where $[0,\underline{\tau}) = \bigcup\nolimits_{i=1}^{m_0}[\underline{\tau}_{i-1},\underline{\tau}_i)$, $P > 0$, $Q_{0,i} > 0$ ($i = 1,\ 2,\cdots,m_0$), $R_0 > 0$, $Q_{2,i} > 0$, $R_{2,i} > 0$ ($i = 1,2,\cdots,m$). It is seen from (9) that (8) is not simply deemed as a system with multiple delays $\tau_i(t)$ ($i = 1,2,\cdots,m$) and $\tau_i(t)$ are still taken as a case of $\tau(t)$ belong to $[\overline{\tau}_{i-1},\overline{\tau}_i)$, which is more accurate than the method in [11].

*Theorem 1:* Given (1), (2), (6), (7), $[0,\underline{\tau}) = \bigcup\nolimits_{i=1}^{m_0}[\underline{\tau}_{i-1},\underline{\tau}_i)$, $\rho_i = \overline{\beta}_i \big/ \sum\nolimits_{j=i}^{m}\overline{\beta}_j$ for $\overline{\beta}_i \ne 0$ and $\rho_i = 0$ for $\overline{\beta}_i = 0$ and $K_i$ ($i = 1,2,\cdots,m$), the closed-loop system (3)-(5) is mean-square exponentially stable with a decay rate $\lambda$, if there exist matrices $P > 0$, $Q_{0,i} > 0$ ($i = 1,2,\cdots,m_0$), $Q_{2,i} > 0$, $R_0 > 0$, $R_{2,i} > 0$ ($i = 1,2,\cdots,m$) of appropriate dimensions such that the following inequalities hold:

$$\Omega_1 + \Omega_2 + \Omega_3 + \Omega_4 + \Pi\Lambda_2\Pi^{\mathrm{T}} < 0 \tag{10}$$

for $\sigma_i = 0$ and 1 with $i = 1,2,\cdots,m$, where

$$\Omega_1 = \begin{bmatrix} PA + A^TP + \lambda P & 0_{n_x\times m_0 n_x} & \Omega_{11} \\ * & & \\ * & & 0_{(m_0+2m)n_x\times(m_0+2m)n_x} \end{bmatrix}$$

$$\Omega_{11} = \overline{\alpha}PB\begin{bmatrix} \overline{\beta}_1K_1 & 0 & \overline{\beta}_2K_2 & 0 & \cdots & \overline{\beta}_mK_m & 0 \end{bmatrix}$$

$$\begin{aligned} \Omega_2 = diag\{ & Q_{0,1}, -e^{-\lambda\underline{\tau}_1}Q_{0,1} + e^{-\lambda\underline{\tau}_1}Q_{0,2},\cdots, \\ & -e^{-\lambda\underline{\tau}_{m_0-1}}Q_{0,m_0-1} + e^{-\lambda\underline{\tau}_{m_0-1}}Q_{0,m_0}, \\ & -e^{-\lambda\underline{\tau}_{m_0}}Q_{0,m_0} + e^{-\lambda\overline{\tau}_0}Q_{2,1}, 0, -e^{-\lambda\overline{\tau}_1}Q_{2,1} + e^{-\lambda\overline{\tau}_1}Q_{2,2},\cdots, \\ & 0, -e^{-\lambda\overline{\tau}_{m-1}}Q_{2,m-1} + e^{-\lambda\overline{\tau}_{m-1}}Q_{2,m}, 0, -e^{-\lambda\overline{\tau}_m}Q_{2,m}\} \end{aligned}$$

$$\Lambda_2 = diag\{\Lambda_1 \quad \Lambda_1 \quad \cdots \quad \Lambda_1\}$$

$$\Lambda_1 = \sum_{i=1}^{m_0}(\underline{\tau}_i - \underline{\tau}_{i-1})^2 R_0 + \sum_{i=1}^{m}(\overline{\tau}_i - \overline{\tau}_{i-1})^2 R_{2,i}$$

$$\Omega_4 = \begin{bmatrix} (1-\overline{\alpha})A^T\Lambda_1 A & 0_{n_x\times(m_0+2m)n_x} \\ * & 0_{(m_0+2m)n_x\times(m_0+2m)n_x} \end{bmatrix}.$$

*Proof:* Along the trajectories of the closed-loop system (8), it follows from (9) that

$$\mathcal{L}V(t,x_t,\dot{x}_t) = \mathcal{L}V_1(t,x_t) + \mathcal{L}V_2(t,x_t) + \mathcal{L}V_3(t,\dot{x}_t) \qquad (11)$$

where

$$\begin{aligned}\mathcal{L}V_1(t,x_t) &= -\lambda V_1(t,x_t) + x^T(t)\lambda Px(t) \\ &\quad +2x^T(t)P\{Ax(t) + \overline{\alpha}\sum_{i=1}^{m}\overline{\beta}_i(k)BK_i x(t-\tau_i(t))\}\end{aligned}$$

$$\begin{aligned}\mathcal{L}V_2(t,x_t) &= -\lambda V_2(t,x_t) + \mathbb{E}\{\sum_{i=1}^{m_0} x^T(t-\underline{\tau}_{i-1})e^{-\lambda\underline{\tau}_{i-1}}Q_{0,i}x(t-\underline{\tau}_{i-1}) \\ &\quad -x^T(t-\underline{\tau}_i)e^{-\lambda\underline{\tau}_i}Q_{0,i}x(t-\underline{\tau}_i)\big|\mathrm{X}_t\} \\ &\quad +\mathbb{E}\{\sum_{i=1}^{m} x^T(t-\overline{\tau}_{i-1})e^{-\lambda\overline{\eta}_{i-1}}Q_{2,i}x(t-\overline{\tau}_{i-1}) \\ &\quad -x^T(t-\overline{\tau}_i)e^{-\lambda\overline{\eta}_i}Q_{2,i}x(t-\overline{\tau}_i)\big|\mathrm{X}_t\}\end{aligned}$$

$$\begin{aligned}\mathcal{L}V_3(t,\dot{x}_t) &= -\lambda V_3(t,\dot{x}_t) + \mathbb{E}\{\dot{x}^T(t)\Lambda_1\dot{x}(t)\big|\mathrm{X}_t\} \\ &\quad +\mathbb{E}\{\sum_{i=1}^{m_0} -(\underline{\tau}_i - \underline{\tau}_{i-1})\int_{t-\underline{\tau}_i}^{t-\underline{\tau}_{i-1}} \dot{x}^T(s)e^{\lambda(s-t)}R_0\dot{x}(s)ds\big|\mathrm{X}_t\} \\ &\quad +\mathbb{E}\{\sum_{i=1}^{m} -(\overline{\tau}_i - \overline{\tau}_{i-1})\int_{t-\overline{\eta}_i}^{t-\overline{\eta}_{i-1}} \dot{x}^T(s)e^{\lambda(s-t)}R_{2,i}\dot{x}(s)ds\big|\mathrm{X}_t\}.\end{aligned}$$

With the closed-loop system in (8), it follows that

$$\begin{aligned}&\mathbb{E}\left\{\dot{x}^T(t)\Lambda_1\dot{x}(t)\big|\mathrm{X}_t\right\} \\ &= (1-\overline{\alpha})x^T(t)A^T\Lambda_1 Ax(t) \\ &+\sum_{i=1}^{m}\overline{\alpha}\overline{\beta}_i\left\{x^T(t)A^T\Lambda_1 Ax(t) + 2x^T(t)A^T\Lambda_1 BK_i x(t-\tau_i(t))\right. \qquad (12) \\ &\left.+x^T(t-\tau_i(t))K_i^T B^T\Lambda_1 BK_i x(t-\tau_i(t))\right\} \\ &= \xi^T(t)\Omega_4\xi(t) + \xi^T(t)\Pi\Lambda_2\Pi^{\mathrm{T}}\xi(t)\end{aligned}$$

where

$$\begin{aligned}\xi(t) = col\{&x(t), x(t-\underline{\tau}_1), \cdots, x(t-\underline{\tau}_{m_0}), \\ &x(t-\tau_1(t)), x(t-\overline{\tau}_1), \cdots, x(t-\tau_m(t)), x(t-\overline{\tau}_m)\}.\end{aligned}$$

By Jensen's inequality, it follows that for $i = 1,2,\cdots,m_0$

$$\begin{aligned}&\mathbb{E}\{-(\underline{\tau}_i - \underline{\tau}_{i-1})\int_{t-\underline{\tau}_i}^{t-\underline{\tau}_{i-1}} e^{\lambda(s-t)}\dot{x}^T(s)R_0\dot{x}(s)ds\big|\mathrm{X}_t\} \\ &\le e^{-\lambda\underline{\tau}_i}\begin{bmatrix} x(t-\underline{\tau}_{i-1}) \\ x(t-\underline{\tau}_i)\end{bmatrix}^T \begin{bmatrix} -R_0 & R_0 \\ R_0 & -R_0\end{bmatrix}\begin{bmatrix} x(t-\underline{\tau}_{i-1}) \\ x(t-\underline{\tau}_i)\end{bmatrix}.\end{aligned} \qquad (13)$$

In this paper the bounding of the other integrals associated with $R_{2,i}$ in (11) takes the distribution of $\tau(t)$ into account. For this purpose, the following decomposition is made:

$$\begin{aligned}&\mathbb{E}\{-(\overline{\tau}_i - \overline{\tau}_{i-1})\int_{t-\overline{\tau}_i}^{t-\overline{\tau}_{i-1}} \dot{x}^T(s)e^{\lambda(s-t)}R_{2,i}\dot{x}(s)ds\big|\mathrm{X}_t\} \\ &= \rho_i(k)\mathbb{E}\{-(\overline{\tau}_i - \overline{\tau}_{i-1})\int_{t-\overline{\tau}_i}^{t-\overline{\tau}_{i-1}} \dot{x}^T(s)e^{\lambda(s-t)}R_{2,i}\dot{x}(s)ds\big|\mathrm{X}_t\} \\ &+(1-\rho_i(k))\mathbb{E}\{-(\overline{\tau}_i - \overline{\tau}_{i-1})\int_{t-\overline{\tau}_i}^{t-\overline{\tau}_{i-1}} \dot{x}^T(s)e^{\lambda(s-t)}R_{2,i}\dot{x}(s)ds\big|\mathrm{X}_t\}\end{aligned} \qquad (14)$$

for $i = 1,2,\cdots,m$. In (14), the first decomposing term is related to the input delays $\tau_i(t)$, and the second one is related to other input delays $\tau_j(t)$ with $j = i+1,\cdots,m$.

As seen in [17], different ways are needed in bounding

$$-\int_{t-\overline{\tau}_i}^{t-\overline{\tau}_{i-1}} \dot{x}^T(s)e^{\lambda(s-t)}R_{2,i}\dot{x}(s)ds$$

with respect to $\tau_i(k,t) \in [\overline{\tau}_{i-1}, \overline{\tau}_i)$ and $\tau_i(k,t) \notin [\overline{\tau}_{i-1}, \overline{\tau}_i)$, respectively. Based on this idea, it follows from Jensen's inequality and the technique similar to that of [17] that

$$\begin{aligned}&\rho_i(k)\mathbb{E}\{-(\overline{\tau}_i - \overline{\tau}_{i-1})\int_{t-\overline{\tau}_i}^{t-\overline{\tau}_{i-1}} \dot{x}^T(s)e^{\lambda(s-t)}R_{2,i}\dot{x}(s)ds\big|\mathrm{X}_t\} \\ &\le \zeta_i^T(t)e^{-\lambda\overline{\tau}_i}\rho_i(k) \\ &\times\left\{\overline{\beta}_i(k)\begin{bmatrix} -(2-\sigma_i)R_{2,i} & (2-\sigma_i)R_{2,i} & 0 \\ (2-\sigma_i)R_{2,i} & -3R_{2,i} & (1+\sigma_i)R_{2,i} \\ 0 & (1+\sigma_i)R_{2,i} & -(1+\sigma_i)R_{2,i}\end{bmatrix}\right. \\ &\left.+(1-\overline{\beta}_i(k))\begin{bmatrix} -R_{2,i} & 0 & R_{2,i} \\ 0 & 0 & 0 \\ R_{2,i} & 0 & -R_{2,i}\end{bmatrix}\right\}\zeta_i(t) \\ &= \zeta_i^T(t)e^{-\lambda\overline{\tau}_i}\rho_i(k)\begin{bmatrix} \Upsilon_i & (2-\sigma_i)\overline{\beta}_i R_{2,i} & (1-\overline{\beta}_i)R_{2,i} \\ * & -3\overline{\beta}_i R_{2,i} & (1+\sigma_i)\overline{\beta}_i R_{2,i} \\ * & * & -(\sigma_i\overline{\beta}_i+1)R_{2,i}\end{bmatrix}\zeta_i(t)\end{aligned} \qquad (15)$$

and

$$\begin{aligned}&(1-\rho_i(k))\mathbb{E}\{-(\overline{\tau}_i - \overline{\tau}_{i-1})\int_{t-\overline{\tau}_i}^{t-\overline{\tau}_{i-1}} \dot{x}^T(s)e^{\lambda(s-t)}R_{2,i}\dot{x}(s)ds\big|\mathrm{X}_t\} \\ &\le \zeta_i^T(t)e^{-\lambda\overline{\tau}_i}(1-\rho_i(k))\begin{bmatrix} -R_{2,i} & 0 & R_{2,i} \\ 0 & 0 & 0 \\ R_{2,i} & 0 & -R_{2,i}\end{bmatrix}\zeta_i(t).\end{aligned} \qquad (16)$$

where $\zeta_i^T(t) = [x^T(t-\overline{\tau}_{i-1}), x^T(t-\tau_i(t)), x^T(t-\overline{\tau}_i)]$, $\Upsilon_i = -(\overline{\beta}_i -\sigma_i\overline{\beta}_i + 1)R_{2,i}$, $\sigma_i = (\tau_i(t) - \overline{\tau}_{i-1})/(\overline{\tau}_i - \overline{\tau}_{i-1})$. It is seen that (15) further takes the distribution of $\tau_i(t)$ into account. From (15) and (16), we have the following

$$\begin{aligned}&\mathbb{E}\{-(\overline{\tau}_i - \overline{\tau}_{i-1})\int_{t-\overline{\tau}_i}^{t-\overline{\tau}_{i-1}} \dot{x}^T(s)e^{\lambda(s-t)}R_{2,i}\dot{x}(s)ds\big|\mathrm{X}_t\} \\ &= \zeta_i^T(t)e^{-\lambda\overline{\tau}_i} \\ &\times\left\{\overline{\beta}_i\rho_i\begin{bmatrix} -(1-\sigma_i)R_{2,i} & (2-\sigma_i)R_{2,i} & -R_{2,i} \\ (2-\sigma_i)R_{2,i} & -3R_{2,i} & (1+\sigma_{2,i})R_{2,i} \\ -R_{2,i} & (1+\sigma_i)R_{2,i} & -\sigma_i R_{2,i}\end{bmatrix}\right.\end{aligned}$$

$$+\begin{bmatrix} -R_{2,i} & 0 & R_{2,i} \\ 0 & 0 & 0 \\ R_{2,i} & 0 & -R_{2,i} \end{bmatrix}\zeta_i(t)\Bigg\}. \tag{17}$$

If inequality (10) holds with $\sigma_i = 0$ and 1 for $i = 1, 2, \cdots, m$, it follows from (11)-(13), (17) that

$$\begin{aligned} &\mathfrak{L}V(t, x_t, \dot{x}_t) + \lambda V(t, x_t, \dot{x}_t) \le \xi^T(t)(\Omega_1 + \Omega_2 + \Omega_3 \\ &+\Omega_4 + \Pi\Lambda_2\Pi^{\mathrm{T}})\xi(t) < 0 \end{aligned} \tag{18}$$

which means that $\mathbb{E}\{V(t, x_t, \dot{x}_t)\} \le e^{-\lambda(t-t_1)}\mathbb{E}\{V(t_1, x_{t_1}, \dot{x}_{t_1})\}$. So it can be concluded by Definition 1 that the closed-loop system (3)-(5) is mean-square exponentially stable under the given conditions of Theorem 1. The proof of Theorem 1 is completed.

*Theorem 2:* Given (1), (2), (6), (7), $[0, \underline{\tau}) = \bigcup_{i=1}^{m_0}[\underline{\tau}_{i-1}, \underline{\tau}_i)$, $\rho_i = \bar{\beta}_i \big/ \sum_{j=i}^{m}\bar{\beta}_j$ for $\bar{\beta}_i \ne 0$ and $\rho_i = 0$ for $\bar{\beta}_i = 0$ ( $i = 1, 2, \cdots, m$ ), the closed-loop system (3)-(5) is mean-square exponentially stabilizable with a decay rate $\lambda$, if there exist matrices $X > 0$, $\tilde{Q}_{0,i} > 0$ $(i = 1, 2, \cdots, m_0)$, $\tilde{Q}_{2,i} > 0$, $\tilde{R}_0 > 0$, $\tilde{R}_{2,i} > 0$, $Y_i$ $(i = 1, 2, \cdots, m)$ of appropriate dimensions such that the following inequalities hold:

$$\begin{bmatrix} \tilde{\Omega}_1 + \tilde{\Omega}_2 + \tilde{\Omega}_3 & \tilde{\Omega}_4\Phi_1 & \tilde{\Pi}\Phi_2 \\ * & -\tilde{\Lambda}_1 & 0 \\ * & * & -\tilde{\Lambda}_2 \end{bmatrix} < 0 \tag{19}$$

for $\sigma_i = 0$ and 1 with $i = 1, 2, \cdots, m$, where

$$\tilde{\Omega}_1 = \begin{bmatrix} AX + XA^T + \lambda X & 0_{n_x \times m_0 n_x} & \tilde{\Omega}_{11} \\ * & & \\ * & & 0_{(m_0+2m)n_x \times (m_0+2m)n_x} \end{bmatrix}$$

$$\tilde{\Omega}_{11} = \bar{\alpha}B\begin{bmatrix} \bar{\beta}_1 Y_1 & 0 & \bar{\beta}_2 Y_2 & 0 & \cdots & \bar{\beta}_m Y_m & 0 \end{bmatrix}$$

$$\begin{aligned} \tilde{\Omega}_2 = diag\{&\tilde{Q}_{0,1}, -e^{-\lambda\underline{\tau}_1}\tilde{Q}_{0,1} + e^{-\lambda\underline{\tau}_1}\tilde{Q}_{0,2}, \cdots, \\ &-e^{-\lambda\underline{\tau}_{m_0-1}}\tilde{Q}_{0,m_0-1} + e^{-\lambda\underline{\tau}_{m_0-1}}\tilde{Q}_{0,m_0}, \\ &-e^{-\lambda\underline{\tau}_{m_0}}\tilde{Q}_{0,m_0} + e^{-\lambda\bar{\tau}_0}\tilde{Q}_{2,1}, 0, -e^{-\lambda\bar{\tau}_1}\tilde{Q}_{2,1} + e^{-\lambda\bar{\tau}_1}\tilde{Q}_{2,2}, \cdots, \\ &0, -e^{-\lambda\bar{\tau}_{m-1}}\tilde{Q}_{2,m-1} + e^{-\lambda\bar{\tau}_{m-1}}\tilde{Q}_{2,m}, 0, -e^{-\lambda\bar{\tau}_m}\tilde{Q}_{2,m}\} \end{aligned}$$

$$\tilde{\Lambda}_1 = diag\{X\tilde{R}_0^{-1}X, X\tilde{R}_{2,1}^{-1}X, \cdots, X\tilde{R}_{2,m}^{-1}X\}$$

$$\Phi_2 = diag\{\underbrace{\Phi_1, \Phi_1, \cdots, \Phi_1}_{m}\}$$

$$\Phi_1 = diag\{\sqrt{\textstyle\sum_{i=1}^{m_0}(\underline{\tau}_i - \underline{\tau}_{i-1})^2}, \bar{\tau}_1 - \bar{\tau}_0, \cdots, \bar{\tau}_m - \bar{\tau}_{m-1}\}$$

$$\tilde{\Pi} = [\tilde{\Pi}_1, \tilde{\Pi}_2, \cdots, \tilde{\Pi}_m]$$

$$\tilde{\Pi}_i = \begin{bmatrix} \underbrace{\begin{matrix} \sqrt{\bar{\alpha}\bar{\beta}_i}XA^T & & \sqrt{\bar{\alpha}\bar{\beta}_i}XA^T \\ 0_{(m_0+2i-2))n_x \times n_x} & \cdots & 0_{(m_0+2i-2))n_x \times n_x} \\ \sqrt{\bar{\alpha}\bar{\beta}_i}Y_i^T B^T & & \sqrt{\bar{\alpha}\bar{\beta}_i}Y_i^T B^T \\ 0_{(2m-2i+1)n_x \times n_x} & & 0_{(2m-2i+1)n_x \times n_x} \end{matrix}}_{1+m} \end{bmatrix}.$$

Furthermore, the controller gains are given by $K_i = Y_i X^{-1}$.

*Proof:* Applying the well known Schur Lemma and congruence transformation to (10) yields Theorem 2.

Inequality (19) is nonlinear for the existing of $X\tilde{R}_{2,i}^{-1}X$, $i = 1, 2, \cdots, m$, and can not be directly solved by LMI toolbox. The feasible problem of nonlinear inequality in Theorem 2 can be transformed by CCL algorithm into a nonlinear convex optimization problem subject to LMI constraints, which can be directly solved by LMI toolbox.

## IV. NUMERICAL EXAMPLE

Consider the linear system in [12] with

$$A = \begin{bmatrix} -1 & 0 & -0.5 \\ 1 & -0.5 & 0 \\ 0 & 0 & 0.5 \end{bmatrix}, \quad B = \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix}.$$

Let $m_0 = 1$, $m = 6$, $\underline{\tau} = 0$, $\bar{\tau}_i - \bar{\tau}_{i-1} = (\bar{\tau} - \underline{\tau})/m$, $\bar{\beta}_i = 1/m$ with $i = 1, 2, \cdots, m$. It is obtained by Theorem 2 that:

*Case 1:* Given $\bar{\alpha} = 1$, $\lambda = 0$, the maximum value of $\bar{\tau}$ is 2.64 with the following feedback gains

$$K_1 = [-0.0015, 0.0002, -0.5285]$$
$$K_2 = [-0.0005, -0.0001, -0.5309]$$
$$K_3 = [-0.0002, -0.0002, -0.5287]$$
$$K_4 = [0.0000, -0.0003, -0.5235]$$
$$K_5 = [0.0002, -0.0003, -0.5172]$$
$$K_6 = [0.0008, -0.0005, -0.5132].$$

*Case 2:* Given $\overline{\alpha} = 0.8$, $\lambda = 0$, the maximum value of $\overline{\tau}$ is $1.70$ with the following feedback gains

$$K_1 = [-0.0045, -0.0031, -0.9652]$$
$$K_2 = [0.0068, -0.0068, -0.9844]$$
$$K_3 = [0.0103, -0.0078, -0.9693]$$
$$K_4 = [0.0122, -0.0082, -0.9269]$$
$$K_5 = [0.0140, -0.0085, -0.8719]$$
$$K_6 = [0.0167, -0.0092, -0.8386].$$

*Case 3:* Given $\overline{\alpha} = 0.8$, $\overline{\tau} = 1.0$, the maximum value of $\lambda$ is $0.44$ with the following feedback gains

$$K_1 = [0.0033, -0.0021, -1.4844]$$
$$K_2 = [0.0095, -0.0024, -1.5318]$$
$$K_3 = [0.0111, -0.0024, -1.5150]$$
$$K_4 = [0.0116, -0.0023, -1.4373]$$
$$K_5 = [0.0117, -0.0022, -1.3199]$$
$$K_6 = [0.0126, -0.0021, -1.2355].$$

## V. CONCLUSION

This paper gives the fast-switching conditions for packet-based NCSs with time-varying transmission delays, packet losses and input missing, which are independent on average dwell time of subsystems. With a multivariate i.i.d. model of input delays and a Bernoulli model of input missing, the NCS is formulated as a switching system with multiple subsystems of different input delays. Appropriate Lyapunov-Krasovskii functional is constructed by a delay decomposition approach. By using the bounding techniques based on Jensen's inequality as in [17], the distribution of input delays is taken into account when bounding the integral terms of the infinitesimal of the functional. The resulting controller design method can be solved by CCL algorithm. Numerical example shows the effectiveness of our results.

*Abstract***— Different tools are used to aid the investigation process. The need of specialized software is required for the acquisition and examination of data gathered from the crime scene. To abide by chain of custody proper crime scene reconstruction or image is acquired from the original source that can be admissible to the court. This paper focuses on the various hardware and software tools that are widely used during a Computer Forensics Investigation.**

***Keywords-component; Computer; Forensics; Investigation; Hardware; Software; Crime; Tool;***

## I. INTRODUCTION

A computer crime is defined as a criminal act in which people commit the offence using the digital knowledge stored in the computer system. To investigate the computer based crime a new field of specialization - forensic computing has been developed, which is the process of computer investigation and analysis technique to gather evidence in a manner that is legally acceptable [1].

Computers and internet continue to spread and occupy our lives by increasing the potential of harm caused by it through increased number of computer crimes. To deal with this rise, new and advance methods of investigations are required. Electronic evidence in the form of data or information of investigative importance is stored or transmitted digitally by means of electronic devices. Electronic evidence by its nature is very fragile. It can be damaged, destroyed or altered by improper handling and examination. For this reason, special precautions or set of rules have to be followed in acquiring, analyzing and reporting this type of evidence, failure to do so may result an inaccurate conclusion. Electronic evidence poses special challenges regarding its admissibility in court [2].

An important tool used by investigators to safeguard evidence, is called chain of custody. Essentially, this means accounting for those who has touched a given piece of evidence, when they touch it and what they did to evidence. It's a way of demonstrating that evidence hasn't been damaged or tampered with while in the care of the investigator. In the book, Criminalistics: An Introduction to Forensic Science, Richard Saferstein notes in 7th Edition (July 31, 2000), "Failure to substantiate the evidence's chain of custody may lead to serious questions regarding the authenticity and integrity of the evidence and the examinations rendered upon it (pg. 48)." As one would imagine, changes to the chain of custody can quickly ruin a case [3].

The paper is organized as follows: Section II describes the scenerio on which the investigation focuses. Section III describes the Hardware tools used in the investigation. Section IV describes the Software tools used in the investigation. Section V concludes the paper.

## II. SCENERIO

The use of computer forensics may be able to show a pattern of activity that will aid in a lawsuit. Through the use of e-mails, deleted data, and other items found during an investigation, the computer forensics specialist can piece together a history of the prior employee's computer usage and this type of information is very useful in a court.

