1.62$ for ASMC-I and $\hat{d} \approx 0.046$ for ASMC-II, which verified the chattering suppression ability of ASMC-II.

## V. Conclusion

The attitude control problem of a rigid spacecraft involving inertia matrix uncertainty and external disturbance has been considered. An effective solution has been presented to address the over-adaptation problem in current ASMC design. Such an improvement is achieved by reducing or eliminating the influence caused by initial system error on the switching gain adaptation. It has been shown by theoretical analysis and simulation results that the proposed strategy can produce a much smaller switching gain as compared with current ASMC design and achieve a smoother system response.

*Abstract*—**This paper considers the non-fragile observer design method for nonlinear switched time delay systems using the delta operator. Based on multiple Lyapunov function method and delta operator theory, an asymptotic stability criterion for delta operator switched system with time delay and Lipschitz nonlinearity is presented. By using the key technical lemma, a new sampling period and delay dependent design approach to the non-fragile observer is addressed. The proposed non-fragile observer can guarantee the estimated state error dynamics of delta operator time delay switched system can be asymptotically convergent for observer gain perturbations. The solution to the observer is formulated in the form of a set of linear matrix inequalities. A numerical example is employed to verify the proposed method.**

## I. INTRODUCTION

Switched systems have attracted the interest of several scientists in the last several years. Switched systems are a class of hybrid systems consisting of subsystems and a switching law, which define a specific subsystem being activated during a certain interval of time. Switched systems exist widely in engineering and social systems, such as mechanical systems, automotive industry, aircraft and air traffic control and many other fields[1-3]. A lot of research in this direction have appeared recently[4,5]. Many important progress and remarkable achievements have been made on issues about stability and stabilization for the system. Based on common quadratic Lyapunov functions (CQLFs), a series of methods and conditions have been given for analyzing the stability of switched systems for arbitrary switching law[6, 7]. As effective tools, multiple Lyapunov function (MLF), switched Lyapunov function(SLF) and the average dwell-time approaches have been proposed to analyze the stability of switched systems, and many valuable results have been obtained for switched systems[8-10].

It is recognized that most discrete-time signals and systems are the results of sampling continuous-time signals and systems. When sampling is fast, all resulting signals and systems tend to become ill conditioned and thus difficult to deal with using the conventional algorithms. The delta operator-based algorithms are numerically better behaved under finite precision implementations for fast sampling[11]. A class of uncertain systems in delta domain has been studied and several results about robust stability for the system have been developed[12,13]. The problem of system instability in fast sampling can be solved by using delta operator model [13].

Recently, delta operator approach is used to investigate robust control for a class of uncertain switched systems, and the stabilization conditions of the delta operator switched systems are formulated in terms of a set of linear matrix inequalities (LMIs) [14]. The developed method is valid for the system. However, in actual operation, the states of the systems are not all measurable. It is necessary to design state observers for systems of this type. Several design procedures have been proposed to design state observers for switched systems[15, 16]. It is considered that the state observer gain variations could not be avoided in several applications, a kind of non-fragile observer is proposed and the design method is proved to be effective[17]. However, to date and to the best of our knowledge, the problem of the non-fragile observer design for time delay delta operator switched nonlinear systems has not been investigated, which motivated us for this study.

In this paper, we deal with the problem of the non-fragile observer design for time delay switched nonlinear systems using a delta operator, where the observer gain perturbations are assumed to be time-varying and unknown, but are norm-bounded. The aim is to design the non-fragile observer such that the estimated state error dynamics can be asymptotically convergent for observer gain perturbations. The desired non-fragile observer can be constructed by solving a set of LMIs. The remainder of the paper is organized as follows. In Section II, problem formulation and some necessary lemmas are given. In Section III, based on the MLF approach and delta operator theory, the stability analysis for a delta operator time delay switched nonlinear system is considered, and the result is dependent of time delay and will be employed to develop a non-fragile observer. A numerical example is given to illustrate the feasibility and effectiveness of the developed technique in Section IV, and concluding remarks are given in Section V.

## II. PROBLEM FORMULATION AND PRELIMINARY

Consider the following delta operator switched nonlinear system with time delay:

$$\delta x_k = A_{\sigma(k)}x_k + A_{d\sigma(k)}x_{k-n} + B_{\sigma(k)}u_k + f_{\sigma(k)}(x_k,k) \tag{1}$$

$$y_k = C_{\sigma(k)}x_k \tag{2}$$

$$x_k = \phi_k, \forall k \in \{-n,-n+1,\cdots,0\} \tag{3}$$

where $x_k \in R^p$ is the state vector at the $k$ th instant, $y_k \in R^m$

This work is supported by the Pre-Research Foundation of PLA University of Science and Technology under Grant No. 20110316.

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

is the measurement output vector. $\phi_k$ is a vector-valued initial function, $f_i(\cdot,\cdot): R^p \times R \to R^p$ is an unknown nonlinear function, $n$ is the state delay of the system. $\sigma(k): Z^+ \to \underline{N} = \{1,2,\cdots,N\}$ is a switching signal. Moreover, $\sigma(k)=i$ means that the $i$ th subsystem is activated. $u_k \in R^l$ is the control input of the $i$ th subsystem at the $k$ th instants. $A_i \in R^{p\times p}, A_{di} \in R^{p\times p}, B_i \in R^{p\times l}, C_i \in R^{m\times p}$ for $i \in \underline{N}$ are known real-valued matrices with appropriate dimensions, $\delta$ denotes the delta operator, the definition can be seen in [11], ie, $\delta x_k = (x_{k+1} - x_k)/T$, where $T$ is a sample period.

We construct the following discrete-time switched system using delta operator to estimate the state of system (1)-(3):

$$\delta\hat{x}_k = A_{\sigma(k)}\hat{x}_k + A_{d\sigma(k)}\hat{x}_{k-n} + B_{\sigma(k)}u_k + f_{\sigma(k)}(\hat{x}_k,k) \quad (4)$$
$$+L_{\sigma(k)}(y_k - \hat{y}_k)$$

$$\hat{y}_k = C_{\sigma(k)}\hat{x}_k \quad (5)$$

$$\hat{x}_k = 0, \forall k \in \{-n,-n+1,\cdots,0\} \quad (6)$$

where $\hat{x}_k \in R^p$ is the estimated state vector of $x_k$, $\hat{y}_k \in R^m$ is the observer output vector, $L_i \in R^{p\times m}$ for $i \in \underline{N}$ is the observer gain.