For example, in an Advertising company they have recently hired a new salesman. Six months after his hire, he leaves the company and forms a competing interest, sending letters or client contacts to another competitive company. The organisation might think this a bit odd and contact an attorney to consider filing a suit. What has occurred is a virtual theft; the salesman stole a copy of your client database. Note that this is a VIRTUAL theft, since you were not deprived of any property (he didn't delete it, just copied it) you will likely not be able to prosecute him criminally.

In order to prove him guilty under law the use of Computer Forensics could be put to practise. The Computer Forensics Tools are of two kinds Hardware tools and Software tools. Data recovery is as much art as it is science. Using industry standard tools, computer data once thought to be lost is restored either in full or at least in part.

When a file is deleted, the space it occupied on the hard drive is not initially overwritten. Additionally, there are snippets of data, previous versions of documents, and other content that may be scattered throughout the hard drive. Computer Forensics experts can recover the lost

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

data. Sometimes this is a simple undelete whereas other times it takes a considerable amount of effort to piece the file back together. In addition to recovering deleted files, we can also break password protected files (such as a Word document for example) and in some cases encrypted files [4].

In order to carry out these procedures of retrieval of data a Computer Forensics expert would use various Hardware and Software Tools, which would be discussed in next section.

## III. HARDWARE TOOLS

A Computer Forensics expert should be aware and familiar with the inside of a computer system. One should know the inside and outside of the system before they could work on the tools to retrieve data. They should have a good knowledge of the hard drives and their settings. There are many hardware tools that could be used by a Forensics expert, this section would be addressing and discussing about FRED in this chapter. FRED is the most common hardware device used by most investigators. FRED stands for Forensic Recovery of Evidence Device. The FRED families of forensic workstations are highly integrated, flexible and modular forensic platforms and now include DI's exclusive ***UltraBay Write Protected Imaging Bay***. There are a lot of versions of FRED like FRED SR, FRED L, etc... [5]

### A. *FRED System*

FRED systems are optimized for stationary laboratory acquisition and analysis. Simply remove the hard drive(s) from the suspect system and plug them into FRED and acquire the digital evidence. FRED will acquire data directly from IDE/EIDE/ ATA/SATA/ATAPI/SCSI I/SCSI II/SCSI III hard drives and storage devices and save forensic images to DVD, CD or hard drives. FRED systems also acquire data from floppies, 100/250/750 MB ZIP cartridges, CD-ROM, DVD-ROM, Compact Flash, Micro Drives, Smart Media, Memory Stick, Memory Stick Pro, xD Cards, Secure Digital Media and Multimedia Cards. Furthermore, with the optional tape drive FRED is capable of archiving to or acquiring evidence from 4mm DAT tapes. With the RAID option FRED has an incredible 1.6 TB (1600 GB) of internal RAID storage. All FRED systems include the UltraBay, custom front panel connections, and removable drive trays so there is no need to open up the processing system to install drives or crawl around the back of the unit to attach devices. Fig 1 illustrates a FRED system; its estimate cost would be $5999.00 [5].

Figure 1. FRED System [5]

#### 1) *The UltraBay II*

The UltraBay II can be used to acquire a forensically sound image of IDE, SATA, SCSI, USB and Firewire using your choice of Forensic Imaging software. Furthermore, drives may be connected/ removed from the UltraBay II without having to shut down the workstation or leaving the GUI. The UltraBay II is exclusively available with Digital Intelligence FRED systems and is not available separately or from any other source. Fig 2 illustrates an UltraBay [5].

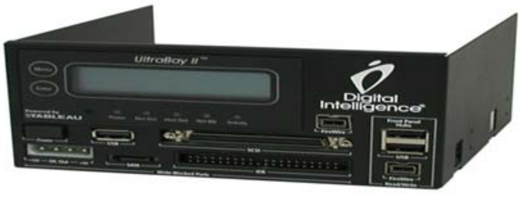

Figure 2. UltraBay II

FRED systems come with two high capacity hard drives. One of these drives is used for your forensic acquisition and processing tools and the other drive as a work drive for restoring and processing digital evidence. With multiple boot menu options FRED can be booted into data acquisition mode and PDBlock loaded automatically, write protecting the suspect hard drive.

Another boot option can be configured to place the FRED in data analysis mode with full access to your forensic analysis tools. FRED systems even come with Linux 9.1 Professional pre-configured! Both hard drives are supplied in removable trays with front panel switches for master/slave configuration [5].

FRED systems have inbuilt network functionality. All FRED systems can be connected directly to a network (10/100/1000 Mb Ethernet) for use as a standard workstation or file server when not processing or acquiring data.

The FRED Systems are usually stationary system used in the Forensics labs. There are other portable devices like the FRED – L, Ultrakit etc. FRED –L is the first laptop member of the FRED family. It as got a price tag of $4999. Though the specifications are less compared to the FRED system usually, FRED-L comes complete with an UltraKit for the ultimate mobile field forensic acquisition kit [5].

#### 2) *FRED – L*

The FRED-L forensic laptop and the included UltraKit work together to quickly, efficiently, and securely image IDE, SATA, and SCSI hard drives in a forensically sound manner. FRED-L is built on the very latest and fastest Intel Core i7-2720QM (2.2GHz, 6MB L3 Cache) Processor with up to 8 GB RAM, built-in FireWire 1394a, USB 2.0, Wireless 802.11 a/b/g/n, and Gigabit (10/100/1000 Mb/s) Ethernet support. This support is provided completely via integrated laptop components and is in no way reliant on add-on or auxiliary cards or devices.

The FRED-L has inbuilt network functionality like FRED systems. FRED-L also has the ability to connect directly to a

10Mb, 100Mb, or even Gigabit Ethernet networks for use as a standard laptop when not processing or acquiring data. FRED-L also includes integrated 802.11b/g wireless capabilities. With the addition of Network Analysis software (Packet Analyzer), FRED-L can also be used to monitor network traffic and communications at the crime scene [5]. Fig 3 illustrates the FRED-L System.

Figure 3. FRED - L

### 3) *Ultrakit III*

The UltraKit is portable kit which contains a complete family of hardware write blockers for use in acquiring a forensically sound image of virtually any hard drive you may encounter (eSATA IDE / SATA, UltraBlock SCSI, UltraBlock USB and an UltraBlock Forensic Card Reader). The UltraKit contains all the write blockers, cables, adapters, and power supplies necessary for use in acquiring images in the field using a standard laptop with FireWire or USB support. Fig 4 illustrates the Ultrakit which comes along with the FRED-L system. An Ultrakit would cost approximately $1369.

Figure 4. Ultrakit

The UltraKit consists of a Write Protected UltraBlock-IDE, UltraBlock-SATA, UltraBlock-SCSI, and a Write Enabled UltraBlock-IDE. FRED-L is designed for use "On Location" at electronic crime scenes. Remove the hard drive(s) from the suspect system and attach them to the appropriate write blocker in the UltraKit. You can then use the FRED-L system to quickly and efficiently create your image file(s) on the acquisition drive attached to the Read/Write UltraBlock. Using the Read/Write UltraBlock device allows you to utilize faster, larger, less costly desktop drives to receive your forensic images. No more worrying about the problems encountered trying to configure parallel devices on suspect equipment in order to use external backup devices. No worries about installing a SCSI adapter into a suspect’s computer [5].

With multiple boot menu options, FRED-L is not limited to use as a Forensic Imaging tool. FRED-L can be booted into DOS 6.22, Windows 98 (Standalone DOS), or Windows XP and Windows 7 and will support any forensic tools which run within those environments. FRED-L also comes complete with a fully configured installation of Suse Linux 9.1 Professional. Capable of configuration with the fastest Intel Centrino Pentium-M mobile processors (2 GHz and beyond), and with an impressive memory capacity (up to 2 GB), FRED-L is also a very formidable processing platform.

There are many more hardware devices that are used for investigation purposes like UltraBlock Forensics card reader, Image MASSter Solo, FastBloc, Acard, etc... , Each Hardware device as its own functionalities and depending on the investigation scenario the hardware’s is used. Hardware required for computer forensics include workstations and blockers such as write blockers needed to prevent contamination of evidence [6].

## IV. SOFTWARE TOOLS

The Software Tools used in Computer Forensics is usually based on the type of investigation that is carried out. If it is a data recovery investigation then Data Recovery Tools are used, each software tools as its own purpose and its own results. Computer forensics software tools would be characterised into Data Recovery Tools, Partition Tools, Disk Clone Tools, Recovery Tools, Testing Tools, RAM Test utility, System Speed Test, Hard Disk Tools, System Information Tools, Dos Tools and Other Tools. Each Tool as a variety of software’s below is few examples of and some description on them. The tools are listed below according to the category of the job.

### A. *Stealth™ Suite*

The Stealth™ Suite is used to assess activity on a computer hard disk drive without the user needing a forensic background. This set of tools helps identify whether or not a targeted computer system was used to access inappropriate information [7] [8].

### B. *Computer Incident Response Suite*

These suites of tools are often used in corporate and government investigations and security risk reviews. This suite is optimized for the lowest cost forensic platform for DOS and Windows processing, DOS. Many of the tools also have version that can be run on a Windows OS. This should be one of your first forensic toolsets. It also makes an excellent set of tools to cross-validate your findings before you go before the court or the board [7] [8].

### C. *Data Elimination Suite™*

This Suite allows you to remove information from a drive and cross-validate that the information has been removed.

This is our most popular suite of software tools for the high assurance government or corporate environment. This suite of tools has been tested and certified by the US Department of

Defence. It eliminates classified data 'leakage' and verifies that the data was properly eliminated [7] [8].

### D. *TextSearch Suite*

TextSearch NT and TextSearch Plus have both been upgraded. TextSearch NT is used to process Windows NT/2000/XP-based computer systems from a DOS command line. The upgraded program provides the same popular interface and features as TextSearch Plus but it identifies many compressed and graphics files using the file header signature, giving the investigator a listing of files that could store information in a compressed or graphic format.

Also included in this suite is HexSearch. This tool provides a similar interface as TextSearch Plus while allowing the user to search for hexadecimal strings, such as file headers, non-printing characters, and more [7] [8].

### E. *NTI Secure ToolKit*

This software is used to secure sensitive files stored on portable and desktop computers. Because it uses NIST tested and approved AES 256 encryption, it qualifies for government use with classified 'Secret' level data. This software exceeds commercial security requirements and it is much easier to use than PGP. It includes a management tool so that corporate information is not lost to the corporation. An export license may be required for locations outside the United States [7] [8].

### F. *SafeBack 3.0*

The industry standard for making evidence grade bit-stream backups of hard drives has gotten even better with version 3.0 [7] [8].

### G. *Guidance Software Encase*

Most of the software’s are packed in suites. EnCase Forensic has become the industry standard tool for uncovering, analyzing and presenting forensic data. Used by investigators in law enforcement, government, small businesses, consulting firms and corporations, EnCase Forensic provides a robust way to authenticate, search and recover computer evidence rapidly and thoroughly.

Computer evidence recovered with EnCase has been admitted into thousands of court proceedings in several countries and jurisdictions, and the EnCase software has been validated by the courts in several published decisions. [CGFI] The following are the advanced features of EnCase:

- Extracts messages from Microsoft PST files.
- Spans multiples Redundant Array of Inexpensive Disk (RAID) volumes.
- Supports NTFS compression and Access Control List (ACL) of files.
- Provides advanced language support.

Several software vendors have recently introduced computing investigation tools that work in Windows. The command line DOS tools you explored in the previous section require a strong understanding of MS-DOS and the various file systems. Because GUI (Graphical User Interface) forensics tools do not require the same level of knowledge, they can simplify computer forensics investigations. These GUI tools have also simplified training for beginning examiners in computer forensics. However DOS forensics should also be known because there are rare cases when the GUI tool would miss out critical evidence and this could be got using a DOS tool [7][8][9].

## V. Conclusion

This paper focuses on the most essential and widely used Hardware tools, there are many more tools used but the main focus was on mainly the ones that are quite common. Also, discussed on the Software tools used but not in depth, as the paper focuses on mainly the ones that are quite common in a Computer Forensics Investigation as there are other softwares as well but due to the scope of this paper it was inadequate to cover all the software tools, given a brief description of a few software’s that are used for evidence collection.

The paper attempts to give the audience to increase the level of understanding with the wide range of tools used for Computer Forensics Investigations.

## Acknowledgment

Special thanks to all other faculty members for helping during the research and giving their valuable suggestion and guidance.

# Adaptive Mutation Based Particle Swarm Optimization Algorithm

Jiyang Dai, Jin Ying
Nondestructive Test Key Laboratory of Ministry Education
Nanchang Hangkong University
Nanchang, China
E-mail: djiyang@163.com, 783026713@qq.com

***Abstract*—In this paper an adaptive mutation based PSO (AMBPSO) is presented for improvement of deficiencies of standard PSO， which is modified by the combination of dynamic adjustment of the inertia weights, the update of position and velocity of each particle by means of randomly adaptive mutation, and the limit of the update for the change in a reasonable range. The optimization results of two standard test functions show that these modifications can enhance particles' activity to improve the algorithm's search precision and convergence speed and to keep away from easily immerging in local minima efficiently compared with standard PSO and general PSO.**

***Keywords-particle swarm optimization*; *swarm intelligent optimization*; *adaptive mutation*; *modified algorithm***

## I. INTRODUCTION

Particle Swarm Optimization (PSO) is a technique modeling swarm intelligence that was developed by Kennedy and Eberhart [1] in 1995, who were inspired by the natural flocking and swarming behavior of birds. Compared with other swarm intelligent optimization algorithms such as Genetic Algorithms [2], it has more intuitive simplicity, less parameter settings and higher efficiency. It is a recently invented high performance optimizer that possesses several highly desirable attributes and especially that is an effective global optimization search algorithm for dealing with the complex nonlinear optimization problem with difficulty to solve by the traditional optimization methods [3-4].

Many advances in PSO development elevated its capabilities to handle a wide class of complex engineering and science optimization problems. Summaries of recent advances in these areas are presented in [5] and [6]. The existed PSO algorithms mainly include PSO with inertia weight, PSO with contraction factor, the binary PSO, the niche PSO and hybrid PSO, etc. Different variants of the PSO algorithm were proposed but the most standard one is the global version of PSO (Gbest model) introduced by Shi and Eberhart [7], where the whole population is considered as a single neighborhood throughout the optimization process. Although a key attractive feature of the PSO approach is its simplicity as it involves only two model equations, it has some disadvantages, such as less sensitive to environmental variations, and easily immerging in local minima frequently [8, 9]. Many improved techniques effectively increased the PSO's local disadvantages to a certain extent, but these problems need to be further resolved [10-14].

In this paper an adaptive mutation-based PSO (AMBPSO) is presented for improvement of the above deficiencies of standard PSO which is modified by the combination of dynamic adjustment of the inertia weights, update of position and velocity of each particle by means of randomly adaptive mutation, and the limit of the update for the change in a reasonable range. These modifications can enhance particles' activity to improve the algorithm's search precision and convergence speed and to keep away from easily immerging in local minima efficiently.

The paper is structured as follows. Section 2 analyses the standard PSO algorithm. Section 3 details an adaptive mutation based PSO algorithm. The optimization calculation and analysis of two standard functions using AMBPSO algorithm are given in Section 4. Conclusions are given in Section 5.

## II. STANDARD PARTICLE SWARM OPTIMIZATION ALGORITHM

### *A. Basic Concept of PSO*

In a standard PSO, a great number of particles move around in a multidimensional space, with each particle memorizing its position vector and velocity vector as well as the time at which it reached its highest level of fitness. The inspiration underlying the development of this algorithm was the social behavior of animals, such as the flocking of birds and the schooling of fish, and the swarm theory. The advantages of PSO are that it involves no evolution operators, such as crossover and mutation operators, and it does not require the adjustment of too many free parameters. PSO begins with a random population and searches for optima by continually updating this population. Moreover, each potential solution is assigned a randomized velocity. The potential solutions, called particles, are the "flown" through the problem space. Related particles can share data at the best-fitness time. The velocity of each particle is updated according to the best positions reached by all particles through iterations, and the best positions are determined by the related particles over the course of multiple generations.

It is Similar to other intelligent optimization strategies that there are individuals called as "particles", all of which

This work was supported in part by the National Natural Science Foundation of China (6116405) and the Aeronautical Science Foundation of China (2011ZA56021)

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

constitute a solution group in particle swarm optimization (PSO) algorithm. As they are flown through the searching space, particles are attracted towards the best solution found by the given particle's neighbors and by the particle itself. Each particle has a position vector and a velocity vector. Suppose that the searching space is $N$-dimensional, and $M$ particles form the colony. The $i$th particle has an N-dimensional position vector $\boldsymbol{X}_i$ ($i$= 1, 2, ⋯, $M$), which means that the $i$th particle is located at $\boldsymbol{X}_i$= $(x_{i1}, x_{i2}, \cdots, x_{iN})^{\mathrm{T}}$ in the searching space. The position of each particle is a potential result. The $i$th particle's "flying" velocity is also an N-dimensional vector, represented by $V_i = (v_{i1}, v_{i2}, \cdots, v_{iN})^{\mathrm{T}}$ ($i$= 1, 2, ⋯, $M$). The best particle among all particles can be represented by $x_d^{gbest}$ ($d$=1, 2, ⋯, $N$) whose fitness is *gbest*. Each particle also keeps track of the value of its best position, which is represented by $x_{id}^{Pbest}$ ($d$=1, 2, ⋯, $N$) corresponding to fitness $Pbset_i$.

In the standard PSO algorithm, the velocity and position of each particle are adjusted as follows:

$$v_{id}^{k+1} = wv_{id}^{k} + c_1 r_1 (x_{id}^{Pbest} - x_{id}^{k}) + c_2 r_2 (x_{d}^{gbest} - x_{id}^{k}) \qquad (1)$$

$$x_{id}^{k+1} = x_{id}^{k} + v_{id}^{k+1} \qquad (2)$$

where $r_1$, $r_2$ ∈(0, 1) are uniformly distributed random numbers between 0 and 1; $c_1$ and $c_2$ are learning rates; and $w$ denotes the inertia weight. $k$ ($k$=1, 2, ⋯, $D$) is the current iteration, and $D$ is the maximum number of iterations.

PSO randomly initializes the flock of birds throughout the searching space; every bird is called a "particle". During each individual generation, each particle adjusts its velocity vector, based on its best solution $x_{id}^{Pbest}$ and that of its neighbors $x_d^{gbest}$, as calculated by means of Eq.(1) and (2). The second part $c_1 r_1 (x_{id}^{Pbest} - x_{id}^{k})$ of Eq. (1) refers to the "cognitive component", which reflects the distance at which a particle is located from the best solution. The particle determines this distance on its own. On the other hand, the last part $c_2 r_2 (x_d^{gbest} - x_{id}^{k})$ of Eq.(1) refers to the "social component", which reflects the distance between a particle and the best solution found by its neighbors. Eq. (1) is used to calculate the particle's new velocity on the basis of its previous velocity, the distance between its current position and its own best previous position, and the collaborative interaction between the particles. This stage features cooperation among all particles in sharing information. Finally, the particle updates its position by means of Eq. (2). The best global position, determined by taking the condition of all particles into consideration, is defined as the particle with the minimum fitness.

The role of inertia weight $w$ is to make a compromise between local optima and global optima. Larger $w$ is beneficial to a wide range of search and smaller w to precise search in a small area. In general, $w$ is set as a function with linearly decreasing in the process of iterations.

$$w = w_{\max} - (w_{\max} - w_{\min})k / D \qquad (3)$$

where $w_{max}$ and $w_{min}$ are the initial and ultimate inertia weights, respectively.

### *B. Parameter Analysis*

The PSO is very simple to operate that involves fewer parameters. The main parameters need to be set as follows: Target Dimensional $N$, Population Size $m$, Inertia Weight $w$, Velocity Coefficient $c_1$, $c_2$, Max Iteration $D$. The parameters of the algorithm and meaning in the general principles of the selection are summarized below [2]:

- The target dimensional $N$, the number of parameters in the PSO need to be optimized, according to the definite corresponding target search space dimension.
- The population size m is generally selected from 10 to 40 suitable for solving most of optimization problems. But according to specific or very complex optimization problem, the population size can be taken between 100 and 200.
- Inertia weight w is generally selected between 0.35 and 0.9 in the practical optimization problem, where the initial and final inertia weights are usually selected as 0.9 and 0.35, respectively.
- Acceleration coefficient $c_1$ and $c_2$ are usually selected between 0 and 4, which are the main parameters for adjustment of particles "Cognitive item (Cognitive Term)" and "Social items (Social Term)". If $c_1$ = 0, then particles do not have cognitive abilities. This moment the particles have the ability to interact and can be expanded to new search space, but the particles in the iteration process are easy to fall into the local minimum; If $c_2$ = 0, the particles do not have the social information sharing capability. This time the PSO will develop random search; If $c_1 = c_2 = 0$, the particles will keep the initial velocity until they reach maximum iterating times to end;
- Maximum iteration $D$ as the threshold value control evolution of the PSO, can reflect the evolution of the algorithm efficiency, and too much iteration will cause a tremendous waste of the algorithm, or too small iteration may not be able to reach the goal of the optimization.

### *C. Implementation Steps*

After determining target search dimension $N$, population size $M$, the maximum number of iterations $D$ and the learning rates $c_1$ and $c_2$, the implemented steps of the PSO are as follows:

1) Initialize $v_{id}^{0}$ and $x_{id}^{0}$ .

2) Calculate the fitness of each particle, and store the best fitness of the individual (*pbest*) and its corresponding position $x_{id}^{Pbest}$, the best fitness of group (*gbest*) and its corresponding position $x_d^{gbest}$, the average value $x_{id}^{mbest}$ of positions of all the best particles relative to their own.

3) Update velocities $v_{id}^{k+1}$ and positions $x_{id}^{k+1}$ according Eq. (1) and (2).

4) Repeat steps 2–3 until a termination criterion is satisfied.

## III. Adaptive Mutation Based PSO

### A. Ideas of Improvement for PSO

Although the PSO has many advantages such as simple operation, fewer parameters, fast convergence speed, but it also has many disadvantages to be overcome, such as:

- In spite of the fact that particles can fly towards the optimal solution in search space according to all members of the group and their own experiences, the improper choice of inertia weight will lead to the lack of precise search ability of particles;
- In the process of particles' searching towards the goal of optimal solution, when a particle is close to the optimal value, its search speed will be small. As a result, the search diversity will be lost and a particle is easy to fall into the local minimum.

In order to overcome the above deficiencies, an adaptive mutation-based PSO (AMBPSO) algorithm is proposed for the improvement of the search accuracy and convergency of the standard PSO algorithm.

Firstly, the inertia weight is modified as a function with gradient descent:

$$w = (w_{\max} - w_{\min}) / k^H + w_{\min} \tag{4}$$

where $H$ is a given positive number. If $k$=1, then $w$=$w_{max}$ and if $k$→∞, then $w$=$w_{min}$.

Secondly, we sort fitness values of all particles in each iteration. According to the ranking, the particles in the top 50% are preserved while the rest in the colony is modified by means of adaptive mutation.

$$v_{bd}^k = v_{gd}^k (1 + \beta r) \tag{5}$$

$$x_{bd}^k = x_{gd}^k (1 + \alpha r) \tag{6}$$

where,

$x_{gd}^k$ and $v_{gd}^k$ are position and velocity of the particles in the top 50% of fitness ranking respectively.

$x_{bd}^k$ and $v_{bd}^k$ are position and velocity of the particles in the rest of 50% worse particles in the colony respectively, which will be modified by adaptive mutation.

$r$ is a uniformly distributed Gaussian random number with a range of [0, 1].

$\alpha$ and $\beta$ are two given positive numbers.

Meanwhile, each particle's position and velocity in AMBPSO algorithm are limited into the given boundaries. If the positions or velocities are out of the given boundaries, they will be replaced by the given boundaries.

Finally, a mutation factor $P$ is introduced as follows:

$$P = x_{id}^{mbest} - x_{d}^{gbest} \tag{7}$$

where $x_{id}^{mbest}$ is a mean value of the positions of the best particles obtained in the $i$th iteration, and $x_d^{gbest}$ is the global position value with the particles of the best fitness obtained so far.

The inertia weight coefficient can be dynamically adjusted on the basis of the following equation:

$$H = H(1 + \gamma r) \tag{8}$$

where $\gamma$ is a positive number and $r$ is a uniformly distributed Gaussian random number with a range of [0, 1].

It is necessary to select the appropriate mutation thresholds $\rho$ according to the actual situation. If $P$ is less than or equal to $\rho$, then $H$ is modified by Eq.(8). The aim on the introduction of mutations factor $P$ is to improve the mutant ability of AMBPSO. Because $x_{id}^{mbest}$ can comprehensively reflect the activities of the individual particles and $x_d^{gbest}$ can refmutationall activities of all particles, the mutations factor $P$ is adopted not only to effectively suppress the AMBPSO premature to early fall into local minima, but also to efficiently ensure the AMBPSO to jump out of the local minima. As a result, it is critical to select an appropriate mutation threshold ρ. A large number of experiments show that, the proposed AMBPSO algorithm can effectively make up for deficiencies on convergence and premature of the standard PSO to improve the search performances of PSO.

### B. Implementation Steps of the AMBPSO

In summary, The AMBPSO algorithm can be described in general as follows:

1) Determine target search dimension $N$, population size $M$, the maximum number of iterations $D$ and the learning rates $c_1$ and $c_2$.

2) Initialize $v_{id}^0$ and $x_{id}^0$ .

3) Calculate the fitness of each particle, and store the best fitness of the individual (*pbest*) and its corresponding position $x_{id}^{Pbest}$, the best fitness of group (*gbest*) and its corresponding position $x_d^{gbest}$, the average value $x_{id}^{mbest}$ of positions of all the best particles relative to their own.

4) Adaptively mutate 50% worse particles $v_{bd}^k$ and $x_{bd}^k$ according to Eq. (5) and (6).

5) Judge mutation factor $P$ according to Eq. (7), dynamically adjust the inertia weight coefficient $H$ according to Eq. (8) and finally calculate the inertia weight $w$ in terms of Eq. (4).

6) Update velocities $v_{id}^{k+1}$ and positions $x_{id}^{k+1}$ according Eq. (1) and (2).

7) Repeat steps 3–6 until a termination criterion is satisfied.

## IV. Calculation and Analysis of Standard Test Functions

In order to validate the performances of the improved particle swarm optimization algorithm, the AMBPSO, the Standard PSO (SPSO) and the PSO are used to test two types of standard functions. The comparison is made from three aspects of the convergence rate, the optimal fitness value and the search precision of the three PSO algorithms. The results on the above three aspects of algorithm performances for standard test functions can indicate which algorithms are much better. Different types of standard test functions are utilized for different types of optimization problems [1].