Let $\tilde{x}_k = x_k - \hat{x}_k$ be the estimated state error. By the definition of the delta operator, we have $\delta\tilde{x}_k = \delta x_k - \delta\hat{x}_k$, then we can obtain the following error system from (1)-(6):

$$\delta\tilde{x}_k = (A_{\sigma(k)} - L_{\sigma(k)}C_{\sigma(k)})\tilde{x}_k + A_{d\sigma(k)}\tilde{x}_{k-n} + f_{\sigma(k)}(x_k,k) \quad (7)$$
$$-f_{\sigma(k)}(\hat{x}_k,k)$$

$$\tilde{x}_k = \phi_k, \forall k \in \{-n,-n+1,\cdots,0\} \quad (8)$$

If the state observer gain variations could not be avoided, a kind of non-fragile state observer will be designed as follows:

$$\delta\hat{x}_k = A_{\sigma(k)}\hat{x}_k + A_{d\sigma(k)}\hat{x}_{k-n} + B_{\sigma(k)}u_k + f_{\sigma(k)}(\hat{x}_k,k) \quad (9)$$
$$+(L_{\sigma(k)} + \Delta L_{\sigma(k)})(y_k - \hat{y}_k)$$

$$\hat{y}_k = C_{\sigma(k)}\hat{x}_k \quad (10)$$

$$\hat{x}_k = 0, \forall k \in \{-n,-n+1,\cdots,0\} \quad (11)$$

where $\Delta L_i \in R^{p\times m}$ are uncertain real-valued matrix functions representing norm-bounded parameter uncertainties.

According to system (1)-(3) and (9)-(11), the dynamic equations of error switched system for non-fragile observer can be prescribed:

$$\delta\tilde{x}_k = [A_{\sigma(k)} - (L_{\sigma(k)} + \Delta L_{\sigma(k)})C_{\sigma(k)}]\tilde{x}_k + A_{d\sigma(k)}\tilde{x}_{k-n} \quad (12)$$
$$+f_{\sigma(k)}(x_k,k) - f_{\sigma(k)}(\hat{x}_k,k)$$

$$\tilde{x}_k = \phi_k, \forall k \in \{-n,-n+1,\cdots,0\} \quad (13)$$

Without loss of generality, we make the following assumptions.

**Assumption 1** $f_i(x_k,k)$ for $i \in \underline{N}$ are nonlinear functions satisfying:

$$\|f_i(x_k,k) - f_i(\hat{x}_k,k)\| \le \|U_i(x_k - \hat{x}_k)\| \quad (14)$$

where $U_i$ are known real constant matrices.

**Assumption 2** The gain perturbations $\Delta L_i$ are of the norm-bounded form:

$$\Delta L_i = H_i F_{ik} E_i \quad (15)$$

where $H_i$, $E_i$ which denote the structure of the uncertainties are known real constant matrices with proper dimensions, and $F_{ik}$ are unknown time-varying matrices which satisfy:

$$F_{ik}^T F_{ik} \le I$$

The unknown matrices $F_{ik}$ contain the uncertain parameters in the linear part of the subsystem and the matrices $H_i$, $E_i$ specify how the unknown parameters in $F_{ik}$ affect the elements of the nominal matrices $L_i$.

The parameter uncertainty structure in equation (15) has been widely used and can represent parameter uncertainty in many physical cases. Equation (15) is called additive gain variations.

**Lemma 1** [18] Let $U$, $V$, $W$ and $X$ be real matrices of appropriate dimensions with $X$ satisfying $X = X^T$, then for all $V^T V \le I$

$$X + UVW + W^T V^T U^T < 0$$

if and only if there exists a scalar $\varepsilon > 0$ such that

$$X + \varepsilon UU^T + \varepsilon^{-1} W^T W < 0$$

**Lemma 2** [19] Consider the following system

$$x_{k+1} = f_k(x_k) \quad (16)$$

If there is a function $V: Z^+ \times R^n \to R$ such that:

(1) $V$ is a positive-definite function, decreasing and radially unbounded.

(2) $\Delta V(k,x_k) = V(k+1,x_{k+1}) - V(k,x_k) < 0$ is negative definite along the solution of (16).

then system (16) is asymptotically stable.

**Lemma 3**[20] For any constant positive semi-definite symmetric matrix $W$, two positive integers $r$ and $r_0$ satisfying $r \ge r_0 \ge 1$, the following inequality holds

$$\left(\sum_{i=r_0}^{r} x(i)\right)^T W \left(\sum_{i=r_0}^{r} x(i)\right) \le \rho \sum_{i=r_0}^{r} x^T(i) W x(i)$$

where $\rho = r - r_0 + 1$.

The objective of this paper is to design non-fragile observer gain $L_i$ for delta operator time delay switched nonlinear systems (1)-(3) such that the estimated state error dynamics is asymptotically convergent.

## III. Main Results

### A. Stability analysis

In this subsection, we investigate the stability of the following delta operator time delay switched nonlinear system

$$\delta x_k = A_{\sigma(k)}x_k + A_{d\sigma(k)}x_{k-n} + f_{\sigma(k)}(x_k,k) \quad (17)$$

where $\|f_i(x_k,k)\| \le \|U_i x_k\|$ for $i \in \underline{N}$. Define the indicator function:

$$\xi(k) = (\xi_1(k), \xi_2(k), \cdots, \xi_N(k))^T \quad (18)$$

with $i \in \{1,2,\cdots,N\}$, where

$$\xi_i(k)=\begin{cases}1 & \text{when the } i\text{th subsystem is activated} \\ 0 & \text{others}\end{cases},$$

then system (17) can be written as

$$\delta x_k=\sum_{i=1}^{N}\xi_i(k)(A_i x_k + A_{di}x_{k-n}+f_{\sigma(k)}(x_k,k))$$

$$\forall i\in\{1,2,\cdots,N\}$$

**Theorem 1** Consider system (17). If there exist symmetric positive definite matrices $P_i>0$, $R_i^{(r)}>0$, $R_i^{(s)}>0$, $Q_i^{(s)}>0$, $Q_i^{(n)}>0$ and scalar $\varepsilon_i>0$, $i\in\{1,2,\cdots,N\}$, $r=1,2,\cdots,s-1$, $s=1,2,\cdots,n-1$, such that

$$P_i<\varepsilon_i I \tag{19}$$

$$R_j^{(r+1)}<R_i^{(r)},\ r=1,2,\cdots,s-1 \tag{20}$$

$$Q_j^{(s+1)}<Q_i^{(s)},\ s=1,2,\cdots,n-1 \tag{21}$$

$$\left[\begin{array}{cc} \begin{array}{l} A_i^TP_j+P_jA_i+TA_i^TP_jA_i+\varepsilon_i(T+1)U_i^TU_i \\ +\frac{1}{T}(P_j-\frac{1}{2}P_i)-\frac{1}{n}R_i^{(s)}+Q_j^{(1)} \end{array} & A_i^TP_i \\ * & -P_i+nT^2R_j^{(1)} \rightarrow \\ * & * \end{array}\right. \tag{22}$$

$$\left.\begin{array}{c} (TA_i^T+I)P_jA_{di}+\frac{1}{n}R_i^{(s)} \\ P_iA_{di} \\ TA_{di}^TP_jA_{di}-Q_i^{(n)}-\frac{1}{n}R_i^{(s)} \end{array}\right]<0$$

$\forall i,j\in\{1,2,\cdots,N\}$, then system (17) is asymptotically stable under arbitrary switching.

**Proof** Consider the following switched Lyapunov-Krasovskii functional:

$$V(k,x_k)=V_1(k,x_k)+V_2(k,x_k)+V_3(k,x_k) \tag{23}$$

with

$$V_1(k,x_k)=\frac{1}{2}x_k^TP(\xi(k))x_k=\frac{1}{2}x_k^T\left(\sum_{i=1}^{N}\xi_i(k)P_i\right)x_k$$

$$V_2(k,x_k)=T\sum_{s=1}^{n}x_{k-s}^TQ^{(s)}(\xi(k))x_{k-s}=T\sum_{s=1}^{n}\sum_{i=1}^{N}x_{k-s}^T\xi_i(k)Q_i^{(s)}x_{k-s}$$

$$V_3(k,x_k)=T\sum_{s=1}^{n}\sum_{r=1}^{s}e_{k-r}^TR^{(r)}(\xi(k))e_{k-r}=T\sum_{s=1}^{n}\sum_{r=1}^{s}\sum_{i=1}^{N}e_{k-r}^T\xi_i(k)R_i^{(r)}e_{k-r}$$

with $P_i$, $Q_i^{(s)}$, $R_i^{(r)}$, $i\in\{1,2,\cdots,N\}$ being symmetric positive-definite matrices and $e_k=x_k-x_{k+1}$.

Then switched Lyapunov-Krasovskii functional in delta domain has the following form:

$$\delta V_1(k,x_k)=\frac{V_1(k+1,x_{k+1})-V_1(k,x_k)}{T}$$

$$=\frac{x_{k+1}^TP(\xi(k+1))x_{k+1}-x_k^TP(\xi(k))x_k}{2T}$$

$$=\frac{(x_k+T\delta x_k)^TP(\xi(k+1))(x_k+T\delta x_k)-x_k^TP(\xi(k))x_k}{2T} \tag{24}$$

$$\le x_k^T[A_i^TP_j+P_jA_i+TA_i^TP_jA_i+\varepsilon_iTU_i^TU_i+\frac{1}{T}(P_j-\frac{1}{2}P_i)]x_k$$

$$+2x_k^T[(TA_i^T+I)P_jA_{di}]x_{k-n}+x_{k-n}^T(TA_{di}^TP_jA_{di})x_{k-n}$$

$$\delta V_2(k,x_k)=\frac{1}{T}[T\sum_{s=1}^{n}x_{k-s+1}^TQ^{(s)}(\xi(k+1))x_{k-s+1}-T\sum_{s=1}^{n}x_{k-s}^TQ^{(s)}(\xi(k))x_{k-s}]$$

$$=x_k^TQ_j^{(1)}x_k-x_{k-n}^TQ_i^{(n)}x_{k-n}+\sum_{s=1}^{n-1}x_{k-s}^T(Q_j^{(s+1)}-Q_i^{(s)})x_{k-s}$$

By (21), we can obtain that

$$\delta V_2(k,x_k)<x_k^TQ_j^{(1)}x_k-x_{k-n}^TQ_i^{(n)}x_{k-n} \tag{25}$$

$$\delta V_3(k,x_k)=\frac{1}{T}[T\sum_{s=1}^{n}\sum_{r=1}^{s}e_{k-r+1}^TR^{(r)}(\xi(k+1))e_{k-r+1}-T\sum_{s=1}^{n}\sum_{r=1}^{s}e_{k-r}^TR^{(r)}(\xi(k))e_{k-r}]$$

$$=ne_k^TR_j^{(1)}e_k+\sum_{s=2}^{n}\sum_{r=1}^{s-1}e_{k-r}^TR_j^{(r+1)}e_{k-r}-\sum_{s=2}^{n}\sum_{r=1}^{s-1}e_{k-r}^TR_i^{(r)}e_{k-r}-\sum_{s=1}^{n}e_{k-s}^TR_i^{(s)}e_{k-s}$$

By (20), we can obtain that

$$\begin{aligned}\delta V_3(k,x_k)&\le ne_k^TR_j^{(1)}e_k-\frac{1}{n}(\sum_{s=1}^{n}e_{k-s})^TR_i^{(s)}(\sum_{s=1}^{n}e_{k-s})\\&=-\frac{1}{n}(x_{k-n}-x_k)^TR_i^{(s)}(x_{k-n}-x_k)+nT^2\delta x_k^TR_j^{(1)}\delta x_k\end{aligned} \tag{26}$$

If $\delta V(k,x_k)<0$ holds under arbitrary switching signal, it follows that this has to hold for special configuration $\xi_i(k)=1$, $\xi_{h\neq i}(k)=0$, $\xi_j(k+1)=1$, $\xi_{g\neq j}(k+1)=0$ and for all $x_k\in R^p$. By (24), (25) and (26), we have

$$\begin{aligned}\delta V(k,x_k)&=\delta V_1(k,x_k)+\delta V_2(k,x_k)+\delta V_3(k,x_k)\\&\le x_k^T[A_i^TP_j+P_jA_i+TA_i^TP_jA_i+\varepsilon_iTU_i^TU_i\\&+\frac{1}{T}(P_j-\frac{1}{2}P_i)]x_k+x_{k-n}^T(TA_{di}^TP_jA_{di})x_{k-n}\\&+2x_k^T[(TA_i^T+I)P_jA_{di}]x_{k-n}+x_k^TQ_j^{(1)}x_k+nT^2\delta x_k^TR_j^{(1)}\delta x_k\\&-x_{k-n}^TQ_i^{(n)}x_{k-n}-\frac{1}{n}(x_{k-n}-x_k)^TR_i^{(s)}(x_{k-n}-x_k)\end{aligned} \tag{27}$$

Notice that

$$0=-2\delta x_k^TP_i(\delta x_k-A_ix_k-A_{di}x_{k-n}-f_i(x_k,k)) \tag{28}$$

Combining (27) and (28) leads to

$$\delta V(k,x_k)\le\eta^T\left[\begin{array}{cc} \begin{array}{l} A_i^TP_j+P_jA_i+TA_i^TP_jA_i+\varepsilon_i(T+1)U_i^TU_i \\ +\frac{1}{T}(P_j-\frac{1}{2}P_i)-\frac{1}{n}R_i^{(s)}+Q_j^{(1)} \end{array} & A_i^TP_i \\ * & -P_i+nT^2R_j^{(1)} \rightarrow \\ * & * \end{array}\right.$$

$$\left.\begin{array}{c} (TA_i^T+I)P_jA_{di}+\frac{1}{n}R_i^{(s)} \\ P_iA_{di} \\ TA_{di}^TP_jA_{di}-Q_i^{(n)}-\frac{1}{n}R_i^{(s)} \end{array}\right]\eta$$

where $\eta = \begin{bmatrix} x_k^T & \delta x_k^T & x_{k-n}^T \end{bmatrix}^T$. From (22), we have $\delta V(k, x_k) < 0$. By Lemma 2, the system (17) is asymptotically stable. The proof is completed.

**Remark 1** When time delay $n \equiv 0$ and $f_{\sigma(k)}(x_k, k) \equiv 0$, system (17) becomes as follows:

$$\delta x_k = \tilde{A}_{\sigma(k)} x_k$$

where $\tilde{A}_{\sigma(k)} = A_{\sigma(k)} + A_{d\sigma(k)}$. From (22), we know that the matrix inequality imply that the following inequality holds:

$$\tilde{A}_i^T P_j + P_j \tilde{A}_i + T \tilde{A}_i^T P_j \tilde{A}_i + \frac{1}{T}(P_j - P_i) < 0$$

The above inequality is just a sufficient condition of stability for the delta operator switched system without time delay, which can be expressed in [14].