Two types of standard test functions are used to validate the three PSO algorithms, which are defined as follows:

1) The first test function is chosen as Generalized Rastrigin function expressed as

$$f(x)=\sum_{i=1}^{n}[x_i^2-10\cos(2\pi x_i)+10]$$

Search range: $-5.12 \le x_i \le 5.12$

Global optimal value: $\min(f)=f(0,\cdots,0)=0$

2) The second test function is chosen as Ackley function expressed as

$$f(x)=-20\,\mathrm{e}^{(-0.2\sqrt{\frac{1}{n}\sum_{i=1}^{n}x_i^2})}-\mathrm{e}^{(\frac{1}{n}\sum_{i=1}^{n}\cos 2\pi x_i)}+20+e$$

Search range: $-32 \le x_i \le 32$

Global optimal value: $\min(f)=f(0,\cdots,0)=0$

There are a great number of local minima contained in the selected test functions due to the effect of the cosine functions in the above standard test functions. If the selected intelligence group optimization algorithms have an inadequate activity for departing from local minimum values, the global optimal values cannot be achieved. These types of test functions are used to better validate the performance that the AMBPSO can make up for deficiency that both of the PSO and the SPSO are easy to get into local minima.

In order to show convincingly that the proposed novel PSO algorithm is more superior to other PSO algorithms by comparing AMBPSO with SPSO and PSO, the selection of control parameters is based on a consistency principle, that is, the basic control parameters of the three optimization algorithms are set as the same in this paper. The parameters are set as follows:

Population size $m$=40, Learning rates $c_1$=$c_2$=2.05, Initial inertia weight $w_{max}$=0.9, Terminal inertia weight $w_{min}$=0.35, Maximal velocity $v_{max}$=1, Minimal velocity $v_{min}$= -1, Maximal position $x_{max}$=10, Minimal position $x_{min}$=0.05, Inertia weight coefficient $H$=0.5096, Mutation Threshold $\rho$=0.0001, Mutation factor of inertia weight coefficient mutation $\gamma$=0.02, Mutation factor of position $\alpha$=0.0005, Mutation factor of velocity $\beta$=0.0005, Maximal iteration numbers *maxgen*=100/500/1000.

Initial speeds and positions in the improved particle swarm optimization algorithm are generated randomly in terms of actual optimization problems. At the same time, the numerical experiments are done on three different maximum iteration numbers. The results are illustrated by only using the fitness graphs at *maxgen*=100.

The curves of the best fitness variations with iterations generated by three PSO algorithms as to the two test functions are shown respectively in Fig.1 and Fig.2. The dimensions of the two selected functions are both set as $n$=20. In order to avoid contingency, 50 times of optimization experiments are done for all the algorithms to analyze and compare the performances of the three PSO algorithms. From Fig. 1 and 2, it can be obviously shown that The AMBPSO is of higher convergence speed than the other two algorithms for both of the selected test functions during the process of iterations.

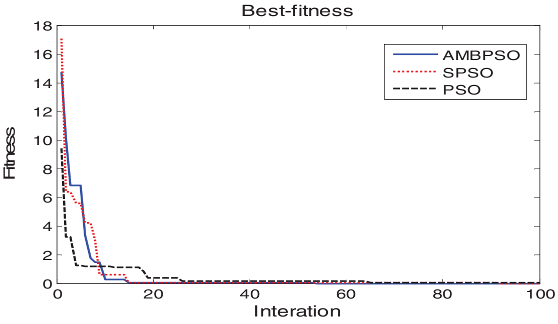

Fig. 1 Fitness curves of Generalized Rastrigin function

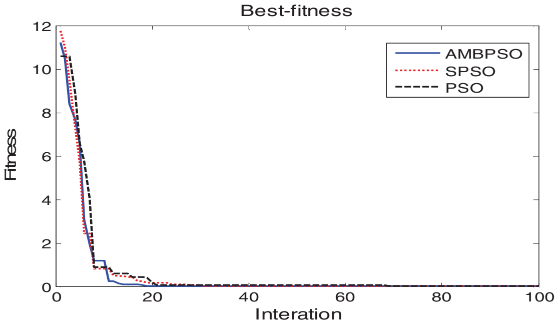

Fig. 2 Fitness curves of Ackley function

As shown in Table 1 are root mean square errors between real optimal values and calculated values by the three PSO algorithms as to the two given test functions at three different terminal iterations.

TABLE I. RMS ERRORS OF OPTIMAL VALUES FOR EACH TEST FUNCTION

| | **Generalized Rastrigin** | | | **Ackley** | | |
|---|---|---|---|---|---|---|
| | AMBPSO | SPSO | PSO | AMBSPO | SPSO | PSO |
| 100 | $3.07\times10^{-4}$ | $4.20\times10^{-3}$ | $3.86\times10^{-2}$ | $6.22\times10^{-6}$ | $2.80\times10^{-3}$ | $1.92\times10^{-2}$ |
| 500 | $7.83\times10^{-9}$ | $1.14\times10^{-4}$ | $6.60\times10^{-3}$ | $8.64\times10^{-10}$ | $7.34\times10^{-5}$ | $4.30\times10^{-3}$ |
| 1000 | $8.88\times10^{-13}$ | $4.44\times10^{-7}$ | $1.21\times10^{-4}$ | $3.14\times10^{-13}$ | $1.52\times10^{-9}$ | $9.24\times10^{-5}$ |

From Table 1, it can be shown that the search precision increases with the increment of the maximal number of iterations given in advance, and that under the same terminal condition the AMBPSO algorithm is of much higher precision and faster convergency rate than the other two PSO algorithms for whichever standard test functions.

## V. CONCLUSIONS

In this paper an adaptive mutation-based PSO (AMBPSO) is presented for improvement of the deficiencies of standard PSO which is modified by the combination of dynamic adjustment of the inertia weights, update of position and velocity of each particle by means of randomly adaptive mutation, and the limit of the update for the change in a reasonable range. The optimization results of two standard test functions show that these modifications can enhance particles' activity to improve the algorithm's search precision and convergence speed and to keep away from easily immerging in local minima efficiently.

*Abstract*—**For CPU chips' cooling task, existing mono-variable control system has the defects of delay, fluctuation and high energy consumption. With the trend of multi-core and high frequency work pulse in CPU chips, traditional system does not fit for future cooling task. Several approaches such as chips' dissipated power nonlinear feed-forward, core temperature tracking and surface temperature feed-back are applied to improve control system. Simulations prove that comparing with the traditional out-core temperature based mono-input-output proportion tracking strategy, the improved system can bring better quality and energy-saving results. Also, the new system has parameters adaptability.**

***Keywords-CPU chip; temperature; cooling; control; power dissipation; usage rate; feed-forward***

## I. INTRODUCTION

In future space mission, more and more high heat integrated circuit chips need to be cooled [1]. Promoting the quality of high heat IC chips' cooling control is just a new study focus. CPU chips are a typical kind of high heat chips and their cooling control is the key of guaranteeing their stability and dynamic properties [2]. Traditional cooling control systems are mono-variable tracking system, and they apply proportional algorithm as control strategy [3-5]. That is, the discrete values of out-core temperature in chip are multiplied by a coefficient and then are used to adjust cooling actuator's driving power.

CPU chip is a body with inside heat sources. Its heat generating mechanism [6-9] makes temperature in chip is a nonstationary random process with delay and many influence factors. This is the bottle-neck for traditional control system to fit for future CPU chips' cooling task. Concretely speaking, uncertain deviation between out-core temperature measuring values and real temperature [7], single system input variable and simple tracking control strategy, and so on, are main reasons. So, it is urgent to find new control system to cope with future challenges. Unluckily, trends of more cores and higher frequency of main pulse of CPU chip, future scheduling strategy of operating system, development of CPU internal structures and techniques, even increasing of cooling actuator's efficiency, will make CPU chip's power, heat and temperature more complex than expected.

To promote the transient and steady state quality of chip's surface temperature, this paper suggests a new system which combines several approaches such as new signals and their processing, more control algorithms and more complicated strategies. In the new system, CPU usage rate which indicates the chip's dissipated power in advance [9-11], and CPU core temperature which is more accurate and more sensitive and no delay, are used as inputs. And, power feed-forward, core temperature tracking and surface temperature feed-back strategies are added. Numerical simulation proved our new method is effective and advanced.

## II. CHIPS' COOLING AND TRADITIONAL CONTROL SYSTEMS

Traditional cooling control system (seeing Fig. 1) uses analogue variables as inputs. It applies proportional strategy in Fig. 2 to determine the excitation voltage $V_{out}$ of the cooling actuator, usually one or two air fan, as follows:

$$V_{out} = k_p T(t) \tag{1}$$

It is obvious that the object itself is not complex. That is, the chip's heat transfer delay and the air fan's cooling time are

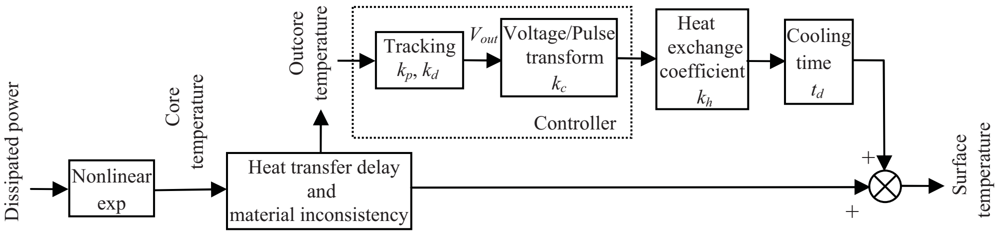

Figure 1. CPU chips' cooling model of tracking control system.

common properties in control systems. But there is peculiar complexity resulting from the nonstationary random and anisotropic inconsistency in temperature field. As being seen in Fig. 3, not only is there nonstationary random in out-core temperature and core temperature, but at least 1 second of time delay and at least 1°C of temperature variance in them as well. Besides, the uncertainty of heat resulted from CPU workloads and the variant cooling time influenced by heat exchanging efficiency of actuator, etc., bring the chips' cooling with difficulties.

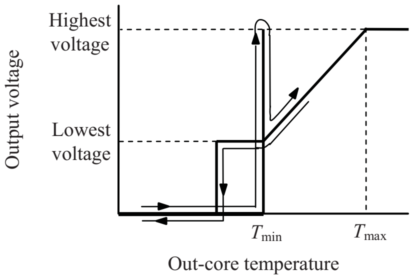

Figure 2. Traditional proportional tracking strategy.

Generally speaking, the traditional proportional tracking strategy cannot further improve the cooling control quality, and cannot face future challenges.

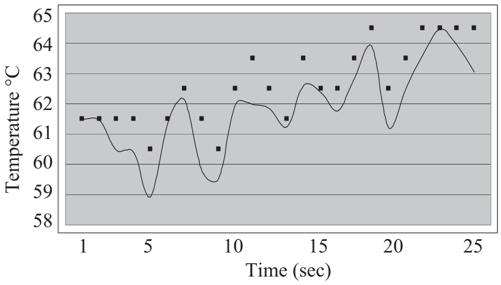

Figure 3. CPU core temp. & out-core temp.

## III. Model of Control System with Dissipated Power Feed-Forward and Multi-Temperature PID

### A. Improved Model of Controller

We noticed that chip's power consumption is in advance to its temperature. On the basis of existing tracking system, we introduce usage feed-forward to reflect the action of CPU's power consumption to temperature. Besides, we substitute out-core temperature with core temperature as input variable, and add algorithms of tracking and feed-back. Certainly, we take short window mean value from sequences of core temperature and usage. Fig. 4 is the improved control system model. In Eq. (2) are several algorithms in the new model such as usage sequence nonlinear feed-forward, core temperature tracking, surface temperature feed-back, etc. In that equation, $k_u$ is usage feed-forward coefficient and the linear item, $k_r$, is added to make up the attenuation with usage increasing. The $k_p$, $k_i$ and $k_d$ are proportional, integral and deviational coefficients of PID algorithm, respectively. The $k_f$ is coefficient of different value feed-back.

$$\begin{aligned}
&k_u \left\{1 - \exp\left(- \mathrm{E}\left[U_n^{L,l}\right]\right) + k_r \mathrm{E}\left[U_n^{L,l}\right]\right\} \\
&k_p\, \mathrm{E}\left[T_n^{L,l}\right] + k_d \frac{\left\{\mathrm{E}\left[T_n^{L,l}\right] - \mathrm{E}\left[T_{n-1}^{L,l}\right]\right\}}{l} \\
&k_i \sum_{i=1}^{n} \left\{T_o(n) - \frac{T_{\max} + T_{\min}}{2}\right\} \\
&k_f \left\{T_o(n-1) - \mathrm{E}\left[T_n^{L,l}\right]\right\}
\end{aligned} \tag{2}$$

In Eq. (2), $\mathrm{E}\left[U_n^{L,l}\right]$ and $E\left[T_n^{L,l}\right]$ are short window mean value of usage sequence and core temperature sequence, respectively.

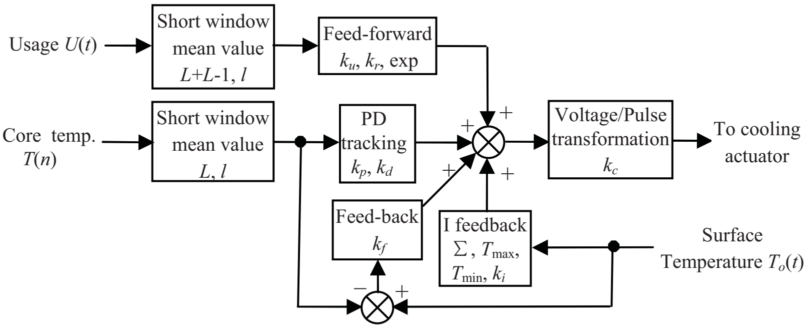
### B. Nonlinear Relation between Usage Rate and Core Temperature

The CPU usage measures microprocessor's workloads. It reflects the power consumption of chip directly and determines the amount of heat generated in the chip [7, 10-11]. For a CPU chip, suppose it gains heat $Q_{gained}$ from its environment, $Q_{transfer}$ is the amount of heat transferred to it during a period of time and $Q_{component}$ is the amount of heat produced by running programs during a period of time. This can be expressed as [10]:

$$\begin{aligned}
&Q_{gained} = Q_{transfer} + Q_{component} = \\
&k\left(T_{out} - T_{source}\right)t + \left[P_{base} + \left(P_{\max} - P_{base}\right)u\right]t
\end{aligned} \tag{3}$$

where $T_{source}$ is core temperature and $T_{out}$ is air temperature, $P_{base}$ is the power consumption when CPU is idle and $P_{\max}$ is the consumption when chip is fully utilized, $u$ is usage rate.

Since $\Delta T = \frac{1}{mc}\Delta Q$, then



Usage $U(t)$
Short window mean value $L$+$L$-1, $l$
Feed-forward $k_u$, $k_r$, exp
Core temp. $T(n)$
Short window mean value $L$, $l$
PD tracking $k_p$, $k_d$
+
+
+
+
Voltage/Pulse transformation $k_c$
To cooling actuator
Feed-back $k_f$
I feedback $\Sigma$, $T_{\max}$, $T_{\min}$, $k_i$
Surface Temperature $T_o(t)$
−
+

Figure 4. Improved model of CPU chip cooling controller.

$$\frac{dQ_{gained}}{dt} + k\left(T_{source} - T_{out}\right) = P_{base} + \left(P_{\max} - P_{base}\right)u$$

$$mc\frac{d\left(T_{source} - T_{out}\right)}{dt} + k\left(T_{source} - T_{out}\right) = \qquad (4)$$

$$P_{base} + \left(P_{\max} - P_{base}\right)u$$

where $m$ is the mass of chip, $c$ is its heat capacity, and $k$ is related to $m$ and $c$.

In Fig. 5 is statistic result of real out-core temperature measuring values. When usage is larger than 10%, the action of dissipated power to out-core temperature can be seen easily. Through fitting, we get the relation between steady temperature values and constant usage values as Eq. (5), where $T_{base}$ is the basic temperature corresponding to zero usage, $k_u$ and $k_r$ are constants. It must be pointed out that Eq. (5) just coincides with the solution form of Eq. (4).

$$T(\infty) = T_{base} + k_u\left(1 - e^{-k_r u}\right) \qquad (5)$$

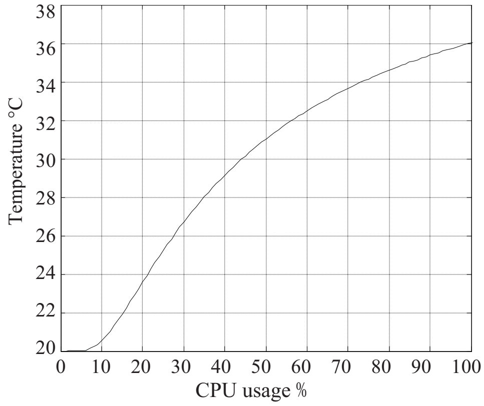


Figure 5. Steady temperature under different usage.

### C. Short Window Mean Value of Core Temperature and Usage Sequences

The discrete sequence of core temperature $\{T_n\}$ is a nonstationary random one with big sampling cycle. It can be proved that the short window mean value of the sequence $\left\{E\left[T_n^{L,l}\right]\right\}$ contains the same heat as $\{T_n\}$. And, the waveform of the former is smoother than that of the latter. This means short window mean value is more fittable for being applied to cooling control than discrete values.

**Brief proof:**

Let frame length $L$ is 2, frame width $l$ is 1, then $\left\{E\left[T_n^{L,l}\right]\right\}$ contains heat

$Q_{aver} = \sum_{i=1}^{n}\int_{i-1}^{i} T_i dt = \frac{T_1}{2} + \sum_{i=1}^{n}\int_{i}^{i+1}\frac{T_i + T_{i+1}}{2}dt + \frac{T_n}{2}$. And $\{T_n\}$ contains heat $Q_{disc} = \frac{T_1}{2} + \sum_{i=1}^{n}\int_{i}^{i+1}\frac{T_i + T_{i+1}}{2}dt$ , if $n$ is large enough, $Q_{aver} \approx Q_{disc}$. Furthermore, if $T_i$+1>$T_i$, then $T_{i+1} > \frac{T_i + T_{i+1}}{2}$, if $T_i$+1<$T_i$, then $T_{i+1} < \frac{T_i + T_{i+1}}{2}$. **Proof end**

As for usage sequence, $U(n)$, we make use of its short window mean value $\left\{E\left[U_n^{L,l}\right]\right\}$, too.

## IV. Simulation and Analysis

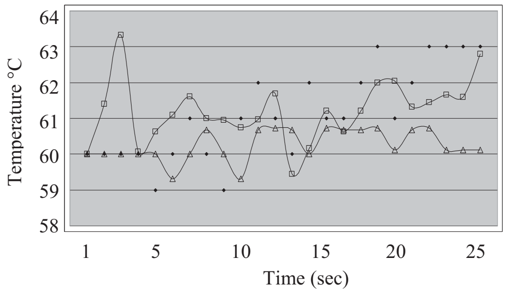
### A. Selection of Parameters

For simplicity, we suppose the power dissipated by cooling driving actuator is all used for cooling. According to experiment experiences, let cooling time, $t_d$, is 1 second, and time constant of heat transfer, $\tau$, is 0.25 second. That means all heat generated from source is taken away to environment by cooling actuator in 1 second.

All parameters' values are taken as follows: $L$=2, $l$=1, $\tau$=0.25s, $t_d$=1s, ($T_{\min}$, $T_{\max}$)=(50°C, 70°C), ($U_{\min}$, $U_{\max}$)=(8V, 12V), $k_p$=0.1, $k_i$=0.01, $k_d$=0.01, $k_f$=0.01, $k_c$=1.2, $k_h$=8, $k_u$=0.1, $k_r$=1.0.

### B. Simulation Results and Analysis

*1) Comparisons between core temperature and out-core temperature as input variable.* The simulation results of pure proportional tracking control (seeing Fig. 1) using out-core temeprature or core temeprature as inputs are showed in Fig. 6, respectively. Obviously, owing to the uncertainty and delay of out-core temeprature, its result is much worse than that of core temeprature. Simulation results indicate that the larger or smaller is $k_p$, the larger is the surface temperature's fluctuation amplitude. This is because the pure proportional tracking strategy can not eliminate the disturbance of uncertain deviation in out-core temperature values. In real application, the effect of $k_p$ is the same as that of heat exchange coefficient of cooling actuator, this means that traditional strategy does not fit for cooling actuator with lower heat exchange efficiency, and not for actuator with higher heat exchange efficiency, either. It is needed to point out that out-core temperature used in our numerical calculating has smaller random deviation. Actual random deviation is bigger and its influence is more serious.



■ ---- outcore temperature as input variable

▲ ---- core temperature as input variable

Figure 6. Control results by traditional system.

*2) Comparisons of control qualities made by different improved strategies.* For improved control system in Fig. 4, we use core temperature in Fig. 2 as input variable to do simulations. At the beginning, the controller only with PD core temperature tracking algorithm make surface temperature having 1°C steady state deviation. Then, after surface temperature feed-back being added, controller eliminates the deviation. Or, after usage nonlinear feed-forward being added, the overshoot of surface temperature is lower. Lastly, once surface temperature feed-back and usage feed-forward are added simultaniously, the result is best both in transient and steady state.(seeing Fig. 7)

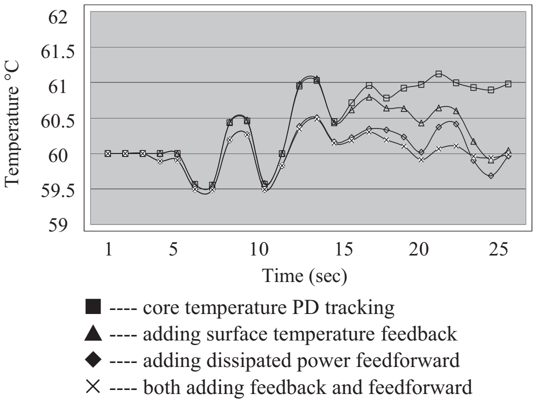


Figure 7. Control results by improved system.

*3) Comparison of power dissipated by cooling actuator.* For the combination strategy of core temperature tracking and surface temperature feed-back, the numerical calculating results of using two different values spent different energy. Control system using discrete values of core temperature makes the actuator spend 2.46053 Joule of energy, whereas system using short window mean values of core temperature makes the actuator spend 1.76581 Joule of energy. In our example, the former spends 0.69472 Joule more energy than the latter during 20 seconds.

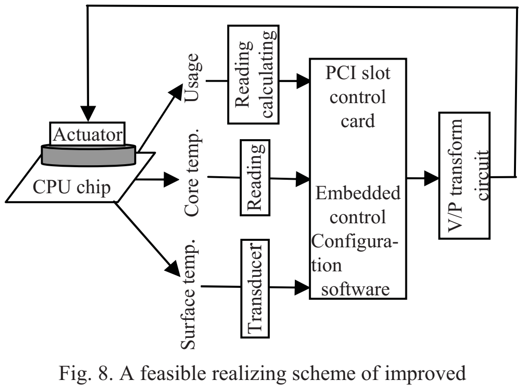

Fig. 8. A feasible realizing scheme of improved chip's cooling control system.

*4) Discussions about feasibility and practicability.* Simulating work indicates that the parameters in new system model such as $k_p$, $k_i$, $k_d$, $k_f$, $k_u$, $k_r$, $L$ and $l$ can be adjusted in wide range to cope with different values of $\tau$, $t_d$, $k_c$, $k_h$. For instance, whether the cooling actuator is air fan or liquid pump or semeconductor thermoelectric patch, i.e., whether the actuators' heat exchange efficiency is high or low, simulating shows our model can give excellent control quality. For example, under the circumstance of CPU core temperature behaving different random properties owing to different operating systems, or different main pulses, or different user softwares, new system can adapt them by using corresponding $L$ and $l$.

## V. Conclusion

This paper studied how to improve CPU chips' cooling control system and suggested several new methods in two aspects: one is of input signals and their processing; the other is of control strategies. Numerical calculating and simulating verified that usage sequence which indicates CPU power and core temperature sequence which is more accurate and more instant can avoid the disadvantages of out-core temperature values. Also, it was verified that power feed-forward and surface temperature feed-back can enhance system's functions and improve its performance. The improved control system has advantages in control quality, energy saving and adaptability. Our improved system can be easily realized by making use of existing techniques. Actually, it does be our coming work. Fig. 8 shows one feasible scheme of our improved control system.

*Abstract*—**Based on the simplified hypersonic air-breathing propulsion model, this paper studies the output regulation/ safety protection multi-objective switching control problem focusing on the safety boundaries existing during the working progressing. Command switching strategy based on the safety margin is researched. In the safe region with a sufficiently large safety margin, the regulation loop is active and the regulated output is controlled to track the reference signal as quickly as possible. But the protected loop will be switched on and the protected output will be forced to escape from dangers once the safety boundaries approach. A dynamical state feedback controller and a protection controller work in turn in a hysteresis switching way to guarantee the asymptotic tracking with certain safety performance. The conditions under which the asymptotic tracking could be guaranteed are given and the control parameters could be calculated by solving optimal problems. It is pointed out in this paper that the designing of the regulation controller and the protection controller could be implemented separately, and the control parameters could be optimized to get certain optimal performance index using numerical method. Finally, simulation researches are performed to verify the effectiveness of the given methods, which also indicate that the commands switching control can improve both safety margin and the dynamical performance indices than the single controller.**

## I. INTRODUCTION

There have been dramatically large amounts of attentions attracted by the modeling and control of hypersonic air-breathing propulsion in the recent years [1], especially since the successful flight experiment of the X-51 aircraft in late May 2010. Usually, a hypersonic air-breathing vehicle is driven by a scramjet engine, and is with the integrated airframe/ scramjet configuration which causes strong couplings among flight dynamics, aerodynamics, propulsion and control [2]. The coupled dynamics results in various engine safety boundaries during the working progressing of a hypersonic air-breathing vehicle, for example, the combustion stabilization boundary, the combustor wall temperature limitation, the inlet channel unstarting boundary, and so on. Disastrous accidents may happen once the system works outside the safety boundaries or even approaches them. On the other hand, due to the requirement of air and space travel, hypersonic vehicle must have a broader flight envelope than any other aircrafts, which brings large parametric uncertainties and quick dynamical changes. To pursue more excellent flight performances, the hypersonic air-breathing vehicles are usually required to flight near the safety boundaries as possible as it can. In order to balance the contradiction between the performance and safety, protection measures must be taken to the hypersonic air-breathing vehicle when it is approaching the safety boundaries. And one of the effective measures to finish this objective is to adopt the multi-objective switching control strategy [3].