**Remark 2** When sample period $T = 0$ and $f_{\sigma(k)}(x_k, k) \equiv 0$, system (17) becomes a continuous-time switched linear system as follows:

$$\dot{x}(t) = A_{\sigma(t)} x(t) + A_{d\sigma(t)} x(t-d) \tag{29}$$

We can obtain sufficient condition of stability for system (29) by Theorem 1.

**Corollary 1** Consider system (29). If there exist symmetric positive definite matrices $P > 0$, $R > 0$, $Q > 0$, such that

$$\begin{bmatrix} A_i^T P + P A_i - \frac{1}{d} R + Q & A_i^T P & P A_{di} + \frac{1}{d} R \\ * & -2P & P A_{di} \\ * & * & -Q - \frac{1}{d} R \end{bmatrix} < 0 \tag{30}$$

$\forall i \in \{1, 2, \cdots, N\}$, then system (29) is asymptotically stable under arbitrary switching.

**Remark 3** Let $\bar{A}_{\sigma(k)} = A_{\sigma(k)} + I$. When sample period $T = 1$ and $f_{\sigma(k)}(x_k, k) \equiv 0$, system (17) becomes a discrete-time switched linear system as follows:

$$x_{k+1} = \bar{A}_{\sigma(k)} x_k + A_{d\sigma(k)} x_{k-n} \tag{31}$$

We can obtain sufficient condition of stability for system (31) by Theorem 1.

**Corollary 2** Consider system (31). If there exist symmetric positive definite matrices $P_i > 0$, $R_i^{(r)} > 0$, $R_i^{(s)} > 0$, $Q_i^{(s)} > 0$, $Q_i^{(n)} > 0$, $i \in \{1, 2, \cdots, N\}$, $r = 1, 2, \cdots, s-1$, $s = 1, 2, \cdots, n-1$, such that

$$R_j^{(r+1)} < R_i^{(r)},\ r = 1, 2, \cdots, s-1 \tag{32}$$

$$Q_j^{(s+1)} < Q_i^{(s)},\ s = 1, 2, \cdots, n-1 \tag{33}$$

$$\begin{bmatrix} \begin{matrix} \bar{A}_i^T P_j + P_j \bar{A}_i + \bar{A}_i^T P_j \bar{A}_i \\ -P_j - P_i - \frac{1}{n} R_i^{(s)} + Q_j^{(1)} \end{matrix} & \bar{A}_i^T P_i & \bar{A}_i^T P_j A_{di} + \frac{1}{n} R_i^{(s)} \\ * & -2P_i + n R_j^{(1)} & P_i A_{di} \\ * & * & A_{di}^T P_j A_{di} - Q_i^{(n)} - \frac{1}{n} R_i^{(s)} \end{bmatrix} < 0 \tag{34}$$

$\forall i, j \in \{1, 2, \cdots, N\}$, then system (31) is asymptotically stable.

*B. Observer Design*

Now we consider system (7)-(8). The following theorem presents sufficient conditions for the existence of asymptotic stability of system (7)-(8).

**Theorem 2** Consider system (7)-(8), if there exist a set of matrices $X_i > 0$, $V_i^{(s)} > 0$, $V_i^{(n)} > 0$, $Z_i^{(r)} > 0$, $Z_i^{(s)} > 0$, $V_{ij}^{(s)} > 0$, $V_{ij}^{(n)} > 0$, $Z_{ij}^{(r)} > 0$, $Z_{ij}^{(s)} > 0$, $\varepsilon_i > 0$, $i \in \{1, 2, \cdots, N\}$, $r = 1, 2, \cdots, s-1$, $s = 1, 2, \cdots, n-1$, and $W_i$ such that the following LMIs have feasible solutions

$$X_i > \varepsilon_i^{-1} I \tag{35}$$

$$Z_{ij}^{(r+1)} < Z_i^{(r)},\ r = 1, 2, \cdots, s-1 \tag{36}$$

$$V_{ij}^{(s+1)} < V_i^{(s)},\ s = 1, 2, \cdots, n-1 \tag{37}$$

$$\left[\begin{matrix} -\frac{1}{2T} X_i + V_{ij}^{(1)} - \frac{1}{n} Z_i^{(s)} & (A_i X_i - W_i)^T & \frac{1}{n} Z_i^{(s)} \\ * & -X_i + n T^2 Z_{ij}^{(1)} & A_{di} X_i \\ * & * & -V_i^{(n)} - \frac{1}{n} Z_i^{(s)} \\ * & * & * \\ * & * & * \end{matrix}\right. \rightarrow \tag{38}$$

$$\left.\begin{matrix} T(A_i X_i - W_i)^T + X_i & X_i U_i^T \\ 0 & 0 \\ T X_i A_{di}^T & 0 \\ -T X_j & 0 \\ * & -\frac{1}{\varepsilon_i (T+1)} I \end{matrix}\right] < 0$$

where $i, j \in \{1, 2, \cdots, N\}$, then the state observer gain $L_i$ satisfying the following equations:

$$L_i C_i = W_i X_i^{-1} \tag{39}$$

can guarantees system (7)-(8) is asymptotically stable under arbitrary switching.

**Proof** Denote

$$M_{ij} = \left[\begin{matrix} \begin{matrix} (A_i - L_i C_i)^T P_j + P_j (A_i - L_i C_i) + T (A_i - L_i C_i)^T P_j (A_i - L_i C_i) \\ + \varepsilon_i (T+1) U_i^T U_i + \frac{1}{T}(P_j - \frac{1}{2} P_i) - \frac{1}{n} R_i^{(s)} + Q_j^{(1)} \end{matrix} & (A_i - L_i C_i)^T P_i \\ * & -P_i + n T^2 R_j^{(1)} \\ * & * \end{matrix}\right. \rightarrow$$

$$\left.\begin{matrix} [T (A_i - L_i C_i)^T + I] P_j A_{di} + \frac{1}{n} R_i^{(s)} \\ P_i A_{di} \\ T A_{di}^T P_j A_{di} - Q_i^{(n)} - \frac{1}{n} R_i^{(s)} \end{matrix}\right]$$

By Theorem 1, if $M_{ij} < 0$, then the system (7)-(8) is asymptotically stable. By Schur Complement, we have $M_{ij} < 0$ is equivalent to

$$\begin{bmatrix} -\frac{1}{2T}P_i+Q_j^{(1)}-\frac{1}{n}R_i^{(s)} \\ +\varepsilon_i(T+1)U_i^TU_i & (A_i-L_iC_i)^TP_i & \frac{1}{n}R_i^{(s)} & T(A_i-L_iC_i)^T+I \\ * & -P_i+nT^2R_j^{(1)} & P_iA_{di} & 0 \\ * & * & -Q_i^{(n)}-\frac{1}{n}R_i^{(s)} & TA_{di}^T \\ * & * & * & -TP_j^{-1} \end{bmatrix}<0 \tag{40}$$