When asked to tracking a large step command as quickly as possible, it is necessary to design regulating/protecting switching controllers for a hypersonic air-breathing vehicle since, in common sense, it is obviously that the rapidity usually conflicts with the security. A regulation/protection switching control system consists of a regulation loop and several protection loops, when the controlled plant is working within the allowed safety limits, the regulation loop works to achieve perfect performances, when the controlled plant trends towards the neighborhood of some safety boundary, the corresponding protection loop will be switched on automatically according to certain previous design to ensure safety. The protection loops are expected to be constructed according to the boundaries so that the designers could relax the safety condition when they are dealing with the regulation loop. It is with more efficiency and is less conservative.

It is notable that the safety protection control problem is similar to the state constrained control problem which is studied via the barrier Lyapunov function in [4], but there are differences between them. First, for example, not only boundary but also transient performances, especially that of the states except the constrained ones, should be considered in the safety protection control problem. Second, the safety protection controller is usually expected to be designed separately from the regulation controller, and sufficient safety margin is also usually needed.

Consisting of the determination of both the controllers and the switching law, design of the switching controller is a complex synthesis procedure of nonlinear controller, even it is for a linear plant. A systematic designing method for the safety protection switching controller is anticipated to come out, by

both the researchers working on the switched systems theory and the engineers working on the practical fields. Most of the currently existing theory results [5], however, focus only on the analysis of stability of switched systems, and few of the switching laws present in the existing theoretical results are so easy to implement. And few results can be referred to design regulation/protection switching controllers. The work [6] uses switching static feedback controller with the maximum control switching law to deal with the constant tracking problem for a linear system with state constraints, but the dynamical response performance is not discussed. In [3], the regulation/ protection switching controller based on the minimum law is studied through simulation, without stability analysis and designing steps mentioned. In our previous work [7] and [8], the switching control based on minimum control switching law and the command switching control scheme are investigated respectively.

Based on our previous work in [8], this paper continue to studies the output regulation/safety protection control problem for the simplified model of the aeroengine via command switching control based on the safety margin. Several modifications are performed to improve the response performance. The proposed asymptotic tracking condition could be used to design the control parameters through solving programming problems. The design of the regulation loop and the protection loop can be finished in steps, and the control parameters can be optimized in a numerical method to get optimal ITEA index. Conditions for the finite times switching and estimation of the safety margin are also mentioned. Finally, in the section of simulation researches, the effectiveness of the given results verified, and it is revealed that the proposed command switching strategy is with superiority both in safety performance and ITAE (Integral of Time-weighted Absolute Error) index comparing to the single controller scheme.

## II. Problem Depiction

As is shown in Figure 1, the linear system studied in this paper can be considered as the simplified model of a hypersonic air-breathing propulsion, where the actuator and the basic engine are simply modeled as inertia units $G_1(s)$ and $G_2(s)$ respectively, while the temperature sensor is considered as a leading unit $G_3(s)$ approximately, where

$$G_1(s) = \frac{1}{T_4 s + 1}, \quad G_2(s) = \frac{1}{T_3 s + 1}, \quad G_3(s) = \frac{T_1 s + 1}{T_2 s + 1}.$$

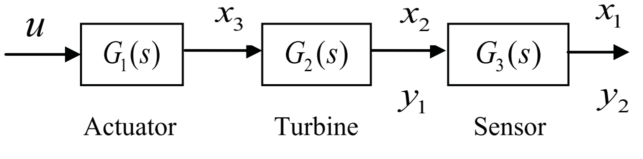

Figure 1. A simplified model of hypersonic air-breathing propulsion

As the regulated output, the rotation velocity of the turbine is expected to track the reference signal as quick as possible. Simultaneously, however, as the protected output, the temperature is not allowed to touch the constant safety boundary. To make the state available, the state variables $x_1$, $x_2$ and $x_3$ are chosen as the temperature, the rotation speed and the output of the actuator respectively, the state space model of the plant is

$$\dot{x} = Ax + bu, \tag{1}$$

where

$$A = -\begin{bmatrix} T_3T_4 & T_4(T_1 - T_3) & -T_1T_4 \\ 0 & T_2T_4 & -T_2T_4 \\ 0 & 0 & T_2T_3 \end{bmatrix} / T_2T_3T_4,$$

$$b = \begin{bmatrix} 0 & 0 & 1/T_4 \end{bmatrix}^T, x = \begin{bmatrix} x_1 & x_2 & x_3 \end{bmatrix}^T \in R^3,$$

$u$ is the output of the controller, $T_1$, $T_2$, $T_3$ and $T_4$ are time constants determined according to identification, the regulated output and the protected output are

$$\begin{aligned} y_1 &= C_1 x, \\ y_2 &= fC_2 x, \end{aligned} \tag{2}$$

where $f$ is a constant feedback gain, and

$$C_1 = \begin{bmatrix} 0 & 1 & 0 \end{bmatrix}, C_2 = \begin{bmatrix} 1 & 0 & 0 \end{bmatrix}.$$

The control objective is to design control strategy to make

$$\lim_{t \to \infty} |y_{r1} - y_1(t)| = 0, \tag{3}$$

$$y_2(t) < y_{boundary}, \forall t, \tag{4}$$

where $y_{r1}$ is a constant reference signal, and $y_{boundary}$ is the constant safety boundary for the temperature $y_2$. In the paper, it is assumed that $y_{r1} < y_{r2} / f$, which stands for that the tracking task does not destroy the safety boundary and the desired equilibrium point of the closed loop is in the safety region.

Usually, it is more practical to think about the safety with some margin than only to consider the critical safety. In this paper, the safety margin $\gamma$ is defined as followed:

$$\gamma \overset{def}{=} \frac{y_{boundary} - y_2}{y_{boundary}}. \tag{5}$$

It is supposed in this paper that $y_{boundary} > 0$, and $0 < \gamma < 1$ implies that the system is working in the safe region, and a larger $\gamma$ stands for the safer status.

## III. Main Results

In this section, the command switching based strategy is adopted to solve the output regulation/safety protection control problem. The asymptotic tracking conditions are given, and the control parameters of the protecting controller could be optimized to minimize the ITAE performance index after the design of the regulation loop is finished.

### *A. Command Switching Control Based on Safety Margin*

In this section, we try to modify the command switching control scheme mentioned in our previous work [8] to obtain better control performances. The modified controllers are directly illustrated as followed:

First of all, a full state dynamical feedback controller is employed instead of a PI controller in the regulation loop to make the poles of the closed loop arbitrarily assignable under the controllable condition:

$$u_1(t) = K_x x(t) + K_q q(t), \tag{6}$$

where $q(t) = \int_0^t (y_{r1} - y_1(\tau))d\tau$ , and $\begin{bmatrix} K_x & K_q \end{bmatrix}$ is to be determined according to the desired poles.

The resulted closed loop equation of the regulation loop is

$$\dot{X} = A_{c1}(X - X_e), \tag{7}$$

where

$$X = [x^T, q]^T, A_{c1} = A_1 + B_1\begin{bmatrix} K_x & K_q \end{bmatrix},$$

$$X_e = -A_{c1}^{-1}\begin{bmatrix} 0_{3\times1} \\ y_{r1} \end{bmatrix}, A_1 = \begin{bmatrix} A & 0_{3\times1} \\ -C_1 & 0 \end{bmatrix}, B_1 = \begin{bmatrix} b \\ 0 \end{bmatrix}.$$

Second, a proportional (P) controller is adopted in the protection loop to help the protected output escape from danger as soon as possible, as the same time, the output of the integrator $q$ is set to vary more quickly during the protection interval than the regulation interval to improve the regulating performance:

$$\begin{aligned} &u_2(t) = K_p(Ly_{boundary} - y_2(t)), \\ &\dot{q}(t) = K(y_{r1} - y_1(t)), \sigma(t) = 2, \end{aligned} \tag{8}$$

where $L < 1, K > 1$ and $K_p$ are constants to be designed. It can be known that when $y_1(t) < y_{r1}$ , a quickly increasing $q$ results in a quickly increasing positive control input, which helps $y_1(t)$ to reach $y_{r1}$ quickly, and that when $y_1(t) > y_{r1}$ , a quickly decreasing $q$ brings a quickly decreasing negative control input, which helps $y_1(t)$ to reduce overshooting and to reduce times of switches. The corresponding equation of the protection loop is

$$\dot{X} = A_{c2}X + \xi_2, \tag{9}$$

where

$$A_{c2} = \begin{bmatrix} A - fK_p bC_2 & 0 \\ -KC_1 & 0 \end{bmatrix}, \xi_2 = \begin{bmatrix} Ly_b K_p b \\ Ky_{r1} \end{bmatrix}.$$

Third, the switching law is based on the safety margin to make the margin easy to estimate and is with hysteresis to better coin with practice, chattering also could be weakened due to the hysteresis:

$$u = u_{\sigma(t)}, \sigma(t) = \begin{cases} 1, \gamma > \gamma_{off}, \\ \sigma(t^-), \gamma_{on} < \gamma < \gamma_{off}, \\ 2, \gamma < \gamma_{on}, \end{cases} \tag{10}$$

where $0 < \gamma_{on} < \gamma_{off} < 1$ are constants to be designed. The switching law means that the protection loop will be switched on when the safety margin falls down to a given small number and will be switched off until the margin rises up to a sufficient large value. It is reasonable to assume that $\gamma(t_0) > \gamma_{off}$ , which means that it is safe enough at the initial moment, so $\sigma(t_0) = 1$ .The asymptotic tracking conditions are proposed as followed:

**Theorem1** Consider the system (1)-(2) controlled by the command switching controller (6), (8) and (10). Suppose that, there exists $t_1 > t_0$ such that for any $t > t_1$ , we have $y_1(t) > y_{r1}$ . If there exist a symmetric positive definite matrix $R$ and a positive constant $\beta$ satisfying

$$A_{c1}^T R + RA_{c1} \le -\beta I, \tag{11}$$

and the maximum value of the following quadratic programming problem (12) is non-positive, then the goal of asymptotic tracking (3) could be achieved:

$$\begin{aligned} \max \quad & (X - X_e)^T (A_{c2}^T R + RA_{c2})(X - X_e) \\ & + 2(A_{c2}X_e + \xi_2)R(X - X_e) \\ s.t. \quad & \begin{bmatrix} fC_2 & 0 \end{bmatrix} X \ge (1 - \gamma_{on}) y_{boundary}, \\ & \begin{bmatrix} C_1 & 0 \end{bmatrix} X \ge y_{r1.} \end{aligned} \tag{12}$$

**Proof**: If the candidate Lyapunov function is selected as

$$V(X) = (X - X_e)^T R(X - X_e), \tag{13}$$

when $\sigma(t) = 2$ , according to (9), we have

$$\begin{aligned} \dot{V} = &(X - X_e)^T (A_{c2}^T R + RA_{c2})(X - X_e) \\ &+ 2(A_{c2}X_e + \xi_2)R(X - X_e). \end{aligned} \tag{14}$$

It can be known from the condition (11) and (12) that $V(X)$ decreases in the whole time weather the regulation or the protection loop is switched on. The objective (3) can be thus realized. The proof is thus completed.

The quadratic programming problem (12) could be straightly solved using the optimal toolbox of Matlab. And the assumption of achievement of $y_1(t) > y_{r1}$ in finite time will be discussed combining with the simulations later.

**Remark1** In common sense, the peak value which a given output of a fixed system could achieve is determined by the initial state. So the safety margin in the proposed frame of command switching control based on the safety margin can be estimated by the following nonlinear programming [9]:

$$\begin{aligned}&\max \quad fC_2[x_e+e^{A_2t_m}(x_0-x_e)]\\ &x_0,t_m s.t.\begin{cases} fC_2x_0=(1-\gamma_{on})y_{boundary},\\ fC_2A_2x_0\geq 0,\\ fC_2A_2[x_e+e^{A_2t_m}(x_0-x_e)]=0.\end{cases}\end{aligned} \tag{15}$$

where $x_0\in R^3, t_m\in R^+$ are variables, and

$$A_2=A-fK_pC_2b,\ x_e=-Ly_bK_pA_2^{-1}b.$$

If the maximum value of (15) $y_m<y_{boundary}$, then we can easily get that $\gamma\geq\dfrac{y_{boundary}-y_m}{y_{boundary}}$.

**Remark2** Suppose that $\{t_{oni}\}$ and $\{t_{offi}\}$ $i=1,2,\cdots$ stand for the instants when the protection loop is switched on and switched off respectively, and $\{y_{2\max i}\}$ is the series formed by the peak values which $y_2(t)$ could achieve from the initial state $X(t_{offi})$ during the regulation intervals. One conclusion lies in that if $\{y_{2\max i}\}$ declines strictly when $y_1(t)>y_{r1}$, then switching must happen finite times and the finally acted loop must be the regulation loop, and the asymptotic tracking is consequently achieved.

### *B. Optimation for the Control Parameters*

The superiority of the multi-objective switching control schedule lies in that controllers corresponding to different goals could be designed separately. Take the command switching strategy proposed in this paper for an example, the control parameters of the protection loop, such as $K$, $K_p$ and $L$ are expected to be determined after the poles of the regulation loop are assigned. In other words, it is desirable that all the information of the regulation loop be available when the protected loop is under designing.

Under the asymptotic tracking condition, the three parameters mentioned above could be optimized by solving the following optimization problem:

$$\begin{aligned}&\min \quad J_{ITAE}\\ &K,K_p,L\ s.t. y_2(t)<y_{boundary},\forall t,\end{aligned} \tag{16}$$

where the performance index is chosen as the famous Integral of Time-weighted Absolute Error (ITAE) index:

$$J_{ITAE}=\int_0^\infty \tau|e(\tau)|d\tau=\int_0^\infty \tau|y_{r1}-y_1(\tau)|d\tau. \tag{17}$$

The parameters minimizing $J_{ITAE}$ of the closed-loop switched system (7)-(10) could be obtained by solving (16). With MATLAB, the powerful calculation tool, the optimization problem can be easily solved depending on pure numerical methods [10].

It is notable that if we can find a group of parameters corresponding to the minimum $J_{ITAE}$, then we have $J_{ITAE}<\infty$, and we have

$$\lim_{t\to\infty} t|y_{r1}-y_1(t)|=0, \tag{18}$$

which implies the conclusion of asymptotic tracking.

### *C. Simulation Researches*

According to the identification to the hypersonic air-breathing propulsion, the four time constants can be determined as followed:

$$T_1=0.4, T_2=0.15, T_3=0.3, T_4=0.15,$$

and we choose $y_{r1}=1, f=1$.

First of all, according to the rapidity requirement, we assign the poles of the regulation loop at $\lambda_{1,2,3,4}=-36$, resulted performance index is $J_{ITAE}=0.0101$, and as is shown in Figure 2, the corresponding trajectory of the protected output $y_2(t)$ goes through the given safety boundary $y_{boundary}=2$, which is not permissible for the safety demand.

The designing of the protection loop is thus necessary, and a group of permitted control parameters of the protection loop and that of the switching law are worked out according to the conditions in Theorem 1:

$$L=-19.5, K=15, K_p=20, \gamma_{on}=0.1, \gamma_{off}=0.11.$$

Figure 3 verifies the effectiveness of Theorem 1.

Moreover, the indices reflecting the performance can be obtained: controlled by the command switching controller, the maximum value of the protected output $y_2(t)$ is reduced to 1.9748, and the corresponding 2% error setting time of the regulated output $y_1(t)$ is $t_s=0.4168s$, and $J_{ITAE}=0.0122$.

It can also be seen from Figure 3 that when $y_1(t)<y_{r1}$, the output of the integrator $q$ is an increasing positive variable no matter which loop is switched on, which makes $y_1(t)$ rise during the regulation intervals, and the regulated output will go through its reference signal since $q$ increases even more quickly during the protection intervals according to (8). After the moment when $y_1(t)>y_{r1}$, during the regulation interval, the positive $q$ will lead $y_1(t)$ to rise, and the declining of the candidate Lyapunov function depicted as condition (12) limits the falling amplitude of $y_1(t)$ during the protection interval, which makes the assumption of achievement of $y_1(t)>y_{r1}$ in finite time used in Theorem1 possible under proper parameters. The curve of the regulated output in Figure 3 could illustrate this assumption.

What can also be illustrated by Figure 3 is the condition of the strict decline of $\{y_{2\max i}\}$ when $y_1(t) > y_{r1}$, as is mentioned in Remark2. After the instant when $y_1(t) > y_{r1}$, the decreasing $q$ leading to the decreasing control input may bring us the declining $\{y_{2\max i}\}$ as long as the positive feedback force during the protection interval is not quite large.

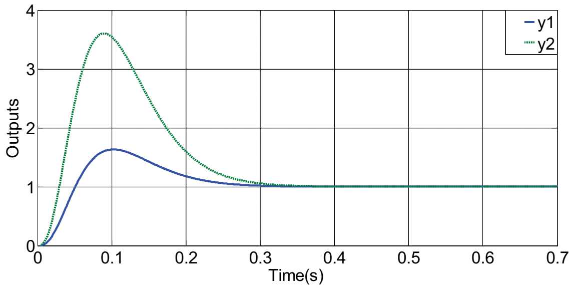

Figure 2. Curves of the regulated output and the protected output under single controller.

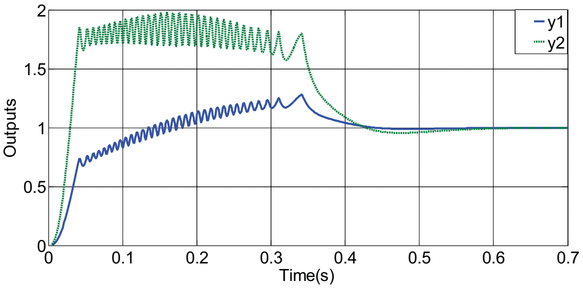

Figure 3. The improvement to the safety performance by the command switching control based on the safety margin.

Of course, replacing the poles of the closed loop nearer to the image axis could also reduce the peak value of the protected output $y_2(t)$, however, this will complicate the design procedure of the controller. And now we try to pull down the peak value of the protected output by replacing the poles in proportion, when the poles are assigned at $\lambda_{1,2,3,4} = -17.7$, as is shown in Figure 4, the peak value of $y_2(t)$ is 1.9911, and $t_s$ is 0.5018s, $J_{ITAE} = 0.0287$.

It could be deduced that pulling down the peak value of $y_2(t)$ to a lower level will make the setting time of the regulated output even longer, which indicates the superiority of the proposed command switching strategy.

To get better performance, we choose

$$L = -19.5, K = 15, K_p = 20$$

as the initial value of the control parameters and solve the optimization problem (16) to search parameters which can minimize the performance index $J_{ITAE}$ using the method introduced in [10], the obtained optimal control parameters are:

$$\begin{bmatrix} L & K & K_p \end{bmatrix} = \begin{bmatrix} -89.2672 & 61.7672 & 15.2793 \end{bmatrix},$$

the corresponding performance index is $J_{ITAE} = 0.0092$, and the curves are shown in Figure 5.

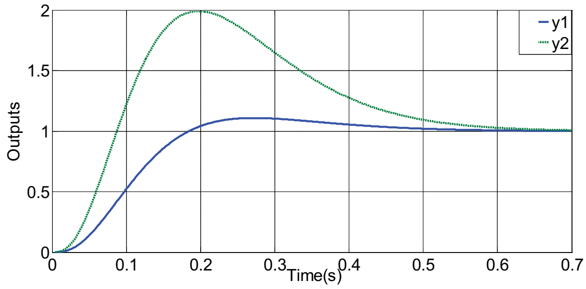

Figure 4. The improvement to the safety performance by replacing the poles of the closed loop nearer to the image axis.

It can be seen that under proper control parameters, the ITAE performance of a system using the command switching controller might be better than that of a system controlled by the single controller with the similar safety performance, and that under optimized control parameters, the ITAE performance of a system using the command switching controller could even be better than that of the single controller controlled system with the same regulation loop parameters (but without the permitted safety performances).

## IV. CONCLUSIONS

This paper investigated the output regulation/ safety protection switching control problem for the simplified aeroengine model. Focusing on the safety boundaries existing during the working progressing, the command switching strategy based on the safety margin are adopted and the scheme mentioned in our previous work is modified in several aspects to get better performances. A dynamical state feedback controller and a proportional protection controller switch in a hysteresis way to balance the regulation and the safety demands. The principles guaranteeing the asymptotic tracking in a safe way asymptotic tracking are proposed. The control

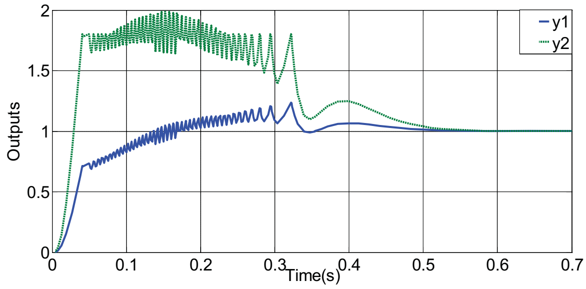

Figure 5. The improvement to the safety performance by the command switching control under the optimized control parameters.

parameters could be calculated by solving optimal problems and could be optimized to obtain some best performance indices. Finally, simulation researches are performed to verify the effectiveness of the given results. It also can be indicated through simulation researches that the commands switching controller bring more improvement in both safety margin and the ITAE index than the single controller.

# Inverse Optimal Robust Control of Singularly Impulsive Dynamical Systems

Dr. Nataša A. Kablar and Vlada Kvrgić

*Abstract*— **In this paper for the class of nonlinear uncertain singularly impulsive dynamical systems we present optimal robust control and inverse robust optimal control results. We consider a control problem for nonlinear uncertain singularly impulsive dynamical systems involving a notion of optimality with respect to an *auxiliary cost* which guarantees a bound on the worst-case value of a nonlinear-nonquadratic hybrid cost criterion over a prescribed uncertainty set. Further we specialize result to affine uncertain systems to obtain controllers predicated on an *inverse optimal hybrid control problem*. In particular, to avoid the complexity in solving the steady-state hybrid Hamilton-Jacobi-Bellman equation we parameterize a family of stabilizing hybrid controllers that minimize some *derived* hybrid cost functional that provides flexibility in specifying the control law. The performance integrand is shown to explicitly depend on the nonlinear singularly impulsive system dynamics, the Lyapunov function of the closed-loop system, and the stabilizing hybrid feedback control law wherein the coupling is introduced via the hybrid Hamilton-Jacobi-Bellman equation. By varying the parameters in the Lyapunov function and the performance integrand, the proposed framework can be used to characterize a class of globally stabilizing hybrid controllers that can meet the closed-loop system response constraints. Obtained results for nonlinear case are further specialized to linear singularly impulsive dynamical systems with polynomial and multilinear performance functional.**

*Index Terms*— **mathematical model, singularly impulsive dynamical systems, optimal robust control, inverse optimal robust control**

## I. Introduction

For the class of nonlinear uncertain singularly impulsive dynamical systems presented in [2], we have developed robust stability results in [7]. In this paper we give optimal robust control and inverse robust optimal control results. For that purpose, we generalize results developed in [3]. We consider a control problem for nonlinear uncertain singularly impulsive dynamical systems involving a notion of optimality with respect to an *auxiliary cost* which guarantees a bound on the worst-case value of a nonlinear-nonquadratic hybrid cost criterion over a prescribed uncertainty set. Further we specialize result to affine uncertain systems to obtain controllers predicated on an *inverse optimal hybrid control problem*. In particular, to avoid the complexity in solving the steady-state hybrid Hamilton-Jacobi-Bellman equation we parameterize a family of stabilizing hybrid controllers that minimize some *derived* hybrid cost functional that provides flexibility in specifying the control law. Obtained results for nonlinear case are further specialized to linear singularly impulsive dynamical systems with polynomial and multilinear performance functional.

Finally, in this paper we use the following standard notation. Let $\mathbb{R}$ denote the set of real numbers, let $\mathcal{N}$ denote the set of nonnegative integers, let $\mathbb{R}^n$ denote the set of $n\times 1$ real column vectors, let $\mathbb{R}^{n\times m}$ denote the set of $n\times m$ real matrices, let $\mathbb{S}^n$ denote the set of $n\times n$ symmetric matrices, and let $\mathbb{N}^n$ (resp., $\mathbb{P}^n$) denote the set of $n\times n$ nonnegative (resp., positive) definite matrices, and let $I_n$ or $I$ denote the $n\times n$ identity matrix. Furthermore, $A\geq 0$ (resp., $A>0$) denotes the fact that the Hermitian matrix is nonnegative (resp., positive) definite and $A\geq B$ (resp., $A>B$) denotes the fact that $A-B\geq 0$ (resp., $A-B>0$). In addition, we write $V'(x)$ for the Fréchet derivative of $V(\cdot)$ at x. Finally, let $\mathrm{C}^0$ denote the set of continuous functions and $\mathrm{C}^\mathrm{r}$ denote the set of functions with $r$ continuous derivatives.