Using $diag\left\{P_i^{-1} \quad P_i^{-1} \quad P_i^{-1} \quad I\right\}$ to pre- and post- multiply the left term of (40) respectively, and denoting $X_i=P_i^{-1}$, $W_i=L_iC_iX_i$, $Z_i^{(s)}=P_i^{-1}R_i^{(s)}P_i^{-1}$, $V_i^{(n)}=P_i^{-1}Q_i^{(n)}P_i^{-1}$, $V_{ij}^{(1)}=P_i^{-1}Q_j^{(1)}P_i^{-1}$, $Z_{ij}^{(1)}=P_i^{-1}R_j^{(1)}P_i^{-1}$, we can obtain

$$\left[\begin{matrix} -\frac{1}{2T}X_i+V_{ij}^{(1)}-\frac{1}{n}Z_i^{(s)} \\ +\varepsilon_i(T+1)X_iU_i^TU_iX_i & X_i(A_i-L_iC_i)^T \\ * & -X_i+nT^2Z_{ij}^{(1)} \\ * & * \\ * & * \end{matrix}\right. \rightarrow \tag{41}$$

$$\left.\begin{matrix} \frac{1}{n}Z_i^{(s)} & TX_i(A_i-L_iC_i)^T+X_i \\ A_{di}X_i & 0 \\ -V_i^{(n)}-\frac{1}{n}Z_i^{(s)} & TX_iA_{di}^T \\ * & -TX_j \end{matrix}\right]<0$$

Using Schur Complement again, we can obtain (38). By the MFL method, $M_{ij}<0$, $\forall i,j\in\{1,2,\cdots,N\}$ can guarantee that the system (7)-(8) is asymptotically stable under arbitrary switching. The proof is completed.

The procedure of observer design of system (7)-(8) can be summarized as follows:

**The Procedure of Observer Design**

**Step 1.** If there exist a set of positive definite symmetric matrices $X_i>0$, $V_i^{(s)}>0$, $V_i^{(n)}>0$, $Z_i^{(r)}>0$, $Z_i^{(s)}>0$, $V_{ij}^{(s)}>0$, $V_{ij}^{(n)}>0$, $Z_{ij}^{(r)}>0$, $Z_{ij}^{(s)}>0$, $\varepsilon_i>0$, $i\in\{1,2,\cdots,N\}$, $r=1,2,\cdots,s-1$, $s=1,2,\cdots,n-1$ and $W_i$, LMIs (35)-(38) have feasible solutions, then go to Step 2.

**Step 2.** If the equations $L_iC_i=W_iX_i^{-1}$ have feasible solutions for unknown matrices $L_i$, then the observer can be constructed as (4)-(6), where $L_i$ are the observer gain.

**Remark 4** For the matrices equations (39), by the matrix theory we can know that the sufficient and necessary condition for the equations having feasible solutions is

$$rank[C_i]=rank[C_i^T\vdots(W_iX_i^{-1})^T]$$

However, when $rank[C_i]\neq rank[C_i^T\vdots(W_iX_i^{-1})^T]$, the equations don not exist feasible solutions. In particular, if $rank[C_i]=p$, that is to say the output matrices $C_i$ is column filled rank matrices, then the equations (39) have feasible solutions. But $rank[C_i]\neq p$ implies that the equations (39) may have not feasible solutions. When there do not exist feasible solutions for the equations (39), we can construct the matrices $B_i$ such that $rank[C_i]=rank[C_i^T\vdots B_i^T]$. Let $W_iX_i^{-1}=B_i$, substituting $W_i=B_iX_i$ to (38), if there exists feasible solutions for LMIs (35)-(38), then the observer gain $L_i$ can be obtain from the equations $L_iC_i=B_i$. Specially, when the matrices $B_i$ are chosen as $C_i$ and LMIs (35)-(38) have feasible solutions, $L_i$ can be constructed as $L_i=I$ obviously, where $I$ denotes the identity matrix.

### C. *Non-fragile Observer Design*

Now consider systems (12)-(13), if there exist additive gain variations in state observer, we can obtain the following result.

**Theorem 3** Consider system (12)-(13), if there exist a set of matrices $X_i>0$, $V_i^{(s)}>0$, $V_i^{(n)}>0$, $Z_i^{(r)}>0$, $Z_i^{(s)}>0$, $V_{ij}^{(s)}>0$, $V_{ij}^{(n)}>0$, $Z_{ij}^{(r)}>0$, $Z_{ij}^{(s)}>0$, $\varepsilon_i>0$, $\mu_i>0$, $i\in\{1,2,\cdots,N\}$, $r=1,2,\cdots,s-1$, $s=1,2,\cdots,n-1$ and $W_i$ such that the following LMIs hold:

$$X_i>\varepsilon_i^{-1}I \tag{42}$$

$$Z_{ij}^{(r+1)}<Z_i^{(r)},\ r=1,2,\cdots,s-1 \tag{43}$$

$$V_{ij}^{(s+1)}<V_i^{(s)},\ s=1,2,\cdots,n-1 \tag{44}$$

$$\left[\begin{matrix} -\frac{1}{2T}X_i+V_{ij}^{(1)}-\frac{1}{n}Z_i^{(s)} & (A_iX_i-W_i)^T & \frac{1}{n}Z_i^{(s)} \\ * & -X_i+nT^2Z_{ij}^{(1)}+\mu_iH_iH_i^T & A_{di}X_i \\ * & * & -V_i^{(n)}-\frac{1}{n}Z_i^{(s)} \\ * & * & * \\ * & * & * \\ * & * & * \end{matrix}\right. \rightarrow \tag{45}$$

$$\left.\begin{matrix} T(A_iX_i-W_i)^T+X_i & X_iU_i^T & -X_iC_i^TE_i^T \\ \mu_iTH_iH_i^T & 0 & 0 \\ TX_iA_{di}^T & 0 & 0 \\ -TX_j+\mu_iT^2H_iH_i^T & 0 & 0 \\ * & -\frac{1}{\varepsilon_i(T+1)}I & 0 \\ * & * & -\mu_iI \end{matrix}\right]<0$$

where $i\in\{1,2,\cdots,N\}$, then the non-fragile state observer gain $L_i$ satisfying the following equations:

$$L_iC_i=W_iX_i^{-1} \tag{46}$$

can guarantees system (12)-(13) is asymptotically stable under arbitrary switching.

**Proof** Denote

$$T_{ij}=\left[\begin{matrix} -\frac{1}{2T}X_i+V_{ij}^{(1)}-\frac{1}{n}Z_i^{(s)} & X_i[A_i-(L_i+\Delta L_i)C_i]^T & \frac{1}{n}Z_i^{(s)} \\ * & -X_i+nT^2Z_{ij}^{(1)} & A_{di}X_i \\ * & * & -V_i^{(n)}-\frac{1}{n}Z_i^{(s)} \\ * & * & * \\ * & * & * \end{matrix}\right. \rightarrow$$

$$\begin{matrix} TX_i[A_i-(L_i+\Delta L_i)C_i]^T+X_i & X_iU_i^T \\ 0 & 0 \\ TX_iA_{di}^T & 0 \\ -TX_j & 0 \\ * & -\dfrac{1}{\varepsilon_i(T+1)}I \end{matrix}\right]$$

Substituting (15) into the above equation leads to

$$T_{ij}=T_{ij}^{(1)}+T_i$$

where

$$T_{ij}^{(1)}=\left[\begin{matrix} -\dfrac{1}{2T}X_i+V_{ij}^{(1)}-\dfrac{1}{n}Z_i^{(s)} & [(A_i-L_iC_i)X_i]^T & \dfrac{1}{n}Z_i^{(s)} \\ * & -X_i+nT^2Z_{ij}^{(1)} & A_{di}X_i \\ * & * & -V_i^{(n)}-\dfrac{1}{n}Z_i^{(s)} \rightarrow \\ * & * & * \\ * & * & * \end{matrix}\right.$$

$$\left.\begin{matrix} T[(A_i-L_iC_i)X_i]^T+X_i & X_iU_i^T \\ 0 & 0 \\ TX_iA_{di}^T & 0 \\ -TX_j & 0 \\ * & -\dfrac{1}{\varepsilon_i(T+1)}I \end{matrix}\right]$$

$$T_i=\begin{bmatrix} 0 & -(H_iF_{ik}E_iC_iX_i)^T & 0 & -T(H_iF_{ik}E_iC_iX_i)^T & 0 \\ * & 0 & 0 & 0 & 0 \\ * & * & 0 & 0 & 0 \\ * & * & * & 0 & 0 \\ * & * & * & * & 0 \end{bmatrix}$$

$$=\begin{bmatrix} 0 \\ H_i \\ 0 \\ TH_i \\ 0 \end{bmatrix}F_{ik}\begin{bmatrix}-E_iC_iX_i & 0 & 0 & 0 & 0\end{bmatrix}+\left(\begin{bmatrix} 0 \\ H_i \\ 0 \\ TH_i \\ 0 \end{bmatrix}F_{ik}\begin{bmatrix}-E_iC_iX_i & 0 & 0 & 0 & 0\end{bmatrix}\right)^T$$

According to Lemma 1, we have

$$T_{ij}\le T_{ij}^{(1)}+\mu_i\begin{bmatrix} 0 \\ H_i \\ 0 \\ TH_i \\ 0 \end{bmatrix}\begin{bmatrix} 0 \\ H_i \\ 0 \\ TH_i \\ 0 \end{bmatrix}^T \tag{47}$$

$$+\mu_i^{-1}\begin{bmatrix}-E_iC_iX_i & 0 & 0 & 0 & 0\end{bmatrix}^T\begin{bmatrix}-E_iC_iX_i & 0 & 0 & 0 & 0\end{bmatrix}$$

Denote $Z_{ij}$ is the right term of inequality (47), by Schur Complement, $Z_{ij}<0$ are equivalent to

$$\left[\begin{matrix} -\dfrac{1}{2T}X_i+V_{ij}^{(1)}-\dfrac{1}{n}Z_i^{(s)} & [(A_i-L_iC_i)X_i]^T & \dfrac{1}{n}Z_i^{(s)} \\ * & -X_i+nT^2Z_{ij}^{(1)}+\mu_iH_iH_i^T & A_{di}X_i \\ * & * & -V_i^{(n)}-\dfrac{1}{n}Z_i^{(s)} \rightarrow \\ * & * & * \\ * & * & * \\ * & * & * \end{matrix}\right.$$

$$\left.\begin{matrix} T[(A_i-L_iC_i)X_i]^T+X_i & X_iU_i^T & -X_iC_i^TE_i^T \\ \mu_iTH_iH_i^T & 0 & 0 \\ TX_iA_{di}^T & 0 & 0 \\ -TX_j+\mu_iT^2H_iH_i^T & 0 & 0 \\ * & -\dfrac{1}{\varepsilon_i(T+1)}I & 0 \\ * & 0 & -\mu_iI \end{matrix}\right]<0 \tag{48}$$

Denote $W_i=L_iC_iX_i$, (48) is equivalent to (45). By Theorem 1, we conclude that system (12)-(13) is asymptotically stable. The proof is completed.

If the state observer gain variations could not be avoided, then the non-fragile observer for system (1)-(3) can be designed according to the following procedure.

**The Procedure of Non-fragile Observer Design**

**Step 1.** If there exist a set of positive definite symmetric matrices $X_i>0$, $V_i^{(s)}>0$, $V_i^{(n)}>0$, $Z_i^{(r)}>0$, $Z_i^{(s)}>0$, $V_{ij}^{(s)}>0$, $V_{ij}^{(n)}>0$, $Z_{ij}^{(r)}>0$, $Z_{ij}^{(s)}>0$, $\varepsilon_i>0$, $\mu_i>0$, $i\in\{1,2,\cdots,N\}$, $r=1,2,\cdots,s-1$, $s=1,2,\cdots,n-1$ and $W_i$, LMIs (42)-(45) have feasible solutions, then go to Step 2.

**Step 2.** If the equations $L_iC_i=W_iX_i^{-1}$ have feasible solutions for unknown matrices $L_i$, then the observer can be constructed as (9)-(11), where $L_i$ are the observer gain.

## IV. NUMERICAL EXAMPLE

In this section, we present an example to illustrate the effectiveness of the proposed approach. Consider system (1)-(3) with parameters as follows:

$$A_1=\begin{bmatrix} 0.1 & 0.2 \\ 0.3 & -0.1 \end{bmatrix},\ A_2=\begin{bmatrix} -0.1 & 0 \\ 0.1 & 0.2 \end{bmatrix},$$

$$A_{d1}=\begin{bmatrix} 0.1 & 0.1 \\ 0 & 0.2 \end{bmatrix},\ A_{d2}=\begin{bmatrix} 0 & 0.1 \\ 0 & 0 \end{bmatrix},$$

$$E_1=\begin{bmatrix} -0.1 & 0 \\ 0.1 & 0 \end{bmatrix},\ E_2=\begin{bmatrix} 0.1 & 0.1 \\ 0 & 0.1 \end{bmatrix},$$

$$U_1=\begin{bmatrix} 0.1 & 0 \\ 0 & 0 \end{bmatrix},U_2=\begin{bmatrix} 0 & 0 \\ -2 & 0 \end{bmatrix}$$

$$H_1=H_2=\begin{bmatrix} 0.2 & 0.1 \\ 0 & 0 \end{bmatrix},$$

$$C_1=C_2=\begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}$$

and the uncertain time-varying parameter matrices $F_{1,k} = F_{2,k} = \begin{bmatrix} \sin k & 0 \\ 0 & \sin k \end{bmatrix}$. The sampling period $T = 0.5$, and the time delay $n = 2$, then using the Matlab LMI Control Toolbox to solve the LMIs in (42) to (45), we obtain the solution as follows:

$$X_1 = \begin{bmatrix} 76.8668 & 0.1346 \\ 0.1346 & 84.1706 \end{bmatrix}, X_2 = \begin{bmatrix} 36.2793 & -0.0023 \\ -0.0023 & 76.7278 \end{bmatrix}$$

$$W_1 = \begin{bmatrix} 90.1949 & 18.2174 \\ 23.3830 & 64.1468 \end{bmatrix}, W_2 = \begin{bmatrix} 28.0449 & -1.0833 \\ 3.6168 & 76.6194 \end{bmatrix}$$

Therefore, by Theorem 3 a desired non-fragile observer gain can be solved from the following equations:

$$L_1 C_1 = W_1 X_1^{-1} \text{ and } L_2 C_2 = W_2 X_2^{-1}$$

The we can obtain that

$$L_1 = \begin{bmatrix} 1.1730 & -0.9584 \\ 0.3029 & 0.4587 \end{bmatrix}, L_2 = \begin{bmatrix} 0.7730 & -0.7871 \\ 0.0998 & 0.8988 \end{bmatrix}.$$

## V. Conclusion

In this paper, we focus on both stability and non-fragile observer design for delta operator time delay switched nonlinear systems. By using the MLF method and choosing Lyapunov-Krasovskii functional in delta domain appropriately, sufficient conditions for the existence of non-fragile observer have been given in terms of LMIs. The result is dependent of sampling period and time delay and can be developed for non-fragile observer problems. Future work will focus on using the proposed design method to solve the problem of stabilization based on non-fragile observer for time delay switched nonlinear systems via delta operator approach.