## II. Optimal Robust Control for Nonlinear Uncertain Singularly Impulsive Dynamical Systems

In this section we consider a control problem for nonlinear uncertain singularly impulsive dynamical systems involving a notion of optimality with respect to an *auxiliary cost* which guarantees a bound on the worst-case value of a nonlinear-nonquadratic hybrid cost criterion over a prescribed uncertainty set. The optimal robust hybrid time-invariant feedback controllers are derived as a direct consequence of Theorem 2.1 given in [7] and provide a generalization of the Hamilton-Jacobi-Bellman conditions for state-dependent singularly impulsive dynamical systems with optimality notions over the infinite horizon with an infinite number of resetting times, for addressing robust feedback controllers of nonlinear uncertain singularly impulsive dynamical systems. To address robust optimal control problem let $\mathcal{D}\subset\mathbb{R}^n$ be an open set with $0\in\mathcal{D}$, and let $\mathcal{C}_\mathrm{c}\subset\mathbb{R}^{m_\mathrm{c}}$, $\mathcal{C}_\mathrm{d}\subset\mathbb{R}^{m_\mathrm{d}}$, where $0\in\mathcal{C}_\mathrm{c}$ and $0\in\mathcal{C}_\mathrm{d}$. Furthermore, let $\mathcal{F}_\mathrm{c}\subset\{F_\mathrm{c}:\mathcal{D}\times\mathcal{C}_\mathrm{c}\to\mathbb{R}^n : F_\mathrm{c}(0,0)=0\}$, and $\mathcal{F}_\mathrm{d}\subset\{F_\mathrm{d}:\mathcal{D}\times\mathcal{C}_\mathrm{d}\to\mathbb{R}^n : F_\mathrm{d}(0,0)=0\}$. For simplicity of exposition, we also define $(F_\mathrm{c}(\cdot,\cdot),F_\mathrm{d}(\cdot,\cdot))\in\mathcal{F}_\mathrm{c}\times\mathcal{F}_\mathrm{d}\triangleq\mathcal{F}$. Next, consider the nonlinear uncertain singularly impulsive controlled dynamical system

$$
\begin{aligned}
E_\mathrm{c}\dot{x}(t) &= F_\mathrm{c}(x(t),u_\mathrm{c}(t)),\quad x(0)=0,\quad x(t)\notin\mathcal{Z}_x,\\
&\qquad\qquad u_\mathrm{c}(t)\in\mathcal{U}_\mathrm{c}, \qquad \text{(II.1)}\\
E_\mathrm{d}\Delta x(t) &= F_\mathrm{d}(x(t),u_\mathrm{d}(t)),\quad x(t)\in\mathcal{Z}_x,\\
&\qquad\qquad u_\mathrm{d}(t)\in\mathcal{U}_\mathrm{d}, \qquad \text{(II.2)}
\end{aligned}
$$

where $t\geq 0$, $x(t)\in\mathcal{D}$ is the state vector, $(u_\mathrm{c}(t),u_\mathrm{d}(t_k))\in\mathcal{U}_\mathrm{c}\times\mathcal{U}_\mathrm{d}\subset\mathcal{C}_\mathrm{c}\times\mathcal{C}_\mathrm{d}$, $k\in\mathcal{N}$, is the hybrid control input,

Lola Institute, Kneza Viseslava 70a, Belgrade 11000, Serbia nkablar.ae01@gtalumni.org

where the control constraint sets $\mathcal{U}_{\rm c},\mathcal{U}_{\rm d}$ are given. We assume $(0,0)\in\mathcal{U}_{\rm c}\times\mathcal{U}_{\rm d}$, $F_{\rm c}:\mathcal{D}\times\mathcal{U}_{\rm c}\to\mathbb{R}^n$ is Lipschitz continuous and satisfies $F_{\rm c}(0,0)=0$, $F_{\rm d}:\mathcal{D}\times\mathcal{U}_{\rm d}\to\mathbb{R}^n$ is continuous and satisfies $F_{\rm d}(0,0)=0$, and $\mathcal{Z}_x\subset\mathbb{R}^n$. To address the robust optimal nonlinear hybrid feedback control problem let $\phi_{\rm c}:\mathcal{D}\to\mathcal{U}_{\rm c}$ be such that $\phi_{\rm c}(0)=0$ and let $\phi_{\rm d}:\mathcal{D}\to\mathcal{U}_{\rm d}$ be such that $\phi_{\rm d}(0)=0$. If $(u_{\rm c}(t),u_{\rm d}(t))=(\phi_{\rm c}(E_{\rm c}x(t)),\phi_{\rm d}(E_{\rm d}x(t)))$, where $x(t)$, $t\geq0$, satisfies (II.1), (II.2), then $(u_{\rm c}(\cdot),u_{\rm d}(\cdot))$ is a *hybrid feedback control*. Given the hybrid feedback control $(u_{\rm c}(t),u_{\rm d}(t))=(\phi_{\rm c}(E_{\rm c}x(t)),\phi_{\rm d}(E_{\rm d}x(t)))$, the closed-loop state-dependent singularly impulsive dynamical system has the form

$$\begin{aligned}E_{\rm c}\dot{x}(t)&=F_{\rm c}(x(t),\phi_{\rm c}(E_{\rm c}x(t))),\qquad x(0)=x_0,\\&\qquad t\geq0,\quad x(t)\notin\mathcal{Z}_x,\qquad\text{(II.3)}\\E_{\rm d}\Delta x(t)&=F_{\rm d}(x(t),\phi_{\rm d}(E_{\rm d}x(t))),\\&\qquad x(t)\in\mathcal{Z}_x,\qquad\text{(II.4)}\end{aligned}$$

for all $(F_{\rm c}(\cdot,\cdot),F_{\rm d}(\cdot,\cdot))\in\mathcal{F}$.

Next we present sufficient conditions for characterizing robust nonlinear hybrid feedback controllers that guarantee robust stability over a class of nonlinear uncertain singularly impulsive dynamical systems and minimize an auxiliary hybrid performance functional. For the statement of this result let $L_{\rm c}:\mathcal{D}\times\mathcal{U}_{\rm c}\to\mathbb{R}$, $L_{\rm d}:\mathcal{D}\times\mathcal{U}_{\rm d}\to\mathbb{R}$ and define the set of asymptotically stabilizing controllers for the nominal nonlinear singularly impulsive dynamical system $(F_{\rm c0}(\cdot,\cdot),F_{\rm d0}(\cdot,\cdot))$ by

$$\begin{aligned}\mathcal{C}(x_0)\triangleq\{(u_{\rm c}(\cdot),u_{\rm d}(\cdot))\ :\ &(u_{\rm c}(\cdot),u_{\rm d}(\cdot))\,\text{is admissible}\\&\text{and the zero solution}\,x(t)\equiv0\\&\text{to (II.1), (II.2)}\\&\text{is asymptotically stable with}\\&(F_{\rm c}(\cdot,\cdot),F_{\rm d}(\cdot,\cdot))\\&=(F_{\rm c0}(\cdot,\cdot),F_{\rm d0}(\cdot,\cdot))\}.\end{aligned}$$

Consider the nonlinear uncertain singularly impulsive dynamical system (II.1), (II.2) with hybrid performance functional

$$\begin{aligned}J(E_{\rm c}x_0,u_{\rm c}(\cdot),u_{\rm d}(\cdot))\ =\ &\int_0^\infty L_{\rm c}(E_{\rm c}x(t),u(t)){\rm d}t\\&+\sum_{k\in\mathcal{N}_{[0,\infty)}}L_{\rm d}(E_{\rm d}x(t_k),u_{\rm d}(t_k)),\qquad\text{(II.5)}\end{aligned}$$

where $(\mathcal{F}_{\rm c}(\cdot,\cdot),\mathcal{F}_{\rm d}(\cdot,\cdot))\in\mathcal{F}$ and $(u_{\rm c}(\cdot),u_{\rm d}(\cdot))$ is an admissible control. Assume there exist functions $V:\mathcal{D}\to\mathbb{R}$, $\Gamma_{\rm c}:\mathcal{D}\times\mathcal{U}_{\rm c}\to\mathbb{R}$, $\Gamma_{\rm d}:\mathcal{D}\times\mathcal{U}_{\rm d}\to\mathbb{R}$, and a hybrid control law $\phi_{\rm c}:\mathcal{D}\to\mathcal{U}_{\rm c}$ and $\phi_{\rm d}:\mathcal{D}\to\mathcal{U}_{\rm d}$, where $V(\cdot)$ is a C$^1$ function, such that

$$\begin{aligned}V(0)&=0,&&\text{(II.6)}\\V(E_{\rm c}x)&\geq0,\quad x\in\mathcal{D},\,x\neq0,&&\text{(II.7)}\\\phi_{\rm c}(0)&=0,&&\text{(II.8)}\\\phi_{\rm d}(0)&=0,&&\text{(II.9)}\\V'(E_{\rm c}x)F_{\rm c}(x,\phi_{\rm c}(x))&\leq V'(E_{\rm c}x)F_{\rm c0}(x,\phi_{\rm c}(x))\\&\quad+\Gamma_{\rm c}(x,\phi_{\rm c}(x)),\quad x\notin\mathcal{Z}_x,\quad F_{\rm c}(\cdot,\cdot)\in\mathcal{F}_{\rm c},&&\text{(II.10)}\end{aligned}$$

$$V'(E_{\rm c}x)F_{\rm c0}(x,\phi_{\rm c}(x))\ +\ \Gamma_{\rm c}(x,\phi_{\rm c}(x))<0,\ x\notin\mathcal{Z}_x,\ x\neq0,\qquad\text{(II.11)}$$

$$\begin{aligned}V(E_{\rm d}x+F_{\rm d}(x,\phi_{\rm d}(x)))\ &-\ V(E_{\rm d}x)\leq\\&V(E_{\rm d}x+F_{\rm d0}(x,\phi_{\rm d}(x)))-V(E_{\rm d}x)\\&+\Gamma_{\rm d}(x,\phi_{\rm d}(x)),\quad x\in\mathcal{Z}_x,\ F_{\rm d}(\cdot,\cdot)\in\mathcal{F}_{\rm d},\qquad\text{(II.12)}\\V(E_{\rm d}x+F_{\rm d0}(x,\phi_{\rm d}(x)))\ &-\ V(E_{\rm d}x)+\Gamma_{\rm d}(x,\phi_{\rm d}(x))\\&\leq0,\qquad x\in\mathcal{Z}_x,\qquad\text{(II.13)}\end{aligned}$$

$$\begin{aligned}H_{\rm c}(E_{\rm c}x,\phi_{\rm c}(x))&=0,\quad x\notin\mathcal{Z}_x,&&\text{(II.14)}\\H_{\rm c}(E_{\rm c}x,u_{\rm c}(x))&\geq0,\quad x\notin\mathcal{Z}_x,\ u_{\rm c}\in\mathcal{U}_{\rm c},&&\text{(II.15)}\\H_{\rm d}(E_{\rm d}x,\phi_{\rm d}(E_{\rm c}x))&=0,\quad x\in\mathcal{Z}_x,&&\text{(II.16)}\\H_{\rm d}(E_{\rm d}x,u_{\rm d}(x))&\geq0,\quad x\in\mathcal{Z}_x,\ u_{\rm d}\in\mathcal{U}_{\rm d},&&\text{(II.17)}\end{aligned}$$

where $(F_{\rm c0}(\cdot,\cdot),F_{\rm d0}(\cdot,\cdot))\in\mathcal{F}$ defines the nominal singularly impulsive dynamical system and

$$H_{\rm c}(E_{\rm c}x,u_{\rm c})\ \triangleq\ L_{\rm c}(E_{\rm c}x,u_{\rm c})+V'(E_{\rm c}x)F_{\rm c0}(x,u_{\rm c})+\Gamma_{\rm c}(x,u_{\rm c}),\qquad\text{(II.18)}$$

$$\begin{aligned}H_{\rm d}(E_{\rm d}x,u_{\rm d})\ \triangleq\ &L_{\rm d}(E_{\rm d}x,u_{\rm d})+V(E_{\rm d}x+F_{\rm d0}(x,u_{\rm d}))\\&-V(xE_{\rm d})+\Gamma_{\rm d}(x,u_{\rm d}).\qquad\text{(II.19)}\end{aligned}$$

Then, with the hybrid feedback control $(u_{\rm c}(\cdot),u_{\rm d}(\cdot))=(\phi_{\rm c}(E_{\rm c}x(\cdot)),\phi_{\rm d}(E_{\rm d}x(\cdot)))$, there exists a neighborhood of the origin $\mathcal{D}_0\subset\mathcal{D}$ such that if $x_0\in\mathcal{D}_0$, the zero solution $x(t)\equiv0$ of the closed-loop system (II.3), (II.4) is locally asymptotically stable for all $(F_{\rm c}(\cdot,\cdot),F_{\rm d}(\cdot,\cdot))\in\mathcal{F}$. Furthermore,

$$\begin{aligned}\sup_{(F_{\rm c}(\cdot,\cdot),F_{\rm d}(\cdot,\cdot))\in\mathcal{F}}\ &J(E_{\rm c}x_0,\phi_{\rm c}(E_{\rm c}x(\cdot)),\phi_{\rm d}(E_{\rm d}x(\cdot)))\\&\leq\mathcal{J}(E_{\rm c}x_0,\phi_{\rm c}(\cdot),\phi_{\rm d}(\cdot))\\&=V(E_{\rm c}x_0),\quad x_0\in\mathcal{D}_0,\qquad\text{(II.20)}\end{aligned}$$

where

$$\begin{aligned}\mathcal{J}(E_{\rm c}x_0,&u_{\rm c}(\cdot),u_{\rm d}(\cdot))\ \triangleq\\&\int_0^\infty[L_{\rm c}(E_{\rm c}x(t),u_{\rm c}(t))+\Gamma_{\rm c}(x(t),u_{\rm c}(t))]{\rm d}t\\&+\sum_{k\in\mathcal{N}_{[0,\infty)}}[L_{\rm d}(E_{\rm d}x(t_k),u_{\rm d}(t_k))+\Gamma_{\rm d}(x(t_k),u_{\rm d}(t_k))],\end{aligned}\qquad\text{(II.21)}$$

and where $(u_{\rm c}(\cdot),u_{\rm d}(\cdot))$ is an admissible control and $x(t)$, $t\geq0$, is a solution of (II.1), (II.2) with $(F_{\rm c}(x(t),u_{\rm c}(t)),F_{\rm d}(x(t),u_{\rm d}(t)))=(F_{\rm c0}(x(t),u_{\rm c}(t)),F_{\rm d0}(x(t),u_{\rm d}(t)))$. In addition, if $x_0\in\mathcal{D}_0$ then the hybrid feedback control $(u_{\rm c}(\cdot),u_{\rm d}(\cdot))=(\phi_{\rm c}(E_{\rm c}x(\cdot)),\phi_{\rm d}(E_{\rm d}x(\cdot)))$ minimizes $J(E_{\rm c}x_0,u_{\rm c}(\cdot),u_{\rm d}(\cdot))$ in the sense that

$$\begin{aligned}&J(E_{\rm c}x_0,\phi_{\rm c}(E_{\rm c}x(\cdot)),\phi_{\rm d}(E_{\rm d}x(\cdot)))=\\&\min\nolimits_{(u_{\rm c}(\cdot),u_{\rm d}(\cdot))\in\mathcal{C}(x_0)}J(E_{\rm c}x_0,u_{\rm c}(\cdot),u_{\rm d}(\cdot)).\qquad\text{(II.22)}\end{aligned}$$

Finally, if $\mathcal{D}=\mathbb{R}^n$, and

$$V(E_{\rm c/d}x)\to\infty\quad\text{as}\quad\|x\|\to\infty,\qquad\text{(II.23)}$$

then the zero solution $x(t)\equiv0$ of the closed-loop system (II.3), (II.4) is globally asymptotically stable for all $(F_{\rm c}(\cdot,\cdot),F_{\rm d}(\cdot,\cdot))\in\mathcal{F}$, [3] and [7].

*Proof:* Local and global asymptotic stability is a direct consequence of (II.6)–(II.13) by applying Theorem 2.1 of [7] to the closed-loop system (II.3), (II.4). Next, let

$(u_{\mathrm{c}}(\cdot), u_{\mathrm{d}}(\cdot)) \in \mathcal{C}(x_0)$ and let $x(\cdot)$ be the solution of (II.1), (II.2) with $(F_{\mathrm{c}}(\cdot,\cdot), F_{\mathrm{d}}(\cdot,\cdot)) = (F_{\mathrm{c}0}(\cdot,\cdot), F_{\mathrm{d}0}(\cdot,\cdot))$.

Then it follows that

$$\begin{aligned} 0 &= -\dot{V}(E_{\mathrm{c}}x(t)) + V'(E_{\mathrm{c}}x(t))F_{\mathrm{c}}(x(t), u_{\mathrm{c}}(t)),\ x(t) \notin \mathcal{Z}_x, && \text{(II.24)} \\ 0 &= -\Delta V(E_{\mathrm{d}}x(t)) + V(E_{\mathrm{d}}x + F_{\mathrm{d}}(x(t), u_{\mathrm{d}}(t))) \\ &\quad -V(E_{\mathrm{d}}x(t)), \qquad x(t) \in \mathcal{Z}_x. && \text{(II.25)} \end{aligned}$$

Hence,

$$\begin{aligned} L_{\mathrm{c}}(E_{\mathrm{c}}x(t), u_{\mathrm{c}}(t)) + \Gamma_{\mathrm{c}}(E_{\mathrm{c}}\tilde{x}(t), u_{\mathrm{c}}(t)) \ &= \\ -\dot{V}(E_{\mathrm{c}}x(t)) + L_{\mathrm{c}}(E_{\mathrm{c}}x(t), u_{\mathrm{c}}(t)) & \\ +V'(E_{\mathrm{c}}x(t))F_{\mathrm{c}0}(x(t), u_{\mathrm{c}}(t)) + \Gamma_{\mathrm{c}}(E_{\mathrm{c}}\tilde{x}(t), u_{\mathrm{c}}(t)) & \\ = -\dot{V}(E_{\mathrm{c}}x(t)) + H_{\mathrm{c}}(E_{\mathrm{c}}x(t), u_{\mathrm{c}}(t)), & \\ x(t) \notin \mathcal{Z}_x. & \qquad \text{(II.26)} \end{aligned}$$

Similarly,

$$\begin{aligned} L_{\mathrm{d}}(E_{\mathrm{d}}x(t), u_{\mathrm{d}}(t)) + \Gamma_{\mathrm{d}}(x(t), u_{\mathrm{d}}(t)) \ &= \\ -\Delta V(E_{\mathrm{d}}x(t)) + L_{\mathrm{d}}(E_{\mathrm{d}}x(t), u_{\mathrm{d}}(t)) & \\ +\Delta V(E_{\mathrm{d}}x(t)) + \Gamma_{\mathrm{d}}(x(t), u_{\mathrm{d}}(t)) & \\ = -\Delta V(E_{\mathrm{d}}x(t)) + H_{\mathrm{d}}(E_{\mathrm{d}}x(t), u_{\mathrm{d}}(t)), & \\ x(t) \in \mathcal{Z}_x. & \qquad \text{(II.27)} \end{aligned}$$

Now, over the interval $[0, t)$ yields

$$\begin{aligned} &\int_0^t [L_{\mathrm{c}}(E_{\mathrm{c}}x(t), u_{\mathrm{c}}(t)) \quad + \quad \Gamma_{\mathrm{c}}(\tilde{x}(t), u_{\mathrm{c}}(t))]\mathrm{d}t \\ &+ \sum_{k \in \mathcal{N}_{[0,t)}} [L_{\mathrm{d}}(E_{\mathrm{d}}x(t_k), u_{\mathrm{d}}(t_k)) + \Gamma_{\mathrm{d}}(x(t_k), u_{\mathrm{d}}(t_k))] \\ &= \int_0^t [-\dot{V}(E_{\mathrm{c}}x(t)) + H_{\mathrm{c}}(x(t), u_{\mathrm{c}}(t))]\mathrm{d}t \\ &+ \sum_{k \in \mathcal{N}_{[0,t)}} [-\Delta V(E_{\mathrm{d}}x(t_k)) + H_{\mathrm{d}}(E_{\mathrm{d}}x(t_k), u_{\mathrm{d}}(t_k))] \\ &= -V(E_{\mathrm{c}}x(t)) + V(E_{\mathrm{c}}x_0) + \int_0^t H_{\mathrm{c}}(E_{\mathrm{c}}x(t), u_{\mathrm{c}}(t))\mathrm{d}t \\ &+ \sum_{k \in \mathcal{N}_{[0,t)}} H_{\mathrm{d}}(E_{\mathrm{d}}x(t_k), u_{\mathrm{d}}(t_k)) \\ &\geq V(E_{\mathrm{c}}x_0) \\ &= \mathcal{J}(E_{\mathrm{c}}x_0, \phi_{\mathrm{c}}(x(\cdot)), \phi_{\mathrm{d}}(x(\cdot))). \qquad \text{(II.28)} \end{aligned}$$

Letting $t \to \infty$ and noting that $V(E_{\mathrm{c/d}}x(t)) \to 0$ for all $x_0 \in \mathcal{D}_0$ yields (II.22). □

Next, we specialize Theorem II to linear uncertain singularly impulsive dynamical systems. Specifically, in this case we consider $\mathcal{F} \triangleq \mathcal{F}_{\mathrm{c}} \times \mathcal{F}_{\mathrm{d}}$ to be the set of uncertain linear singularly impulsive dynamical systems, where

$$\begin{aligned} \mathcal{F}_{\mathrm{c}} &= \{(A_{\mathrm{c}} + \Delta A_{\mathrm{c}})x + B_{\mathrm{c}}u_{\mathrm{c}} : x \in \mathbb{R}^n, A_{\mathrm{c}} \in \mathbb{R}^{n\times n}, \\ &\quad B_{\mathrm{c}} \in \mathbb{R}^{n\times m_{\mathrm{c}}}, \Delta A_{\mathrm{c}} \in \boldsymbol{\Delta}_{A_{\mathrm{c}}}\}, \\ \mathcal{F}_{\mathrm{d}} &= \{(A_{\mathrm{d}} + \Delta A_{\mathrm{d}} - E_{\mathrm{d}})x + B_{\mathrm{d}}u_{\mathrm{d}} : x \in \mathbb{R}^n, A_{\mathrm{d}} \in \mathbb{R}^{n\times n}, \\ &\quad B_{\mathrm{d}} \in \mathbb{R}^{n\times m_{\mathrm{d}}}, \Delta A_{\mathrm{d}} \in \boldsymbol{\Delta}_{A_{\mathrm{d}}}\}, \end{aligned}$$

where $\boldsymbol{\Delta}_{A_{\mathrm{c}}}, \boldsymbol{\Delta}_{A_{\mathrm{d}}} \subset \mathbb{R}^{n\times n}$, are given bounded uncertainty sets of uncertain perturbations $\Delta A_{\mathrm{c}}, \Delta A_{\mathrm{d}}$ of the nominal system matrices $A_{\mathrm{c}}, A_{\mathrm{d}}$, such that $0 \in \boldsymbol{\Delta}_{A_{\mathrm{c}}}$ and $0 \in \boldsymbol{\Delta}_{A_{\mathrm{d}}}$. For simplicity of exposition, we also define $(\Delta A_{\mathrm{c}}, \Delta A_{\mathrm{d}}) \in \boldsymbol{\Delta}_{A\mathrm{c}} \times \boldsymbol{\Delta}_{A\mathrm{d}} \triangleq \boldsymbol{\Delta}$. For the following result let $R_{\mathrm{c}1} \in \mathbb{P}^n$, $R_{\mathrm{c}2} \in \mathbb{P}^{m_{\mathrm{c}}}$, $R_{\mathrm{d}1} \in \mathbb{N}^n$, $R_{\mathrm{d}2} \in \mathbb{N}^{m_{\mathrm{d}}}$ be given.

Consider the linear state-dependent uncertain singularly impulsive controlled dynamical system

$$\begin{aligned} E_{\mathrm{c}}\dot{x}(t) &= (A_{\mathrm{c}} + \Delta A_{\mathrm{c}})x(t) + B_{\mathrm{c}}u_{\mathrm{c}}(t), \quad x(0) = x_0, \\ &\qquad t \geq 0, \quad x(t) \notin \mathcal{Z}, \qquad \text{(II.29)} \\ E_{\mathrm{d}}\Delta x(t) &= (A_{\mathrm{d}} + \Delta A_{\mathrm{d}} - E_{\mathrm{d}})x(t) + B_{\mathrm{d}}u_{\mathrm{d}}(t),\ x(t) \in \mathcal{Z}, \\ &\qquad \text{(II.30)} \end{aligned}$$

with performance functional

$$\begin{aligned} &J_{\Delta A_{\mathrm{c}}, \Delta A_{\mathrm{d}}}(E_{\mathrm{c}}x_0, u_{\mathrm{c}}(\cdot), u_{\mathrm{d}}(\cdot)) \triangleq \\ &\quad \int_0^\infty [x^{\mathrm{T}}(t)E_{\mathrm{c}}^{\mathrm{T}}R_{\mathrm{c}1}E_{\mathrm{c}}x(t) + u_{\mathrm{c}}^{\mathrm{T}}(t)R_{\mathrm{c}2}u_{\mathrm{c}}(t)]\mathrm{d}t \\ &\quad + \sum_{k \in \mathcal{N}_{[0,\infty)}} [x^{\mathrm{T}}(t_k)E_{\mathrm{d}}^{\mathrm{T}}R_{\mathrm{d}1}E_{\mathrm{d}}x(t_k) + u_{\mathrm{d}}^{\mathrm{T}}(t_k)R_{\mathrm{d}2}u_{\mathrm{d}}(t_k)], \\ &\qquad \text{(II.31)} \end{aligned}$$

where $(u_{\mathrm{c}}(\cdot), u_{\mathrm{d}}(\cdot))$ is admissible, $(\Delta A_{\mathrm{c}}, \Delta A_{\mathrm{d}}) \in \boldsymbol{\Delta}$. Furthermore, assume there exist $P \in \mathbb{P}^n$, $\Omega_{\mathrm{c}} : \mathbb{P}^n \to \mathbb{N}^n$, $\Omega_{\mathrm{d}xx} : \mathbb{P}^n \to \mathbb{N}^n$, $\Omega_{\mathrm{d}xu_{\mathrm{d}}} : \mathbb{N}^n \to \mathbb{R}^{n\times m_{\mathrm{d}}}$, and $\Omega_{\mathrm{d}u_{\mathrm{d}}u_{\mathrm{d}}} : \mathbb{N}^n \to \mathbb{N}^{m_{\mathrm{d}}}$, such that

$$\begin{aligned} x^{\mathrm{T}}(\Delta A_{\mathrm{c}}^{\mathrm{T}}E_{\mathrm{c}}^{\mathrm{T}}P + P\Delta A_{\mathrm{c}}E_{\mathrm{c}})x &\leq x^{\mathrm{T}}E_{\mathrm{c}}^{\mathrm{T}}\Omega_{\mathrm{c}}(P)E_{\mathrm{c}}x, \\ x \notin \mathcal{Z}, \quad \Delta A_{\mathrm{c}} &\in \boldsymbol{\Delta}_{A\mathrm{c}}, \qquad \text{(II.32)} \end{aligned}$$

$$\begin{aligned} &x^{\mathrm{T}}(\Delta A_{\mathrm{d}}^{\mathrm{T}}PA_{\mathrm{d}} + A_{\mathrm{d}}^{\mathrm{T}}P\Delta A_{\mathrm{d}} - \Delta A_{\mathrm{d}}PB_{\mathrm{d}}(R_{\mathrm{d}2} \\ &\quad +B_{\mathrm{d}}^{\mathrm{T}}PB_{\mathrm{d}} + \Omega_{\mathrm{d}u_{\mathrm{d}}u_{\mathrm{d}}}(P))^{-1} \\ &\quad (B_{\mathrm{d}}^{\mathrm{T}}PA_{\mathrm{d}} + E_{\mathrm{d}}^{\mathrm{T}}\Omega_{\mathrm{d}xu_{\mathrm{d}}}^{\mathrm{T}}(P)E_{\mathrm{d}}) - (B_{\mathrm{d}}^{\mathrm{T}}PA_{\mathrm{d}} \\ &\quad +\Omega_{\mathrm{d}xu_{\mathrm{d}}}^{\mathrm{T}}(P))^{\mathrm{T}}(R_{\mathrm{d}2} + B_{\mathrm{d}}^{\mathrm{T}}PB_{\mathrm{d}} + \Omega_{\mathrm{d}u_{\mathrm{d}}u_{\mathrm{d}}}(P))^{-1} \\ &\quad B_{\mathrm{d}}^{\mathrm{T}}P\Delta A_{\mathrm{d}} + \Delta A_{\mathrm{d}}^{\mathrm{T}}P\Delta A_{\mathrm{d}})x \leq x^{\mathrm{T}}(E_{\mathrm{d}}^{\mathrm{T}}\Omega_{\mathrm{d}xx}(P)E_{\mathrm{d}}^{\mathrm{T}} \\ &\quad -\Omega_{\mathrm{d}xu_{\mathrm{d}}}(P) \\ &\quad (R_{\mathrm{d}2}+B_{\mathrm{d}}^{\mathrm{T}}PB_{\mathrm{d}} + \Omega_{\mathrm{d}u_{\mathrm{d}}u_{\mathrm{d}}}(P))^{-1} \\ &\quad (B_{\mathrm{d}}^{\mathrm{T}}PA_{\mathrm{d}}+\Omega_{\mathrm{d}xu_{\mathrm{d}}}^{\mathrm{T}}(P)) \\ &\quad -(B_{\mathrm{d}}^{\mathrm{T}}P+\Omega_{\mathrm{d}xu_{\mathrm{d}}}^{\mathrm{T}}(P))^{\mathrm{T}}(R_{\mathrm{d}2} + B_{\mathrm{d}}^{\mathrm{T}}PB_{\mathrm{d}} + \Omega_{\mathrm{d}u_{\mathrm{d}}u_{\mathrm{d}}}(P))^{-1} \\ &\quad \Omega_{\mathrm{d}xu_{\mathrm{d}}}^{\mathrm{T}}(P) \\ &\quad +(B_{\mathrm{d}}^{\mathrm{T}}PA_{\mathrm{d}} + \Omega_{\mathrm{d}xu_{\mathrm{d}}}^{\mathrm{T}}(P))^{\mathrm{T}}(R_{\mathrm{d}2} + B_{\mathrm{d}}^{\mathrm{T}}PB_{\mathrm{d}}+ \\ &\quad \Omega_{\mathrm{d}u_{\mathrm{d}}u_{\mathrm{d}}}(P))^{-1} \\ &\quad \cdot\Omega_{\mathrm{d}u_{\mathrm{d}}u_{\mathrm{d}}}(P)(R_{\mathrm{d}2} + B_{\mathrm{d}}^{\mathrm{T}}PB_{\mathrm{d}} \\ &\quad +\Omega_{\mathrm{d}u_{\mathrm{d}}u_{\mathrm{d}}}(P))^{-1}(B_{\mathrm{d}}^{\mathrm{T}}PA_{\mathrm{d}} + \Omega_{\mathrm{d}xu_{\mathrm{d}}}^{\mathrm{T}}(P)))x, \\ &\quad x \in \mathcal{Z}, \\ &\quad \Delta A_{\mathrm{d}} \in \boldsymbol{\Delta}_{A\mathrm{d}}. \qquad \text{(II.33)} \end{aligned}$$

Furthermore, suppose there exists $P \in \mathbb{P}^n$ satisfying

$$\begin{aligned} 0 &= x^{\mathrm{T}}(A_{\mathrm{c}}^{\mathrm{T}}PE_{\mathrm{c}} + E_{\mathrm{c}}^{\mathrm{T}}PA_{\mathrm{c}} + E_{\mathrm{c}}^{\mathrm{T}}R_{\mathrm{c}1}E_{\mathrm{c}} + \Omega_{\mathrm{c}}(P) - \\ &\quad PB_{\mathrm{c}}R_{\mathrm{c}2}^{-1}B_{\mathrm{c}}^{\mathrm{T}}P)E_{\mathrm{c}}x, \qquad x \notin \mathcal{Z}, && \text{(II.34)} \\ 0 &< R_{\mathrm{d}2} + B_{\mathrm{d}}^{\mathrm{T}}PB_{\mathrm{d}} + \Omega_{\mathrm{d}u_{\mathrm{d}}u_{\mathrm{d}}}(P), && \text{(II.35)} \\ 0 &= x^{\mathrm{T}}(A_{\mathrm{d}}^{\mathrm{T}}PA - E_{\mathrm{d}}^{\mathrm{T}}PE_{\mathrm{d}} + E_{\mathrm{d}}^{\mathrm{T}}R_{\mathrm{d}1}E_{\mathrm{d}} \\ &\quad +\Omega_{\mathrm{d}xx}(P) - (B_{\mathrm{d}}^{\mathrm{T}}PA_{\mathrm{d}} + \Omega_{\mathrm{d}xu_{\mathrm{d}}}^{\mathrm{T}}(P))^{\mathrm{T}} \\ &\quad (R_{\mathrm{d}2} + B_{\mathrm{d}}^{\mathrm{T}}PB_{\mathrm{d}} + \Omega_{\mathrm{d}u_{\mathrm{d}}u_{\mathrm{d}}}(P))^{-1} \\ &\quad \cdot(B_{\mathrm{d}}^{\mathrm{T}}PA_{\mathrm{d}} + \Omega_{\mathrm{d}xu_{\mathrm{d}}}^{\mathrm{T}}(P)))x, \\ &\qquad x \in \mathcal{Z}. && \text{(II.36)} \end{aligned}$$

Then, with hybrid feedback control $(u_{\rm c}, u_{\rm d}) = (\phi_{\rm c}(x), \phi_{\rm d}(x)) = (-R_{{\rm c}2}^{-1} B_{\rm c}^{\rm T} P E_{\rm c} x,\ -(R_{{\rm d}2} + B_{\rm d}^{\rm T} P B_{\rm d} + \Omega_{{\rm d}u_{\rm d}u_{\rm d}}(P))^{-1}(B_{\rm d}^{\rm T} P A_{\rm d} + \Omega_{{\rm d}xu_{\rm d}}^{\rm T}(P))x)$ the zero solution $x(t) \equiv 0$ to (II.29), (II.30) is globally asymptotically stable for all $x_0 \in \mathbb{R}^n$, $(\Delta A_{\rm c}, \Delta A_{\rm d}) \in \boldsymbol{\Delta}_{A{\rm c}} \times \boldsymbol{\Delta}_{A{\rm d}}$ and

$$\sup_{(\Delta_{\rm c},\Delta_{\rm d})\in\boldsymbol{\Delta}} J_{(\Delta A_{\rm c},\Delta A_{\rm d})}(E_{\rm c}x_0) \leq \mathcal{J}(E_{\rm c}x_0, \phi_{\rm c}(\cdot), \phi_{\rm d}(\cdot)) = x_0^{\rm T} E_{\rm c}^{\rm T} P E_{\rm c} x_0, \quad x_0 \in \mathbb{R}^n, \tag{II.37}$$

where

$$\begin{aligned}\mathcal{J}(E_{\rm c}x_0, u_{\rm c}(\cdot), u_{\rm d}(\cdot)) &\triangleq \int_0^\infty [x^{\rm T}(t)E_{\rm c}^{\rm T}R_{{\rm c}1}E_{\rm c}x(t) \\ &+u_{\rm c}^{\rm T}(t)R_{{\rm c}2}u_{\rm c}(t) + x^{\rm T}(t)\Omega_{\rm c}(P)x(t)]{\rm d}t \\ &+ \sum_{k\in\mathcal{N}_{[0,\infty)}} [x^{\rm T}(t_k)E_{\rm d}^{\rm T}R_{{\rm d}1}E_{\rm d}x(t_k) \\ &+u_{\rm d}^{\rm T}(t_k)R_{{\rm d}2}u_{\rm d}(t_k) + x^{\rm T}(t_k)\Omega_{{\rm d}xx}(P)x(t_k) \\ &+2x^{\rm T}(t_k)\Omega_{{\rm d}xu_{\rm d}}(P)u_{\rm d}(t_k) + u_{\rm d}^{\rm T}(t_k) \\ &\cdot\Omega_{{\rm d}u_{\rm d}u_{\rm d}}(P)u_{\rm d}(t_k)],\end{aligned} \tag{II.38}$$

(II.39)

and where $(u_{\rm c}, u_{\rm d})$ is admissible and $x(t)$, $t \geq 0$, is a solution to (II.29), (II.30) with $(\Delta A_{\rm c}, \Delta A_{\rm d}) = (0, 0)$. Furthermore,

$$\mathcal{J}(E_{\rm c}x_0, \phi_{\rm c}(x(\cdot)), \phi_{\rm d}(x(\cdot))) = min_{(u_{\rm c}(\cdot),u_{\rm d}(\cdot))\in\mathcal{C}(x_0)}\mathcal{J}(E_{\rm c}x_0, u_{\rm c}(\cdot), u_{\rm d}(\cdot)), \tag{II.40}$$

where $\mathcal{C}(x_0)$ is the set of asymptotically stabilizing hybrid controllers for the nominal singularly impulsive dynamical system and $x_0 \in \mathbb{R}^n$, [3] and [7].

*Proof:* The detailed proof is given in [7]. □

## III. Inverse Optimal Robust Control for Nonlinear Affine Uncertain Singularly Impulsive Dynamical Systems

In this section we specialize Theorem II to affine uncertain systems. The controllers obtained are predicated on an *inverse optimal hybrid control problem*. In particular, to avoid the complexity in solving the steady-state hybrid Hamilton-Jacobi-Bellman equation we do not attempt to minimize a *given* hybrid cost functional, but rather, we parametrize a family of stabilizing hybrid controllers that minimize some *derived* hybrid cost functional that provides flexibility in specifying the control law. The performance integrand is shown to explicitly depend on the nonlinear singularly impulsive system dynamics, the Lyapunov function of the closed-loop system, and the stabilizing hybrid feedback control law wherein the coupling is introduced via the hybrid Hamilton-Jacobi-Bellman equation. Hence, by varying the parameters in the Lyapunov function and the performance integrand, the proposed framework can be used to characterize a class of globally stabilizing hybrid controllers that can meet the closed-loop system response constraints.

Consider the state-dependent affine (in the control) uncertain singularly impulsive dynamical system

$$\begin{aligned}E_{\rm c}\dot{x}(t) &= f_{\rm c}(x(t)) + \Delta f_{\rm c}(x(t)) + G_{\rm c}(x(t))u_{\rm c}(t), \\ &\qquad x(0) = x_0,\ x(t) \notin \mathcal{Z}_x,\end{aligned} \tag{III.41}$$

$$\begin{aligned}E_{\rm d}\Delta x(t) &= f_{\rm d}(x(t)) + \Delta f_{\rm d}(x(t)) + G_{\rm d}(x(t))u_{\rm d}(t), \\ &\qquad x(t) \in \mathcal{Z}_x,\end{aligned} \tag{III.42}$$

where $t \geq 0$, $f_{{\rm c}0}, f_{{\rm d}0} : \mathcal{D} \to \mathbb{R}^n$ and satisfies $f_{{\rm c}0}(0) = 0, f_{{\rm d}0}(0) = 0$, $\mathcal{D} = \mathbb{R}^n$, $\mathcal{U}_{\rm c} = \mathcal{C}_{\rm c} = \mathbb{R}^{m_{\rm c}}$, $\mathcal{U}_{\rm d} = \mathcal{C}_{\rm d} = \mathbb{R}^{m_{\rm d}}$, and $(\Delta f_{\rm c}, \Delta f_{\rm d}) \in \mathcal{F}_{\rm c} \times \mathcal{F}_{\rm d} \triangleq \mathcal{F}$, where

$$\Delta f_{\rm c}(\cdot) \in \mathcal{F}_{\rm c} \subset \{\Delta f_{\rm c} : \mathbb{R}^n \to \mathbb{R}^n : \Delta f_{\rm c}(0) = 0\},$$
$$\Delta f_{\rm d}(\cdot) \in \mathcal{F}_{\rm d} \subset \{\Delta f_{\rm d} : \mathbb{R}^n \to \mathbb{R}^n : \Delta f_{\rm d}(0) = 0\}.$$

In this section no explicit structure is assumed for the elements of $\mathcal{F}$. Furthermore, we consider performance integrands $L_{\rm c}(E_{\rm c}x, u_{\rm c})$ and $L_{\rm d}(E_{\rm d}x, u_{\rm d})$ of the form

$$L_{\rm c}(E_{\rm c}x, u_{\rm c}) = L_{{\rm c}1}(E_{\rm c}x) + u_{\rm c}^{\rm T}R_{{\rm c}2}(x)u_{\rm c},\ x \notin \mathcal{Z}, \tag{III.43}$$
$$L_{\rm d}(E_{\rm d}x, u_{\rm d}) = L_{{\rm d}1}(E_{\rm d}x) + u_{\rm d}^{\rm T}R_{{\rm d}2}(x)u_{\rm d}, \quad x \in \mathcal{Z}, \tag{III.44}$$

where $L_{{\rm c}1} : \mathbb{R}^n \to \mathbb{R}$ and satisfies $L_{{\rm c}1}(E_{\rm c}x) \geq 0$, $x \in \mathbb{R}^n$, $R_{{\rm c}2} : \mathbb{R}^n \to \mathbb{P}^{m_{\rm c}}$, $L_{{\rm d}1} : \mathbb{R}^n \to \mathbb{R}$ and satisfies $L_{{\rm d}1}(E_{\rm d}x) \geq 0$, $x \in \mathbb{R}^n$, and $R_{{\rm d}2} : \mathbb{R}^n \to \mathbb{P}^{m_{\rm d}}$ so that (II.5) becomes

$$\begin{aligned}J(E_{\rm c}x_0, u_{\rm c}(\cdot), u_{\rm d}(\cdot)) &= \int_0^\infty [L_{{\rm c}1}(E_{\rm c}x(t)) + \\ &u_{\rm c}^{\rm T}(t)R_{{\rm c}2}(x(t))u_{\rm c}(t)]{\rm d}t + \sum_{k\in\mathcal{N}_{[0,\infty)}} [L_{{\rm d}1}(E_{\rm d}x(t_k)) \\ &+u_{\rm d}^{\rm T}(t_k)R_{{\rm d}2}(x(t_k))u_{\rm d}(t_k)].\end{aligned} \tag{III.45}$$

Consider the nonlinear uncertain controlled affine singularly impulsive system (III.41), (III.42) with performance functional (III.45). Assume there exists a $C^1$ function $V : \mathbb{R}^n \to \mathbb{R}$, and functions $P_{12} : \mathbb{R}^n \to \mathbb{R}^{1\times m_{\rm d}}$, $P_2 : \mathbb{R}^n \to \mathbb{N}^{m_{\rm d}}$, $P_{1f_{\rm d}} : \mathbb{R}^n \to \mathbb{R}^{1\times n}$, $P_{2f_{\rm d}} : \mathbb{R}^n \to \mathbb{N}^{n\times n}$, $P_{u_{\rm d}f_{\rm d}} : \mathbb{R}^n \to \mathbb{R}^{m_{\rm d}\times n}$, $\Gamma_{\rm c} : \mathbb{R}^n \to \mathbb{R}$, $\Gamma_{{\rm d}xx} : \mathbb{R}^n \to \mathbb{R}^n$, $\Gamma_{{\rm d}xu_{\rm d}} : \mathbb{R}^n \to \mathbb{R}^{1\times m_{\rm d}}$, and $\Gamma_{{\rm d}u_{\rm d}u_{\rm d}} : \mathbb{R}^n \to \mathbb{N}^{m_{\rm d}}$ such that

$$P_{12}(0) = 0, \tag{III.46}$$
$$P_{1f_{\rm d}}(0) = 0, \tag{III.47}$$
$$\Gamma_{{\rm d}xu_{\rm d}}(0) = 0, \tag{III.48}$$
$$V(0) = 0, \tag{III.49}$$
$$V(E_{\rm c}x) \geq 0, \quad x \in \mathbb{R}^n, \quad x \neq 0, \tag{III.50}$$

$$\begin{aligned}V'(E_{\rm c}x)\Delta f_{\rm c}(x) \leq \Gamma_{\rm c}(x),\ x \notin \mathcal{Z}_x, \\ \Delta f_{\rm c} \in \mathcal{F}_{\rm c},\end{aligned} \tag{III.51}$$

$$\begin{aligned}V'(E_{\rm c}x)[f_{{\rm c}0}(x) - \tfrac{1}{2}G_{\rm c}(x)R_{{\rm c}2}^{-1}(x)G_{\rm c}^{\rm T}(x)V'^{\rm T}(E_{\rm c}x)] \\ +\Gamma_{\rm c}(x) < 0, \\ x \notin \mathcal{Z}_x, \quad x \neq 0,\end{aligned} \tag{III.52}$$

$$\begin{aligned}P_{1f_{\rm d}}(x)\Delta f_{\rm d}(x) + \Delta f_{\rm d}^{\rm T}(x)P_{1f_{\rm d}}^{\rm T}(x) \\ +\Delta f_{\rm d}^{\rm T}(x)P_{2f_{\rm d}}(x)\Delta f_{\rm d}(x) + \phi_{\rm d}^{\rm T}(E_{\rm d}x)P_{u_{\rm d}f_{\rm d}}(x)\Delta f_{\rm d}(x) \\ +\Delta f_{\rm d}^{\rm T}(x)P_{u_{\rm d}f_{\rm d}}^{\rm T}(x)\phi_{\rm d}(x) \\ \leq \Gamma_{{\rm d}xx}(x) + \Gamma_{{\rm d}xu_{\rm d}}(x)\phi_{\rm d}(x) + \phi_{\rm d}^{\rm T}(x)\Gamma_{{\rm d}u_{\rm d}u_{\rm d}}(x)\phi_{\rm d}(x), \\ x \in \mathcal{Z}_x, \Delta f_{\rm d}(\cdot) \in \mathcal{F}_{\rm d},\end{aligned} \tag{III.53}$$

$$V(E_{\rm d}x+f_{\rm d0}(x))-V(E_{\rm d}x)+P_{12}(x)\phi_{\rm d}(x)+$$
$$\phi_{\rm d}(x)^{\rm T}P_2(x)\phi_{\rm d}(x)$$
$$+\Gamma_{{\rm d}xx}(x)+\Gamma_{{\rm d}xu_{\rm d}}(x)\phi_{\rm d}(x)+$$
$$\phi_{\rm d}^{\rm T}(x)\Gamma_{{\rm d}u_{\rm d}u_{\rm d}}(x)\phi_{\rm d}(x)\leq 0,\quad x\in\mathcal{Z}_x,$$

$$V(E_{\rm d}x+f_{\rm d0}(x)+G_{\rm d}(x)u_{\rm d})=V(E_{\rm d}x+f_{\rm d0}(x))$$
$$+P_{12}(x)u_{\rm d}+u_{\rm d}^{\rm T}P_2(x)u_{\rm d},$$

$$V(E_{\rm d}x+f_{\rm d0}(x)+\Delta f_{\rm d}(x)+G_{\rm d}(x)u_{\rm d})-V(E_{\rm d}x)=$$
$$V(E_{\rm d}x+f_{\rm d0}(x)+G_{\rm d}(x)u_{\rm d})-V(E_{\rm d}x)+P_{1f_{\rm d}}(x)\Delta f_{\rm d}(x)+$$
$$\Delta f_{\rm d}^{\rm T}(x)P_{1f_{\rm d}}^{\rm T}(x)+\Delta f_{\rm d}^{\rm T}(x)$$
$$\cdot P_{2f_{\rm d}}(x)\Delta f_{\rm d}(x)+u_{\rm d}^{\rm T}P_{u_{\rm d}f_{\rm d}}(x)\Delta f_{\rm d}(x)$$
$$+\Delta f_{\rm d}^{\rm T}(x)P_{u_{\rm d}f_{\rm d}}^{\rm T}(x)u_{\rm d},$$
$$x\in\mathcal{Z}_x,\quad u_{\rm d}\in\mathbb{R}^{m_{\rm d}},\Delta f_{\rm d}(\cdot)\in\mathcal{F}_{\rm d},$$

and

$$V(E_{\rm c/d}x)\to\infty \text{ as } \|x\|\to\infty. \tag{III.61}$$

Then the zero solution $x(t)\equiv 0$ to the closed-loop system

$$\begin{aligned}E_{\rm c}\dot{x}(t) &= f_{\rm c}(x(t))+\Delta f_{\rm c}(x(t))+G_{\rm c}(x(t))\phi_{\rm c}(x(t)),\\ &\qquad x(0)=x_0,\ x(t)\notin\mathcal{Z}_x, \qquad\qquad (\text{III.62})\\ E_{\rm d}\Delta x(t) &= f_{\rm d}(x(t))+\Delta f_{\rm d}(x(t))+G_{\rm d}(x(t))\phi_{\rm d}(x(t)),\\ &\qquad x(t)\in\mathcal{Z}_x, \qquad\qquad (\text{III.63})\end{aligned}$$

is globally asymptotically stable for all $(\Delta f_{\rm c},\Delta f_{\rm d})\in\mathcal{F}$ with the hybrid feedback control law

$$\begin{aligned}\phi_{\rm c}(x) &= -\tfrac{1}{2}R_{\rm c2}^{-1}(x)G_{\rm c}^{\rm T}(x)V'^{\rm T}(E_{\rm c}x),\quad x\notin\mathcal{Z}_x, \qquad (\text{III.64})\\ \phi_{\rm d}(x) &= -\tfrac{1}{2}(R_{\rm d2}(x)+P_2(x)+\Gamma_{{\rm d}u_{\rm d}u_{\rm d}}(x))^{-1}\\ &\quad\cdot(P_{12}+\Gamma_{{\rm d}xu_{\rm d}(x)})^{\rm T}(x),\ x\in\mathcal{Z}_x, \qquad (\text{III.65})\end{aligned}$$

and performance functional (III.45), satisfies

$$J(E_{\rm c}x_0,\phi_{\rm c}(x(\cdot)),\phi_{\rm d}(x(\cdot)))\ =\ \min_{(u_{\rm c}(\cdot),u_{\rm d}(\cdot))\in\mathcal{C}(x_0)} J(E_{\rm c}x_0,u_{\rm c}(\cdot),u_{\rm d}(\cdot)),\ x_0\in\mathbb{R}^n, \tag{III.66}$$

where

$$\begin{aligned}\mathcal{J}(E_{\rm c}x_0,u_{\rm c}(\cdot),u_{\rm d}(\cdot)) &\triangleq \int_0^\infty [L_{\rm c}(E_{\rm c}x(t),u_{\rm c}(t))\\ &+\Gamma_{\rm c}(\tilde{x}(t),u_{\rm c}(t))]{\rm d}t+\sum_{k\in\mathcal{N}_{[0,\infty)}}[L_{\rm d}(x(t_k),u_{\rm d}(t_k))+\\ &\Gamma_{\rm d}(x(t_k),u_{\rm d}(t_k))],\end{aligned} \tag{III.67}$$

and

$$\begin{aligned}\Gamma_{\rm c}(x,u_{\rm c}) &= \Gamma_{{\rm c}xx}(x),\quad x\notin\mathcal{Z}_x, \qquad (\text{III.68})\\ \Gamma_{\rm d}(x,u_{\rm d}) &= \Gamma_{{\rm d}xx}(x)+\Gamma_{{\rm d}xu_{\rm d}}(x)u_{\rm d}+u_{\rm d}^{\rm T}\Gamma_{{\rm d}u_{\rm d}u_{\rm d}}(x)u_{\rm d},\\ &\qquad x\in\mathcal{Z}_x, \qquad (\text{III.69})\end{aligned}$$

and where $(u_{\rm c}(\cdot),u_{\rm d}(\cdot))$ is an admissible control and $x(t)$, $t\geq 0$, is a solution of (III.41), (III.42) with $(\Delta f_{\rm c},\Delta f_{\rm d})=(0,0)$.

(III.54)In addition, the hybrid performance functional (III.67), with

$$\begin{aligned}L_{\rm c1}(E_{\rm c}x) &= \phi_{\rm c}^{\rm T}(x)R_{\rm c2}(x)\phi_{\rm c}(x)-V'(E_{\rm c}x)f_{\rm c0}(x)\\ &\quad-\Gamma_{{\rm c}xx}(x), \qquad (\text{III.70})\\ L_{\rm d1}(E_{\rm d}x) &= \phi_{\rm d}^{\rm T}(x)(R_{\rm d2}(x)+P_2(x)+\Gamma_{{\rm d}u_{\rm d}u_{\rm d}}(x))\phi_{\rm d}(x)\\ &\quad-V(E_{\rm d}x+f_{\rm d0}(x))+V(E_{\rm d}x)-\Gamma_{{\rm d}xx}(x), \qquad (\text{III.71})\end{aligned}$$

(III.55)

(III.56)

(III.57)is minimized in the sense that

(III.58)

$$\mathcal{J}(E_{\rm c}x_0,\phi_{\rm c}(E_{\rm c}x(\cdot)),\phi_{\rm d}(E_{\rm d}x(\cdot)))\ =\ \min_{(u_{\rm c}(\cdot),u_{\rm d}(\cdot))\in\mathcal{C}(x_0)}\mathcal{J}(E_{\rm c}x_0,u_{\rm c}(\cdot),u_{\rm d}(\cdot)). \tag{III.72}$$

[3] and [7].