*Abstract*—**This paper is concerned with the mean-square exponential stabilization of packet-based networked systems with time-varying transmission delays, packet losses and input missing. Based on a multivariate i.i.d. model of input delays and a Bernoulli model of input missing, the packet-based networked system is formulated as a switching system with multiple subsystems of different input delays. The sufficient fast-switching conditions are directly established for the closed-loop mean-square exponential stability via an appropriate Lyapunov-Krasovskii approach different from average dwell time approach. The resulting controller design method can be obtained by cone complementarity linearization (CCL). Numerical example is also given to substantiate the effectiveness of our results.**

***Keywords—Networked systems; packet-based; transmission delays; packet losses; input missing***

## I. INTRODUCTION

Networked control systems (NCSs) have attracted much attention in recent years for its advantages over conventional control systems, such as low installation cost, less power consumption, simple maintenance and flexible configuration [1]-[3]. But transmission delays, packet losses, and input missing are common phenomena in NCSs, which often degrade the system performance and even lead to the closed-loop instability.

Transmission delays and packet losses are time-varying and random in nature, and often taken as input delays of NCSs [2], [3]. Bernoulli process is widely used to model discrete transmission delays and packet losses [4]-[6]. By transforming continuous input delays as discrete interval-distributed variables, Bernoulli process is also an appropriate model to explore the binary interval-distributed property of continuous input delays [7]-[9]. Recently, the multivariate independent and identically distributed process (i.i.d) has been proposed as a more realistic and general model to formulate discrete and continuous random input delays [10]-[13]. Based on i.i.d. models, NCSs with time-varying transmission delays and packet losses were essentially switching systems. NCSs with discrete i.i.d. input delays have attracted much research attention and many results have been reported in the literatures, see [10] and [11] for overall system performance conditions dependent and independent on average dwell time of switching subsystems, respectively. But for continuous i.i.d. input delays, most of results are additionally dependent on average dwell time of switching subsystems to guarantee closed-loop mean-square stability, except [7]-[9] where continuous binary i.i.d. input delays, i.e. continuous Bernoulli input delays, were considered. Unfortunately, the results of [7]-[9] could not be extended to the case of continuous multivariate i.i.d. input delays.

Input missing, resulted from control failure, actuator failure or energy-saving consideration, is a common event in NCSs and has an innegligible effect on system performance [14]-[16]. So it is practically important to take it into account in the modeling, analysis and synthesis of NCSs. Input missing is often modeled as Bernoulli process. But all results in [14]-[16] are derived via the average dwell time approach and are essentially slow switching conditions, which would reduce the performance room in system synthesis.

In this paper, the mean-square exponential stabilization problem is considered for packet-based networked systems with time-varying transmission delays, packet losses and input missing. It is known that packet-based scheme is an effective way to compensate time-varying transmission delays and packet losses [12], [13]. But the existing results are all dependent on average dwell time of subsystems. Here input delays are modeled as a continuous multivariate i.i.d. process, and input missing is modeled as a Bernoulli process. Then the NCS is described as a switching system with multiple subsystems of different input delays. A new Lyapunov-Krasovskii approach is proposed for the packet-based networked systems, which takes the distribution information of input delays into account both in constructing the Lyapunov-Krasovskii functional and bounding its infinitesimal. Based on this approach, the fast-switching conditions are directly derived for the closed-loop mean-square

exponential stability as well as the resulting controller design method. Numerical examples show the effectiveness and advantage of our results.

*Notation:* The superscript '$T$' denotes matrix transposition. $\mathbb{N}$ and $\mathbb{R}^n$ denote the sets of positive integers and $n\times n$ real matrices, respectively. The notation $P>0$ ($\geq 0$) means that $P$ is real symmetric and positive definite (semi-definite). $I$ and $0$ denote an identity matrix and a zero matrix of appropriate dimensions, respectively. For given positive integers $n_1$ and $n_2$, $I_{n_1}$ denotes the $n_1\times n_1$ identity matrix, and $0_{n_1\times n_2}$ the $n_1\times n_2$ zero matrix. $\mathbb{E}\{\bullet\}$ denotes the mathematical expectation. The space of functions $\phi:[-\bar{\eta},0]\to\mathbb{R}^n$, which are absolutely continuous functions on $[-\bar{\eta},0]$, have a finite $\lim_{\theta\to 0^-}\phi(\theta)$, and have square integrable first-order derivatives is denoted by $\Gamma$ with the norm

$$\|\phi\|_\Gamma = \max_{\theta\in[-\bar{\eta},0]}|\phi(\theta)| + [\int_{-\bar{\eta}}^{0}|\dot{\phi}(s)|^2\, ds]^{1/2}$$

Denote $x_t(\theta)=x(t+\theta)$ where $\theta\in[-\bar{\eta},0]$.

## II. Problem Formulation

Packet-based networked system is plotted in Figure 1. Assume that: 1) the sensor is clock-driven while the controller and the zero-order hold (ZOH) are event-driven, and all of them are connected through network; 2) Feedback and control data packets are transmitted in one packet, and there exist time-varying transmission delays and packet losses in the channels from the sensor to the controller and from the controller to the ZOH; 3) The ZOH suffers from input missing; 4) The controller and the ZOH can determine if a data packet is new, only new data packets are accepted, and $u(t)=0$ before the first updating instant.

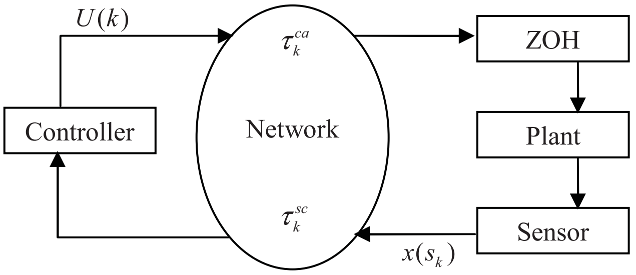

Figure 1. Block diagram of pakcet-based networked systems

Let $t_0$ denotes the initial instant of NCS, $k\in\mathbb{N}$ the number of new data packet arriving at the ZOH, $t_k$ the corresponding arriving instant, $s_k$ the associated sensor's sampling instant, and $\tau_k^{sc}$ and $\tau_k^{ca}$ are the transmission delays from the sensor to the controller and from the controller to the ZOH, respectively. It is seen that $t_k - s_k = \tau_k^{sc}+\tau_k^{ca}$. In the packet-based NCS, when the controller receives a new state feedback $x(s_k)$, it computes a sequence $U(k)$ of controls associated with different input delays, and then sends the sequence in one data packet to the ZOH. The ZOH selects different controls from the received new data packet according to the real input delays of the closed-loop systems, and then performs them.