*Proof:* The result is a direct consequence of Theorem II with $\mathcal{D}=\mathbb{R}^n$, $\mathcal{U}_{\rm c}=\mathbb{R}^{m_{\rm c}}$, $\mathcal{U}_{\rm d}=\mathbb{R}^{m_{\rm d}}$, $F_{\rm c}(x,u_{\rm c})=f_{\rm c0}(x)+\Delta f_{\rm c}(x)+G_{\rm c}(x)u_{\rm c}$, $F_{\rm c0}(x,u_{\rm c})=f_{\rm c0}(x)+G_{\rm c}(x)u_{\rm c}$, $L_{\rm c}(E_{\rm c}x,u_{\rm c})$ (III.59) given by (III.43), $\Gamma_{\rm c}(x,u_{\rm c})$ given by (III.68), for (III.60) $x\notin\mathcal{Z}_x$, $F_{\rm d}(x,u_{\rm d})=f_{\rm d0}(x)+\Delta f_{\rm d}(x)+G_{\rm d}(x)u_{\rm d}$, $F_{\rm d}(x,u_{\rm d})=f_{\rm d0}(x)+G_{\rm d}(x)u_{\rm d}$, $L_{\rm d}(E_{\rm d}x,u_{\rm d})$ given by (III.44), $\Gamma_{\rm d}(x,u_{\rm d})$ given by (III.69), for $x\in\mathcal{Z}$. Specifically, with (III.41)–(III.44), (III.68), and (III.69), the Hamiltonian have the form

$$\begin{aligned}H_{\rm c}(E_{\rm c}x,u_{\rm c}) &= L_{\rm c1}(E_{\rm c}x)+u_{\rm c}^{\rm T}R_{\rm c2}(x)u_{\rm c}\\ &\quad+V'(E_{\rm c}x)(f_{\rm c0}(x)+G_{\rm c}(x)u_{\rm c})+\Gamma_{{\rm c}xx}(x),\\ &\quad x\notin\mathcal{Z}_x,\ u_{\rm c}\in\mathcal{U}_{\rm c}, \qquad (\text{III.73})\\ H_{\rm d}(E_{\rm d}x,u_{\rm d}) &= L_{\rm d1}(E_{\rm d}x)+u_{\rm d}^{\rm T}R_{\rm d2}(x)u_{\rm d}\\ &\quad+V(E_{\rm d}x+f_{\rm d0}(x)+G_{\rm d}(x)u_{\rm d})-V(E_{\rm d}x)\\ &\quad+\Gamma_{{\rm d}xx}(x)+\Gamma_{{\rm d}xu_{\rm d}}(x)u_{\rm d}+u_{\rm d}^{\rm T}\Gamma_{{\rm d}u_{\rm d}u_{\rm d}}(x)u_{\rm d},\\ &\qquad x\in\mathcal{Z}_x,\quad u_{\rm d}\in\mathcal{U}_{\rm d}. \qquad (\text{III.74})\end{aligned}$$

Now, the hybrid feedback control law (III.64), (III.65) is obtained by setting $\frac{\partial H_{\rm c}}{\partial u_{\rm c}}=0$ and $\frac{\partial H_{\rm d}}{\partial u_{\rm d}}=0$. With (III.64) and (III.65) it follows that (III.51)–(III.60) imply (II.10)–(II.13). Next, since $V(\cdot)$ is C$^1$ and $x=0$ is a local minimum of $V(\cdot)$, it follows that $V'(0)=0$, and hence, since by assumption $P_{12}(0)=0$ and $\Gamma_{{\rm d}xu_{\rm d}}(0)=0$, it follows that $\phi_{\rm c}(0)=0$ and $\phi_{\rm d}(0)=0$ which proves (II.8), (II.9). Next, with $L_{\rm c1}(E_{\rm c}x)$ and $L_{\rm d1}(E_{\rm d}x)$ given by (III.70) and (III.71), respectively, and $\phi_{\rm c}(x)$, $\phi_{\rm d}(x)$ given by (III.64) and (III.65), (II.14) and (II.16) hold. Finally, since

$$\begin{aligned}H_{\rm c}(E_{\rm c}x,u_{\rm c}) &= H_{\rm c}(E_{\rm c}x,u_{\rm c})-H_{\rm c}(E_{\rm c}x,\phi_{\rm c}(x))\\ &= [u_{\rm c}-\phi_{\rm c}(x)]^{\rm T}R_{\rm c2}(x)[u_{\rm c}-\phi_{\rm c}(x)],\quad x\notin\mathcal{Z}_x, \qquad (\text{III.75})\\ H_{\rm d}(E_{\rm d}x,u_{\rm d}) &= H_{\rm d}(E_{\rm d}x,u_{\rm d})-H_{\rm d}(E_{\rm d}x,\phi_{\rm d}(x))\\ &= [u_{\rm d}-\phi_{\rm d}(x)]^{\rm T}(R_{\rm d2}(x)\\ &\quad+P_2(x+\Gamma_{{\rm d}u_{\rm d}u_{\rm d}}(x)))[u_{\rm d}-\phi_{\rm d}(x)],\\ &\qquad x\in\mathcal{Z}_x, \qquad (\text{III.76})\end{aligned}$$

where $R_{\rm c2}(x)>0$, $x\notin\mathcal{Z}_x$, and $R_{\rm d2}(x)+P_2(x)+\Gamma_{{\rm d}u_{\rm d}u_{\rm d}}(x)>0$, $x\in\mathcal{Z}_x$, conditions (II.15) and (II.17) hold. The result now follows as a direct consequence of Theorem II. □

## IV. Robust Nonlinear Hybrid Control with Polynomial Performance Functional

In this section we specialize the results of Section IV to linear singularly impulsive systems controlled by inverse optimal nonlinear hybrid controllers that minimize a derived polynomial cost functional. Specifically, assume $\mathcal{F} \triangleq \mathcal{F}_{\mathrm{c}} \times \mathcal{F}_{\mathrm{d}}$ to be the set of uncertain systems, where

$$\begin{aligned}\mathcal{F}_{\mathrm{c}} = \{&(A_{\mathrm{c}} + \Delta A_{\mathrm{c}})x + B_{\mathrm{c}}u_{\mathrm{c}} : x \in \mathbb{R}^n,\\ &A_{\mathrm{c}} \in \mathbb{R}^{n\times n}, B_{\mathrm{c}} \in \mathbb{R}^{n\times m_{\mathrm{c}}}, \Delta A_{\mathrm{c}} \in \mathbf{\Delta}_{A_{\mathrm{c}}}\},\end{aligned} \tag{IV.77}$$

$$\begin{aligned}\mathcal{F}_{\mathrm{d}} = \{&(A_{\mathrm{d}} + \Delta A_{\mathrm{d}})x : x \in \mathbb{R}^n,\\ &A_{\mathrm{d}} \in \mathbb{R}^{n\times n}, \Delta A_{\mathrm{d}} \in \mathbf{\Delta}_{A_{\mathrm{d}}}\},\end{aligned} \tag{IV.78}$$

where $\mathbf{\Delta}_{A_{\mathrm{c}}}, \mathbf{\Delta}_{A_{\mathrm{d}}} \subset \mathbb{R}^{n\times n}$ are given bounded uncertainty sets of uncertain perturbations $\Delta A_{\mathrm{c}}, \Delta A_{\mathrm{d}}$ of the nominal asymptotically stable system matrices $A_{\mathrm{c}}, A_{\mathrm{d}}$ such that $0 \in \mathbf{\Delta}_{A_{\mathrm{c}}}$ and $0 \in \mathbf{\Delta}_{A_{\mathrm{d}}}$. For simplicity of exposition, we also define $(\Delta A_{\mathrm{c}}, \Delta A_{\mathrm{d}}) \in \mathbf{\Delta}_{A\mathrm{c}} \times \mathbf{\Delta}_{A\mathrm{d}} \triangleq \mathbf{\Delta}$. For the results in this section we assume $u_{\mathrm{d}}(t) \equiv 0$. Furthermore, let $R_{1\mathrm{c}} \in \mathbb{P}^n$, $R_{1\mathrm{d}} \in \mathbb{N}^n$, $R_{2\mathrm{c}} \in \mathbb{P}^{m_{\mathrm{c}}}$, $\hat{R}_q, \hat{\hat{R}}_q \in \mathbb{N}^n$, $q = 2, \ldots, r$, be given, where $r$ is a positive integer, and define $S_{\mathrm{c}} \triangleq B_{\mathrm{c}}R_{2\mathrm{c}}^{-1}B_{\mathrm{c}}^{\mathrm{T}}$.

Consider the linear uncertain controlled singularly impulsive system

$$\begin{aligned}E_{\mathrm{c}}\dot{x}(t) &= (A_{\mathrm{c}} + \Delta A_{\mathrm{c}})x(t) + B_{\mathrm{c}}u_{\mathrm{c}}(t), \quad x(0) = x_0,\\ &\qquad x(t) \notin \mathcal{Z}_x,\end{aligned} \tag{IV.79}$$

$$E_{\mathrm{d}}\Delta x(t) = (A_{\mathrm{d}} + \Delta A_{\mathrm{d}} - E_{\mathrm{d}})x(t), \quad x(t) \in \mathcal{Z}_x, \tag{IV.80}$$

where $u_{\mathrm{c}}$ is admissible and $(\Delta A_{\mathrm{c}}, \Delta A_{\mathrm{d}}) \in \mathbf{\Delta}$. Let $\Omega_{\mathrm{c}}, \Omega_{\mathrm{d}} : \mathcal{N}_{\mathrm{P}} \subseteq \mathbb{S}^n \to \mathbb{N}^n$, $P \in \mathcal{N}_{\mathrm{P}}$, be such that

$$\begin{aligned}&x^{\mathrm{T}}(\Delta A_{\mathrm{c}}^{\mathrm{T}}PE_{\mathrm{c}} + E_{\mathrm{c}}^{\mathrm{T}}P\Delta A_{\mathrm{c}})x \le x^{\mathrm{T}}\Omega_{\mathrm{c}}(P)x,\\ &\qquad x \notin \mathcal{Z}, \quad \Delta A_{\mathrm{c}} \in \mathbf{\Delta}_{A\mathrm{c}},\end{aligned} \tag{IV.81}$$

$$\begin{aligned}&x^{\mathrm{T}}(\Delta A_{\mathrm{d}}^{\mathrm{T}}P\Delta A_{\mathrm{d}} + \Delta A_{\mathrm{d}}^{\mathrm{T}}PA_{\mathrm{d}} + \Delta A_{\mathrm{d}}^{\mathrm{T}}P\Delta A_{\mathrm{d}})x\\ &\le x^{\mathrm{T}}\Omega_{\mathrm{d}}(P)x, \qquad x \in \mathcal{Z}, \quad \Delta A_{\mathrm{d}} \in \mathbf{\Delta}_{A\mathrm{d}}.\end{aligned} \tag{IV.82}$$

Assume there exist $P \in \mathbb{P}^n$ and $M_q \in \mathbb{N}^n$, $q = 2, \ldots, r$, such that

$$\begin{aligned}0 &= x^{\mathrm{T}}(A_{\mathrm{c}}^{\mathrm{T}}PE_{\mathrm{c}} + E_{\mathrm{c}}^{\mathrm{T}}PA_{\mathrm{c}} + E_{\mathrm{c}}^{\mathrm{T}}R_{1\mathrm{c}}E_{\mathrm{c}} + \Omega_{\mathrm{c}}(P) - PS_{\mathrm{c}}P)x,\\ &\qquad x \notin \mathcal{Z}_x,\end{aligned} \tag{IV.83}$$

$$\begin{aligned}0 &= x^{\mathrm{T}}[(A_{\mathrm{c}} - S_{\mathrm{c}}P)^{\mathrm{T}}M_qE_{\mathrm{c}} + E_{\mathrm{c}}^{\mathrm{T}}M_q(A_{\mathrm{c}} - S_{\mathrm{c}}P) + \hat{R}_q]x,\\ &\qquad x \notin \mathcal{Z}_x, q = 2, \ldots, r,\end{aligned} \tag{IV.84}$$

$$\begin{aligned}0 &= x^{\mathrm{T}}(A_{\mathrm{d}}^{\mathrm{T}}PA_{\mathrm{d}} - E_{\mathrm{d}}^{\mathrm{T}}PE_{\mathrm{d}} + E_{\mathrm{d}}^{\mathrm{T}}R_{1\mathrm{d}}E_{\mathrm{d}} + \Omega_{\mathrm{d}}(P))x,\\ &\qquad x \in \mathcal{Z}_x,\end{aligned} \tag{IV.85}$$

$$\begin{aligned}0 &= x^{\mathrm{T}}(A_{\mathrm{d}}^{\mathrm{T}}M_qA_{\mathrm{d}} - E_{\mathrm{d}}^{\mathrm{T}}M_qE_{\mathrm{d}} + \hat{\hat{R}}_q)x,\\ &\qquad x \in \mathcal{Z}_x, q = 2, \ldots, r.\end{aligned} \tag{IV.86}$$

Then the zero solution $x(t) \equiv 0$ of the uncertain closed-loop system

$$\begin{aligned}E_{\mathrm{c}}\dot{x}(t) &= (A_{\mathrm{c}} + \Delta A_{\mathrm{c}})x(t) + B_{\mathrm{c}}\phi_{\mathrm{c}}(x(t)), \; x(0) = x_0,\\ &\qquad x(t) \notin \mathcal{Z}_x,\end{aligned} \tag{IV.87}$$

$$E_{\mathrm{d}}\Delta x(t) = (A_{\mathrm{d}} + \Delta A_{\mathrm{d}} - E_{\mathrm{d}})x(t), \qquad x(t) \in \mathcal{Z}_x, \tag{IV.88}$$

is globally asymptotically stable with the feedback control law

$$\begin{aligned}\phi_{\mathrm{c}}(x) &= -R_{2\mathrm{c}}^{-1}B_{\mathrm{c}}^{\mathrm{T}}(P + \sum_{q=2}^{r}(x^{\mathrm{T}}E_{\mathrm{c}}^{\mathrm{T}}M_qE_{\mathrm{c}}x)^{q-1}M_q)E_{\mathrm{c}}x,\\ &\qquad x \notin \mathcal{Z}_x,\end{aligned} \tag{IV.89}$$

and the performance functional (III.45) satisfies

$$\begin{aligned}&\sup_{(\Delta A_{\mathrm{c}},\Delta A_{\mathrm{d}})\in\mathbf{\Delta}} J_{\Delta A_{\mathrm{c}},\Delta A_{\mathrm{d}}}(E_{\mathrm{c}}x_0, \phi_{\mathrm{c}}(x_0))\\ &\qquad \le \mathcal{J}(E_{\mathrm{c}}x_0, \phi_{\mathrm{c}}(x_0))\\ &= x_0^{\mathrm{T}}E_{\mathrm{c}}^{\mathrm{T}}PE_{\mathrm{c}}x_0 + \sum_{q=2}^{r}\frac{1}{q}(x_0^{\mathrm{T}}E_{\mathrm{c}}^{\mathrm{T}}M_qE_{\mathrm{c}}x_0)^q, \; x_0 \in \mathbb{R}^n,\end{aligned} \tag{IV.90}$$

where

$$\begin{aligned}\mathcal{J}(E_{\mathrm{c}}x_0, u_{\mathrm{c}}(\cdot)) \triangleq &\int_0^{\infty}[L_{\mathrm{c}}(E_{\mathrm{c}}x(t), u_{\mathrm{c}}(t)) + \Gamma_{\mathrm{c}}(\tilde{x}(t), u_{\mathrm{c}}(t))]\mathrm{d}t\\ &+ \sum_{k\in\mathcal{N}_{[0,\infty)}}[L_{\mathrm{d}}(E_{\mathrm{d}}x(t_k)) + \Gamma_{\mathrm{d}}(x(t_k))],\end{aligned} \tag{IV.91}$$

and where $u_{\mathrm{c}}$ is admissible, and $x(t)$, $t \ge 0$, is a solution to (IV.79), (IV.80) with $(\Delta A_{\mathrm{c}}, \Delta A_{\mathrm{d}}) = (0, 0)$, and

$$\begin{aligned}\Gamma_{\mathrm{c}}(x, u_{\mathrm{c}}) &= x^{\mathrm{T}}(\Omega_{\mathrm{c}}(P) + \sum_{q=2}^{r}(x^{\mathrm{T}}E_{\mathrm{c}}^{\mathrm{T}}M_qE_{\mathrm{c}}x)^{q-1}\Omega_{\mathrm{c}}(M_q))E_{\mathrm{c}}x,\\ &\qquad x \notin \mathcal{Z}_x\end{aligned} \tag{IV.92}$$

$$\begin{aligned}\Gamma_{\mathrm{d}}(x) &= x^{\mathrm{T}}\Omega_{\mathrm{d}}(P)x + \sum_{q=2}^{r}\frac{1}{q}[(x^{\mathrm{T}}\hat{\hat{R}}_qx)\sum_{j=1}^{q}(x^{\mathrm{T}}E_{\mathrm{d}}^{\mathrm{T}}M_qE_{\mathrm{d}}x)^{j-1}\\ &\quad \cdot(x^{\mathrm{T}}(A_{\mathrm{d}}^{\mathrm{T}}M_qA_{\mathrm{d}} + \Omega_{\mathrm{d}}(x))x)^{q-j}\\ &\quad -(x^{\mathrm{T}}A_{\mathrm{d}}^{\mathrm{T}}M_qA_{\mathrm{d}}x)^{q-j}], \quad x \in \mathcal{Z}_x,\end{aligned} \tag{IV.93}$$

where $u_{\mathrm{c}}$ is admissible and $(\Delta A_{\mathrm{c}}, \Delta A_{\mathrm{d}}) \in \mathbf{\Delta}$. In addition, the performance functional (III.45), with $R_{2\mathrm{c}}(x) = R_{2\mathrm{c}}$ and

$$\begin{aligned}L_{1\mathrm{c}}(E_{\mathrm{c}}x) &= x^{\mathrm{T}}(E_{\mathrm{c}}^{\mathrm{T}}R_{1\mathrm{c}}E_{\mathrm{c}} + \sum_{q=2}^{r}(x^{\mathrm{T}}E_{\mathrm{c}}^{\mathrm{T}}M_qE_{\mathrm{c}}x)^{q-1}\hat{R}_q\\ &+[\sum_{q=2}^{r}(x^{\mathrm{T}}E_{\mathrm{c}}^{\mathrm{T}}M_qE_{\mathrm{c}}x)^{q-1}M_q]^{\mathrm{T}}S_{\mathrm{c}}\\ &\qquad [\sum_{q=2}^{r}(x^{\mathrm{T}}E_{\mathrm{c}}^{\mathrm{T}}M_qE_{\mathrm{c}}x)^{q-1}M_q])x,\end{aligned} \tag{IV.94}$$

$$\begin{aligned}L_{1\mathrm{d}}(E_{\mathrm{d}}x) &= x^{\mathrm{T}}E_{\mathrm{d}}^{\mathrm{T}}R_{1\mathrm{d}}E_{\mathrm{d}}x + \sum_{q=2}^{r}\frac{1}{q}[(x^{\mathrm{T}}\hat{\hat{R}}_qx)\\ &\qquad \sum_{j=1}^{q}(x^{\mathrm{T}}E_{\mathrm{d}}^{\mathrm{T}}M_qE_{\mathrm{d}}x)^{j-1}\\ &\cdot(x^{\mathrm{T}}A_{\mathrm{d}}^{\mathrm{T}}M_qA_{\mathrm{d}}x)^{q-j}],\end{aligned} \tag{IV.95}$$

is minimized in the sense that J(E$_{\mathrm{c}}x_0, \phi_{\mathrm{c}}(x(\cdot))) = \min_{u_{\mathrm{c}}(\cdot)\in\mathcal{C}(x_0)} J(E_{\mathrm{c}}x_0, u_{\mathrm{c}}(\cdot)), \quad x_0 \in \mathbb{R}^n, (IV.95)$where $\mathcal{C}(x_0)$ is the set of asymptotically stabilizing controllers for the nominal system and $x_0 \in \mathbb{R}^n$, [3] and [7].

*Proof:* The result is a direct consequence of Corollary III. □

## V. Robust Nonlinear Hybrid Control with Multilinear Performance Functional

Finally, we specialize the results of Section VI to linear singularly impulsive systems controlled by inverse optimal hybrid controllers that minimize a derived multilinear functional. First, however, we give several definitions involving multilinear forms. A scalar function $\psi : \mathbb{R}^n \to \mathbb{R}$ is $q$-*multilinear* if $q$ is a positive integer and $\psi(x)$ is a linear combination of terms of the form $x_1^{i_1}x_2^{i_2}\ldots x_n^{i_n}$, where $i_j$ is a nonnegative integer for $j = 1, \ldots, n$, and $i_1 + i_2 + \ldots + i_n = q$. Furthermore, a $q$-multilinear function $\psi(\cdot)$ is nonnegative definite (resp., positive definite) if $\psi(x) \geq 0$ for all $x \in \mathbb{R}^n$ (resp., $\psi(x) > 0$ for all nonzero $x \in \mathbb{R}^n$). Note that if $q$ is odd then $\psi(x)$ cannot be positive definite. If $\psi(\cdot)$ is a $q$-multilinear function then $\psi(\cdot)$ can be represented by means of Kronecker products, that is, $\psi(x)$ is given by $\psi(x) = \Psi x^{[q]}$, where $\Psi \in \mathbb{R}^{1\times n^q}$ and $x^{[q]} \triangleq x \otimes x \otimes \cdots \times x$ ($q$ times), where $\otimes$ denotes Kronecker product. For the next result recall the definition of $S_{\mathrm{c}}$, let $R_{1\mathrm{c}} \in \mathbb{P}^n$, $R_{1\mathrm{d}} \in \mathbb{P}^n$, $R_{2\mathrm{c}} \in \mathbb{P}^{m_{\mathrm{c}}}$, $\hat{R}_{2q}, \hat{\hat{R}}_{2q} \in \mathcal{N}^{(2q,n)}$, $q = 2, \ldots, r$, be given, where $\mathcal{N}^{(2q,n)} \triangleq \{\Psi \in \mathbb{R}^{1\times n^{2q}} : \Psi x^{[2q]} \geq 0,\ x \in \mathbb{R}^n\}$, and define the repeated ($q$ times) Kronecker sum as $\overset{q}{\oplus} A \triangleq A \oplus A \oplus \cdots \oplus A$.

Consider the linear controlled singularly impulsive system (IV.79), (IV.80). Assume there exist $P \in \mathbb{P}^n$ and $\hat{P}_q \in \mathcal{N}^{(2q,n)}$, $q = 2, \ldots, r$, such that

$$\begin{aligned} 0 &= x^{\mathrm{T}}(A_{\mathrm{c}}^{\mathrm{T}}PE_{\mathrm{c}} + E_{\mathrm{c}}^{\mathrm{T}}PA_{\mathrm{c}} + E_{\mathrm{c}}^{\mathrm{T}}R_{1\mathrm{c}}E_{\mathrm{c}} - PB_{\mathrm{c}}R_{2\mathrm{c}}^{-1}B_{\mathrm{c}}^{\mathrm{T}}P)x, \\ &\quad x \notin \mathcal{Z}_x, \qquad \text{(V.96)} \\ 0 &= x^{\mathrm{T}}(\hat{P}_q[\overset{2q}{\oplus}(E_{\mathrm{c}}^{\mathrm{T}}A_{\mathrm{c}} - S_{\mathrm{c}}P)] + \hat{R}_{2q})x, \\ &\quad x \notin \mathcal{Z}_x, \quad q = 2, \ldots, r, \qquad \text{(V.97)} \\ 0 &= x^{\mathrm{T}}(A_{\mathrm{d}}^{\mathrm{T}}PA_{\mathrm{d}} - E_{\mathrm{d}}^{\mathrm{T}}PE_{\mathrm{d}} + E_{\mathrm{d}}^{\mathrm{T}}R_{1\mathrm{d}}E_{\mathrm{d}})x, \\ &\quad x \in \mathcal{Z}_x, \qquad \text{(V.98)} \\ 0 &= x^{\mathrm{T}}(\hat{P}_q[A_{\mathrm{d}}^{[2q]} - E_{\mathrm{d}}^{[2q]}] + \hat{\hat{R}}_{2q})x, \\ &\quad x \in \mathcal{Z}_x, \qquad q = 2, \ldots, r. \qquad \text{(V.99)} \end{aligned}$$

Then the zero solution $x(t) \equiv 0$ of the closed-loop system (IV.79), (IV.80) is globally asymptotically stable with the feedback control law

$$\begin{aligned} \phi_{\mathrm{c}}(x) &= -R_{2\mathrm{c}}^{-1}B_{\mathrm{c}}^{\mathrm{T}}(PE_{\mathrm{c}}x + \tfrac{1}{2}g'^{\mathrm{T}}(E_{\mathrm{c}}x)), \\ &\quad x \notin \mathcal{Z}_x, \qquad \text{(V.100)} \end{aligned}$$

where $g(x) \triangleq \sum_{q=2}^{r} \hat{P}_q E_{\mathrm{c}} x^{[2q]}$, and the performance functional (III.45), with $R_{2\mathrm{c}}(x) = R_{2\mathrm{c}}$ and

$$\begin{aligned} L_{1\mathrm{c}}(E_{\mathrm{c}}x) &= x^{\mathrm{T}}E_{\mathrm{c}}R_{1\mathrm{c}}xE_{\mathrm{c}} + \sum_{q=2}^{r}\hat{R}_{2q}E_{\mathrm{c}}x^{[2q]} \\ &\quad + \tfrac{1}{4}g'(E_{\mathrm{c}}x)S_{\mathrm{c}}g'^{\mathrm{T}}(E_{\mathrm{c}}x), \qquad \text{(V.101)} \\ L_{1\mathrm{d}}(x) &= x^{\mathrm{T}}E_{\mathrm{d}}^{\mathrm{T}}R_{1\mathrm{d}}E_{\mathrm{d}}x + \sum_{q=2}^{r}\hat{\hat{R}}_{2q}E_{\mathrm{d}}x^{[2q]}, \text{(V.102)} \end{aligned}$$

is minimized in the sense that

$$\begin{aligned} J(E_{\mathrm{c}}x_0, \phi_{\mathrm{c}}(x(\cdot))) &= \\ &\min_{u_{\mathrm{c}}(\cdot)\in\mathcal{C}(x_0)} J(E_{\mathrm{c}}x_0, u_{\mathrm{c}}(\cdot)), \quad x_0 \in \mathbb{R}^n. \text{(V.103)} \end{aligned}$$

Finally,

$$\begin{aligned} J(E_{\mathrm{c}}x_0, \phi_{\mathrm{c}}(x(\cdot))) &= x_0^{\mathrm{T}}E_{\mathrm{c}}^{\mathrm{T}}PE_{\mathrm{c}}x_0 + \sum_{q=2}^{r}\hat{P}_qE_{\mathrm{c}}x_0^{[2q]}, \\ &\quad x_0 \in \mathbb{R}^n. \qquad \text{(V.104)} \end{aligned}$$

[3] and [7].