For $t\in[t_k,t_{k+1})$, let $\tau(t)=t-s_k$ denotes the time-varying input delays induced by transmission delays and packet losses. It is assumed that there exist scalars $\bar{\tau}>0$ and $\underline{\tau}\geq 0$ such that

$$\underline{\tau}\leq\tau(t)<\bar{\tau}\ ,\ t\in[t_k,t_{k+1}) \tag{1}$$

To implement the packet-based framework, the distributed interval $[\underline{\tau},\bar{\tau})$ of input delays interval is divided as

$$[\underline{\tau},\bar{\tau})=\sum\nolimits_{i=1}^{m}[\bar{\tau}_{i-1},\bar{\tau}_i) \tag{2}$$

where $\bar{\tau}_0=\underline{\tau}$ and $\bar{\tau}_m=\bar{\tau}$, and the controller adopts different feedback gains for $\tau(t)$ in different subintervals $[\bar{\tau}_{i-1},\bar{\tau}_i)$, i.e. $\tau(t)\in[\bar{\tau}_{i-1},\bar{\tau}_i)$. Let $\tau_i(t)$ denote the input delays $\tau(t)\in[\bar{\tau}_{i-1},\bar{\tau}_i)$. It is seen that $\tau(t)\in[\underline{\tau},\bar{\tau})$ are now represented as $m$ discrete variables $\tau_i(t)\in[\bar{\tau}_{i-1},\bar{\tau}_i)$.

The plant considered in this paper is of the form

$$\dot{x}(t)=Ax(t)+Bu(t) \tag{3}$$

where $x(t)\in\mathbb{R}^{n_x}$ and $u(t)\in\mathbb{R}^{n_u}$ are state vector and control input vector, respectively, and $A$ and $B$ are constant matrices with appropriate dimensions. In packet-based NCS with input missing, the input is represented as

$$u(t)=\alpha(t)\sum\nolimits_{i=1}^{m}\beta_i(t)u_i(k)\ ,\ t\in[t_k,t_{k+1}) \tag{4}$$

where $u_i(k)$ is a control signal of the sequence $U(k)=[u_1(k), u_2(k),\cdots,u_m(k)]$ and is given as

$$u_i(k)=K_i x(s_k) \tag{5}$$

where $x(s_k)$ is the state feedback, and $K_i$ is the feedback gain associated with $\tau_i(t)$. The random variable $\beta_i(t)$ is defined as follows

$$\beta_i(t)=\begin{cases}1 & \tau(t)\in[\bar{\tau}_{i-1},\bar{\tau}_i)\\ 0 & \tau(t)\notin[\bar{\tau}_{i-1},\bar{\tau}_i)\end{cases} \tag{6a}$$

with the probability $\bar{\beta}_i$ given as

$$\bar{\beta}_i=\Pr\{\tau(t)\in[\bar{\tau}_{i-1},\bar{\tau}_i)\}=\mathbb{E}\{\beta_i(t)\}=\lim_{t\to\infty}\frac{1}{t}\int_{t_1}^{t}\beta_i(s)ds \tag{6b}$$

It is seen that $\{\beta(t)\}$ is actually a continuous multivariate i.i.d. process with respect to $t$, where $\beta(t)=col\{\beta_1(t),\beta_2(t),\cdots,\beta_m(t)\}$. The random variable $\alpha(t)\in\{1,0\}$ denotes if the input missing occurs, where 1 and 0 correspond to the situations with and without input missing, respectively, and the related probability is computed as

$$\bar{\alpha}=\Pr\{\alpha(t)=1\}=\mathbb{E}\{\alpha(t)\}=\lim_{t\to\infty}\frac{1}{t}\int_{t_1}^{t}\alpha(s)ds \tag{7}$$

So $\{\alpha(t)\}$ is a continuous Bernoulli process with respect to $t$. Then the closed-loop packet-based NCS in (3)-(5) is formulated as

$$\dot{x}(t) = Ax(t) + B\alpha(t)\sum\nolimits_{i=1}^{m}\beta_i(t)K_i x(t-\tau_i(t)) \tag{8}$$

It is seen that (8) is essentially a switching system.

The purpose of this paper is to develop the fast-switching conditions of the mean-square exponential stability for the packet-based NCS with time-varying transmission delays, packet losses and input missing basing on (6)-(8). Before giving our main results, we introduce the following definitions.

*Definition 1:* The closed-loop system (3)-(5) is said to be mean square exponentially stable if for any finite initial condition $x_{t_1}$, there exist scalars $\varepsilon > 0$ and $\lambda > 0$ such that

$$\mathrm{E}\{\| x(t) \|^2\} \le \varepsilon e^{-\lambda(t-t_1)} \| x_{t_1} \|_{\Gamma}^2$$

*Definition 2:* The infinitesimal operator is defined as

$$\mathcal{L}V(t,x_t,\dot{x}_t) = \lim_{\vartheta\to 0^+}\frac{1}{\vartheta}\mathrm{E}\{V(t+\vartheta, x_{t+\vartheta}, \dot{x}_{t+\vartheta}) - V(t,x_t,\dot{x}_t)\}$$

where $\mathrm{X}_t = \{x_t\}$.

## III. Main Results

To derive the fast-switching conditions of the mean-square exponential stability of (3)-(5), we construct the following Lyapunov-Krasovskii functional via delay-decomposition approach:

$$V(t,x_t,\dot{x}_t) = V_1(t,x_t) + V_2(t,x_t) + V_3(t,\dot{x}_t) \tag{9a}$$

$$V_1(t,x_t,\dot{x}_t) = x^T(t)Px(t) \tag{9b}$$

$$\begin{aligned} V_2(t,x_t,\dot{x}_t) = {} & \sum_{i=1}^{m_0}\int_{t-\underline{\tau}_i}^{t-\underline{\tau}_{i-1}} e^{\lambda(s-t)}x^T(s)Q_{0,i}x(s)ds \\ & + \sum_{i=1}^{m}\int_{t-\overline{\tau}_i}^{t-\overline{\tau}_{i-1}} e^{\lambda(s-t)}x^T(s)Q_{2,i}x(s)ds \end{aligned} \tag{9c}$$

$$\begin{aligned} V_3(t,\dot{x}_t,\dot{x}_t) = {} & \sum_{i=1}^{m_0}(\underline{\tau}_i - \underline{\tau}_{i-1})\int_{-\underline{\tau}_i}^{-\underline{\tau}_{i-1}}\int_{t+\theta}^{t} e^{\lambda(s-t)}\dot{x}^T(s)R_0\dot{x}(s)dsd\theta \\ & + \sum_{i=1}^{m}(\overline{\tau}_i - \overline{\tau}_{i-1})\int_{-\overline{\tau}_i}^{-\overline{\tau}_{i-1}}\int_{t+\theta}^{t} e^{\lambda(s-t)}\dot{x}^T(s)R_{2,i}\dot{x}(s)dsd\theta \end{aligned} \tag{9d}$$