*Proof:* The result is a direct consequence of Theorem II with $f_{\mathrm{c}}(x) = A_{\mathrm{c}}x$, $f_{\mathrm{d}}(x) = (A_{\mathrm{d}} - E_{\mathrm{d}})x$, $G_{\mathrm{c}}(x) = B_{\mathrm{c}}$, $G_{\mathrm{d}}(x) = 0$, $u_{\mathrm{d}} = 0$, $R_{2\mathrm{c}}(x) = R_{2\mathrm{c}}$, $R_{2\mathrm{d}}(x) = I_{m_{\mathrm{d}}}$, and $V(E_{\mathrm{c/d}}x) = x^{\mathrm{T}}E_{\mathrm{c/d}}^{\mathrm{T}}PE_{\mathrm{c/d}}x + \sum_{q=2}^{r}\hat{P}_qE_{\mathrm{c}}x^{[2q]}$. Specifically, for $x \notin \mathcal{Z}_x$ it follows from (IV.81), (V.97), and (V.100) that

$$\begin{aligned} V'(E_{\mathrm{c}}x)[f_{\mathrm{c}}(x) &- \tfrac{1}{2}G_{\mathrm{c}}(x)R_{2\mathrm{c}}^{-1}(x)G_{\mathrm{c}}^{\mathrm{T}}(x)V'^{\mathrm{T}}(E_{\mathrm{c}}x)] = \\ &-x^{\mathrm{T}}E_{\mathrm{c}}^{\mathrm{T}}R_{1\mathrm{c}}E_{\mathrm{c}}x - \sum_{q=2}^{r}\hat{R}_{2q}E_{\mathrm{c}}x^{[2q]} \\ &-\phi_{\mathrm{c}}^{\mathrm{T}}(x)R_{2\mathrm{c}}\phi_{\mathrm{c}}(x) - \tfrac{1}{4}g'(E_{\mathrm{c}}x)S_{\mathrm{c}}g'^{\mathrm{T}}(x), \end{aligned}$$

which implies (2.2.13). For $x \in \mathcal{Z}_x$ it follows from (V.98) and (V.99) that

$$\begin{aligned} \Delta V(E_{\mathrm{d}}x) &= V(E_{\mathrm{d}}x + f_{\mathrm{d}}(x)) - V(E_{\mathrm{d}}x) = \\ &-x^{\mathrm{T}}E_{\mathrm{d}}^{\mathrm{T}}R_{1\mathrm{d}}E_{\mathrm{d}}x - \sum_{q=2}^{r}\hat{\hat{R}}_{2q}x^{[2q]}, \end{aligned}$$

which implies (2.2.14) with $G_{\mathrm{d}}(x) = 0$. Finally, with $u_{\mathrm{d}} = 0$, condition is automatically satisfied so that all the conditions of Corollary V are satisfied. □

## VI. Conclusion

In this paper we have developed optimal robust control and inverse optimal robust control results for the class of nonlinear uncertain singularly impulsive dynamical systems [5]. Results are based on Lyapunov and asymptotic stability theorems developed in [6], and results presented in [7].

## VII. Future Work

Further work will specialize results of this paper to time-delay systems.

## Acknowledgments

The author thanks to all of that were supportive and creative in achieving this results.

***Abstract*— this research paper will set out to explore the degree to which the practice of ISO 9001:2000 is used in Searle Pakistan limited in developing quality products that meets the customer requirement. The paper focuses on developing the understanding the operation and effectiveness of quality management systems and why companies are also committed to the needs of ISO9001:2000. A survey was conducted on Searle Pakistan limited registered with ISO 9001:2000 to evaluate the head office unit and factory units of the company to know how effective ISO9001:2000 standard to meet customer requirement which enhance to customer satisfaction. Also, to investigate the role of ISO9001:2000 standard that how its implementation help to improve business operation and its impact regarding to quality of the Searle Pakistan limited within the head office unit and factory unit.**

## I. INTRODUCTION

At any time in history, the quest for qualities is probably more widespread and intense globally. Organizations have realized that the key to increased productivity and profitability is improving quality and in order to survive competition from local market and international market, they are forced to return to the basics of better quality management and cost competitiveness measures for their products and services. The factors that relate to business performance can be divided into two categories. First, those that improve the product or service quality differential against competitors and, second, those factors that reduces the cost of quality. An effective quality management system determines the product and service quality conformance as its primary goal. As Jacobson and Aaker found product quality had a positive influence on return on investment, market share and price [1].

Such quality efforts at an international level can be address with the implementation of the ISO 9001:2000 international standard. An effective quality management system based on ISO9001:2000 determine process control as an essential activity. Better process control would be consistently associated with less rework and hence lower costs. These lower costs will lead to better comparative business performance. Therefore, it is methodically line up regarding to importance of quality in line, with Deming who reasons that, as quality improves, waste is eliminated, costs are reduced, and performance improves [2].

An ISO9001:2000 is a set of processes that describe the organisational attitude and clearly define the areas of responsibility. It creates a common language, a common picture for the entire organisation. An ISO9001:2000 in this definition has two primary purposes.

Firstly, if one needs to perform some work that is not the usual day-to-day work task, the documents serve as support and guideline for carrying out the work.

Secondly, the documents are used if there is a need to review some processes and working procedures due to problems or improvement work.

Nowadays, pharmaceutical companies come across to many new challenges to ensure efficient business operations. There are external challenges from competitors, generic drug manufacturers, health-care organisations, in addition to internal challenges to decrease the costs of sales, R&D, and manufacturing. Government guidelines in the form of regulatory requirements need to be received, interpreted and disseminated in a timely manner to ensure compliance [8].

Therefore, the most fundamental focus of the pharmaceutical companies is an effective quality management system for efficient business operations and to improve the quality to meet the customer requirements which enhance to 'customer satisfaction'. Hence, ISO9001:2000 is an essential part of any organization regarding to its standardization. However, in order to ensure that Pakistani companies do not fall behind whilst competing in world markets all organizations implement quality management system practices for their customer satisfaction.

Searle is one of the leading Pakistani companies in pharmaceutical sector. Searle have a very smart manufacturing plant follow all modern rules. They are consistently investing heavily in new technologies and state-of-the-art equipment; this has been instrumental in improving plant efficiencies and curtailing manufacturing costs. Searle is one of the largest national pharmaceutical companies of Pakistan. As per 4th quarter 2008 of Pakistan Pharmaceutical Index (IMS) which is regarded as a reference publication by Pharmaceutical Industry,

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

Searle corporate ranking is 11th in the Pakistan Pharmaceuticals market with a market share of 2.4% [3].

The paper is organized as follows: Section II gives the research strategy. Section III describes the research method. Section IV introduces data collecting evidence. Section V describes how the data was collected. Section VI describes the quality of research. Section VII gives the research map. Section VIII describes how the sampling is done. Section IX concludes the result presentation and Section X concludes the paper.

## II. Research Strategy

A central part of research strategy of the survey is to evaluate current practice of ISO9001:2000, awareness of principle of quality management system, flexibility of ISO9001:2000 and give clear concept about the need of ISO9001:2000 standard by research techniques. The research strategy covered the following stages:

- Utilization of existing information, including published and unpublished research and secondary data.
- Qualitative method and Quantitative method for e.g. questionnaire based survey.

## III. Research Method

There are many research methods available which comes from these approaches. No research method is one hundred percent qualitative or quantitative but each method can be considered to be on a continuum.

This survey based on both qualitative and quantitative approaches. Random samples of employees are analysed by both approaches, which allows drawing conclusion based on the results.

## IV. Data Collecting Evidence

The methods use in this survey is:

- Documents; in the form of reports to shareholders, books, journal and newspapers.
- Articles in form of brochures and product descriptions.
- Direct observation in the form of informal observations and notes taken during the period of the study.
- Participant observation; in the form of field-notes taken after facilitating questionnaire survey.

## V. Collecting The Data

Questionnaire was designed to evaluate the current practices of ISO9001:2000 within the two areas of Searle Pakistan limited. Two types of questionnaire are formulated for the two different areas of the organisation which are head office and factory. A total of Fifty-Seven employees including directors, general manager ,manager assistant manager, technical staff and sale persons in both areas of **Searle Pakistan limited** approaches to provide the primary input into the study. Although there are commonalities in the nature of questions used in them, each one was adapted to ensure relevance and suitability for each type of areas of the **Searle Pakistan limited**.

Each questionnaire divides into three main areas:

- **Part A:** General
- **Part B:** Quality management system's strategies
- **Part C:** Practice and experience of ISO9001:2000

The questionnaire contains mainly 'open' questions where respondents are invited to express their opinions. In addition there are a number of questions involving rating or scale as well as Yes/No choice. The layout of the questionnaire design so that it seems easy to complete and this involve using some widely accepted principles of good practice:

- Provide a short covering letter explaining the purpose of research.
- A brief description of the subject areas under consideration.
- A brief instruction about how to complete.
- Started with simpler factual questions (e.g. biographical details such as age and length of service), moving on to items of opinion or values.
- Types of question varied occasionally.

Enclosed envelops is distribute to appropriate employees in head office and factory areas. Each envelope contains a covering letter, questionnaire and reply envelope which delivered and collected from the reception of head office and factory.

It requested to reply within a week such that the study may proceed to next stage.

It was assured to the respondents that completed forms will be treated as strictly confidential. A summary of the final results will be made available upon requested.

## VI. Quality of the Research

The quality of research depends on:

### A. *Validity*

For a successful research attitude the quality of it must be high, to judge this the *validity* and *reliability* is assessed.

Validity concerns the issue whether or not the findings can be shown to be valid for the problem that is being investigated. Data collected must be relevant to the problem and the purpose of the research otherwise there will be low validity. Irrelevant data and unnecessary information leads to low validity [4]. There are six strategies that can be used to check validity

- Triangulation,
- Checks,
- Long-term observation,
- Peer examination,

- Participatory/ collaborative models of research,
- Researcher's biases [5].

In this survey all the irrelevant questions have been ignored and all the relevant questions are included and secondary data collected from the reliable and trusted sources. This data base is updated at regular intervals of time, just after conducting them so that all information stores correctly and these factors will make to feel that the contents is relevant to the purpose of the research.

### *B. Reliability*

Reliability concerns the issue of consistent results of the study if it was replicated. A good guideline is to make sure that if someone did the project again, the same results would be found [6]. Reliability is an important aspect of doing a survey and the goal of reliability is to minimise biases and errors in the research study. A prerequisite for reliability is that all the documentation is in proper order and can be easily found [4].

Trying to maintain a transparency in how sense is made from the raw data the designed questions is follow a specific or set agenda in order to generate relevant and reliable results; however answers from employees is highly subjective as they give response on perception. Questionnaire is designed in a clear understandable manner so that question doesn't mislead employees and helps them in giving reliable and consistent answers.

A written statement is given about the extent to which will disclose the information about the organisation in this report, and also the secrecy of the questionnaire, so that they give vital and the exact information which helped in doing this research. Each case recorded and referred with a code but not with any personal detail.

The findings of the survey can be applied to other organisations in Pakistan. The results identify important factors in the development process and it believes that the research will be both valid and reliable.

## VII. Research Map

To fulfill the research aim and objectives, it is essential the collection of data in pre-planned manner and to use the available data in an effective format. Table I shows how the collected information fulfils the required objectives.

**TABLE I. HOW TO FIND THE ESSENTIAL INFORMATION TO FULFIL RESEARCH OBJECTIVES**

| **Research Objective** | **Research Map** |
|---|---|
| ***What to find Out*** | ***How the essential information find*** |
| To understand the operation and effectiveness of quality management systems is and why companies are also committed to the needs of ISO9001:2000. | Literature Review, Comprehensive search on internet such as company's web site, Journals, articles and annual report.<br>Literature Review, study of market segments, questionnaire with the managers of the firm follow up with lots of informal chats.<br>Articles about the performance of the firm in the recent years, annual reports. |
| To determine the actual experiences and opinions of the operating managers and employees in relation to ISO (9001:2000) in their organisation. | Questionnaire to target managers and employees in order to gauge view and some informal interviews if necessary |
| The main focus would be identifying how companies can exploit their use of ISO(9001:2000) to gain competitive advantage and also to improve the flexibility and efficiency of the organisation | Comprehensive data analysis from which required results can be collected and manipulated to establish conclusion and recommendations. |

## VIII. Sampling

The sampling frame that was adopted for this research findings is probability sampling because; smaller number of cases for possible a higher overall data means that more time can be spend designing and piloting the means of collecting these data. Using sampling makes possible a higher overall accuracy. And the sampling technique will be 'Simple Random Sampling' technique because it depends on research questions and objectives, selecting the sample of employees at random from the sampling edge [7].

## IX. Result Presentation

This section provides a result of the response of the survey. This analysis based on the survey respondents of gender, age group, number of years with present employer, and the source of quality management knowledge. This is followed by an overview of the results from the questionnaires sent to head office and factory of Searle pharmaceutical company.

### *A. Rate of response to the survey*

Table II shows that the overall response rate to the questionnaire survey is 66.6%.A breakdown of the response rate by head office and the factory are shown below:

**TABLE II.** OVERALL RESPONSE RATE

| **Unit** | **Total Sent Out** | **Total Recieved** | **% Received** |
|---|---|---|---|
| Factory | 32 | 20 | 62.5 |
| Head Office | 25 | 18 | 72 |
| Total | 57 | 38 | 66.6 |

Whilst, the overall response rate of 66.6 % is not significant surprise, the 72% returned from the head office and .62.5% returned from the factory. Keeping in mind that there are some major concerns over Factory's sensitivity and security therefore, given the current response from the factory is understandable.

The response rate could have been higher with improved questionnaire design. On reflection, the length of the questionnaire probably over reflected the amount of time required for completion. Whilst all sections did not necessarily require completing this may not have been readily apparent.

However, even with the responses received a great deal of consistent and quantitative results have been established.

### B. *Profile of respondents*

The proportion of women responding to the questionnaire is 29% and this consisted six individuals from head office and five individuals from factory. The proportion of men responding to the questionnaire is 71% and this consisted twelve individuals from head office and fifteen individuals from factory .all respondents are aged in over eighteen years consisted 5.55% under twenty,44.44% twenty plus ,33.33%thirty plus and 16.66% of forty years old. Just 16.66% of the respondents have spent ten plus years with their present employer, 16.66% up to two years service, 44.44% of two plus year's service and 22.22% of five years service with their present employer in the head office.

In the factory 10% up to two years,40% two plus years,30 % five plus years and 20 % ten plus years of service with their present employer in the factory.

By far most common source of ISO knowledge is by way of training consisted 85% in factory and 86% in the head office. From the work experience 15 % in factory and 12% in head office. 4% respondent from head office claimed that their source of knowledge regarding to ISO knowledge is seminars.

### C. *By source of ISO knowledge*

An evaluation of the responses by sex and age group failed to generate any significant differences in the analysis of questionnaires.

This is because tapered distribution across these ranges. However, respondent which indicated work experience as the source of their knowledge of ISO provided a detail qualitative data and this tends to be positive impact by comparison. But, the wide range of knowledge sources claimed by the head office and factory unit is training. It is because of number of years with present employer consisted of 40% from factory and 44.44% head office is 2-4years. These employees have only source of knowledge of ISO is training, which reflected in a more holistic view in terms of the depth and detail of the responses provided.

## X. Conclusion

Results indicated that a vast majority of respondents were satisfied with most aspects of the ISO9001:2000. The ISO9001:2000 indicate that achieving conformance to specification with low levels of rework has a direct effect on competitive advantage and as well as in terms of 'Customer Satisfaction'. In general, satisfied customers are likely to engaged in repeat purchase and reflect strong loyalty toward the Searle. Seeing as ISO9001:2000 is an important component of the total package of value required by customers, and the Searle use accreditation of ISO9001:2000 to attract new customers from local market as well as international markets. Employees are a significant part of the service delivery process and play a significant role in company-customer interaction.

The results of the study show that the majority of Searle employees are well trained regarding to ISO9001:2000 standard. Outstanding figures of respondents were aware of quality management principles and its generic requirements due to training conducted periodically in both units of Searle. Majority of employees are young. They are currently working in Searle which impact on the company is optimistic as aspects of improving their skills due to training conducted periodically. As it seen that young people can adopt changes more quickly and effectively which is very beneficial for both of units of Searle which directly lead to quality improvement.

Also, employee's awareness and usage rates are fairly high for key quality management principles and general requirements of ISO9001:2000. As high-quality control and processes are related to competitive advantage.ISO9001:2000 is an effective quality management system which has process control as an essential activity. Better process control, be consistently associated with less rework and hence lower costs. These lower costs will lead to better comparative business performance. This is lined up with Deming [2] who reasons that, as quality improves, waste is eliminated, costs are reduced, and financial performance improves. The results also indicate that ISO9001:2000 company's management system provides a framework for controlling and improving business activities. Which Adds value to products, services and competitiveness and provides a marketing edge.

## Acknowledgment

The authors acknowledge the encouragement, support and guidance given by **Finance Director, Qamar Mashkoor, Searle Pakistan Limited**.

Special thanks to all other faculty members for helping during the research and giving their valuable suggestion and guidance.

*Abstract*—**Fault detection and isolation (FDI) have become one of the most important aspects of automobile design. Fault detection and isolation for engine open loop system was investigated in many research. In fact, the simulation results obtained from engine open loop system do not reflect the real situation for automotive engine. In the practice the engine works as closed-loop control system. In this paper, a new FDI scheme is developed for automotive engines under closed-loop control system. Test the method using closed-loop system has been done. The method uses an independent radial basis function (RBF) neural network model to model engine dynamics, and the modeling errors are used to form the basis for residual generation. Furthermore, another RBF network is used as a fault classifier to isolate occurred fault from other possible faults in the system. The performance of the developed scheme is assessed using an engine benchmark, the Mean Value Engine Model (MVEM) with Matlab/Simulink. Six faults have been simulated on the MVEM, including four sensor faults, one component fault and one actuator fault. The simulation results show that all the simulated faults can be clearly detected and isolated in dynamic conditions throughout the engine operating range.**

***Keywords: Automotive engines under closed-loop control, independent RBF model, RBF neural network, fault detection, fault isolation.***

## I. INTRODUCTION

A fault is any type of malfunction of components that may happen in a system and this fault will degrade the system performance. Fault detection is the program which informs us that something wrong in the system and needs to be repaired. Also, fault isolation is way to determine which fault occurs among the possible faults. To detect faults we usually compare the outputs of the real system which is in this paper the MVEM, and the outputs of a neural network model of the engine. Rolf Isermann has proposed Model-based fault-detection and diagnosis methods for some technical processes [1]. On-line sensor fault detection, isolation, and accommodation in automotive engines had been studied by Domenico Capriglione [2]. Fault detection and isolation for MVEM open loop control system were achieved in previous paper of the authors [3]. However, in the practice the engine does not work as an open loop control system. Automotive engine works under close loop control system with feedback control. Fault detection and isolation using close loop system is quite different comparing with open loop system. The main points are: fault detection and isolation is much more difficult than using open loop system. The reason is the process outputs in close loop system will be fed back and this will affect the sensor faults. Secondly, in MVEM open loop system, Air fuel ratio (AFR) was not controlled at the 14.7, because the feature of feed-back did not use in the open loop control system. In this paper, a new fault detection and isolation method will be implemented by using MVEM when this model is under close loop control system. An independent RBFNN model is used to model a dynamic system using RAS throttle angle as an input. Feed-back (FB) and feed-forward (FF) control methods will be applied to the MVEM. The K-means clustering algorithm is used to choose the centres of RBFFNN. Recursive least squares (RLS) algorithm is used to update for each new sample the parameter matrix W.

## II. CONTROL STRUCTURE FOR MVEM

Fig. 1 shows the Simulink model of the automatic control loop for the MVEM including feed-forward and feed-back controllers. Where the MVEM control input u is the injected fuel mass mfi and the disturbance input Ø is the throttle angle position. The feed-forward controller that correlates the steady state value between the MVEM control input mfi and the disturbance Ø will be used in the feed-forward path. In order to achieve better transient response, feed-forward and feed-back controllers will be designed as following.

### *A. FF controller design*

The feed-forward controller will be implemented by look-up table configuration. The data of this table were determined from the MVEM. Firstly, throttle angle position value have been given to the MVEM starting from 20 to 60 degree by step 5 degree in order to cover 9 cases, secondly, the gain k has been changed for each case to adjust the air fuel ratio equal to 14.7. Finally, the suitable corresponding injected fuel mass can be determined for each throttle angle value by using (1).

$$mfi = k \times \phi \tag{1}$$

Omar AL-Mukhtar University, Libya

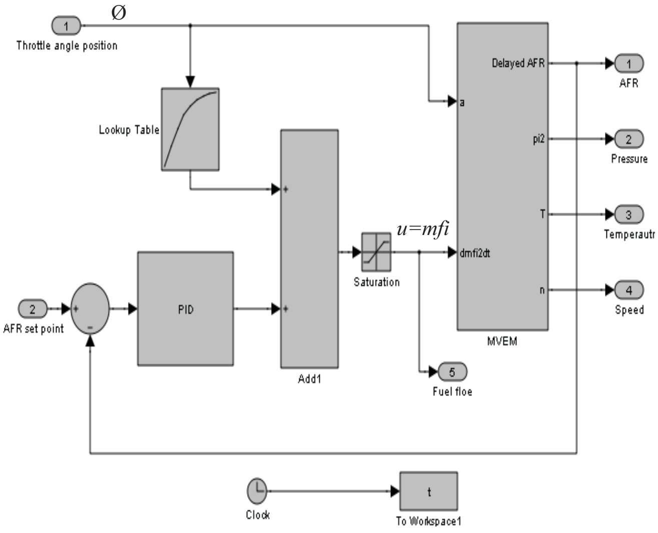

Figure 1. Simulink model for the automatic control loop for the MVEM including feed-forward and feedback controllers

### B. PID controller design

In general, the transfer function of PID is illustrated in (2), where, $K_p$, $K_i$ and $K_d$ are proportional, integral and differential gains respectively.

$$G_c(s) = K_p + \frac{K_i}{s} + K_d s \quad (2)$$

Where:

$$K_i = \frac{K_p}{T_i} \quad (3)$$

$$K_d = K_p T_d \quad (4)$$

Where:

$T_i$: Integral time.

$T_d$: Derivative time.

In order to find out the PID controller parameters ($K_p$, $Ki$ and $K_d$), many numerous tuning rules for PID controller can be found in the literature. The process of selecting the controller parameters to meet given performance specification is known as controller tuning. The rules for determining values of the $K_p$, $T_i$ and $T_d$ based on the transient response characteristics of given plant have been proposed by Zigler and Nichols [4]. All the PID parameters were determined by using the Matlab software R2009a. Equation 5 shows the transfer function of the PID controller after calculate all its parameters.

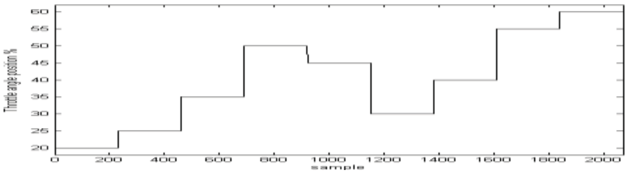
$$G_c(s) = 0.00001(1 + \frac{1}{100s} + 0.01s) \quad (5)$$

## III. Evaluation of closed loop control system

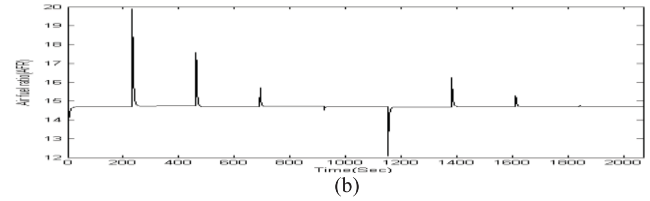
In order to evaluate the MVEM under close loop control system, a set of signal was used for the throttle angle position to obtain a representative set of input data.The range of this excitation signals was bounded between 20 and 60 degrees. This almost covers the whole throttle angle position in normal operation condition. The outputs of the PID and feed forward controllers will be used as a second input of the MVEM (see Fig. 1). Fig. 2(a ,b) illustrate the input signal of throttle angle position and the AFR output response of the MVEM close loop control obtained from the block diagram shown in Fig. 1. The AFR is to be controlled at 14.7. From the Fig. 2 it can be seen that the PID controller has good performance and the obtained results were very accurate, therefore the AFR has been controlled at 14.7.

## IV. Engine modeling

The first step in the engine modeling by using RBFNN is the generation of a suitable training RAS data set of throttle angle position and setpoint of AFR. As the training data will influence the accuracy of the neural network modeling performance, the objective of experiment design on training data is to make the measured data become maximally informative, subject to constraints that may be at hand. As mentioned above, a set of random amplitude signals (RAS) were designed for the throttle angle position and AFR setpoint to obtain a representative set of input data of MVEM close loop. The sample time of 0.02 sec was used. The second step is to determine the input variables of the RBF model. The SI engine to be modeled has two input variables: throttle angle and the outputs of the PID and feed forward controller which is fuel flow rate, and four outputs: air manifold temperature, air manifold pressure, crank shaft rotary speed and air fuel ratio. The network input that generated the smallest modeling errors was selected, and has first-order for the two process inputs and third order for process output. As selected above, the RBF model has 16 inputs and 4 outputs. The hidden layer nodes have been selected as 15. Before the training, 15 centres were chosen using the K-means clustering algorithm, and the width σ was chosen using the p-nearest-neighbours algorithm. All Gaussian functions in the 15 hidden layer nodes used the same width. For training the weights W the recursive least squares algorithm [5] was applied and the following initial values were used: $\mu$= 0.98, w (0) =$1.0\times10^{-6}\times U$ (nh×4), P(0)=$1.0\times10^{8}\times I$ (*nh*), where $\mu$ is the forgetting factor, $I$ is an identity matrix and $U$ is the matrix with all element unity, *nh* is the number of hidden layer nodes. Totally a data set with 7000 samples was collected from the MVEM. Before training and testing, the raw data is scaled linearly into the range of [0 1]. Fig. 3 show the model training results of the last 500 samples in the training data set and the first 500 samples in the test data set.



(a)



(b)

(c)

(d)

Figure 3. ,a,b,c and d. The simulation results of the speed, pressure, temperature and air fuel ratio engine model output and the RBFNN s output respectively

From Fig. 3, it can be seen that there is a good match between the two outputs with a very small error, in general. The modeling error of the training data set is smaller than the test data set. The mean absolute error (MAE) index is used to evaluate the modeling effects. For this model the MAE values of crankshaft speed, manifold pressure, manifold temperature and air fuel ratio are 0.0014, 0.0061, 0.0031 and 0.0031 respectively.

## V. SIMULATING FAULTS

Before the developed method is tested on a real engine with real faults, it was tested in this research on the nonlinear simulation of SI engines, the MVEM with different faults simulated on it. One component fault, one actuator fault and four sensor faults with different levels of intensity have been investigated as practical examples of spark ignition (SI) engine faults. The component fault is air leakage in the intake manifold. The actuator fault is a malfunction of the fuel injector. The four sensor faults are malfunction of the intake manifold pressure sensor, manifold temperature sensor, crank shaft speed sensor and air fuel ratio sensor. Details of the simulation of these faults are described as follows.

### *A. Component fault*

Equation (6) of the manifold pressure [6] is modified to (7) in order to collect the engine data subjected to the air leakage fault.

$$\dot{p}_i = \frac{T_i R}{V_i}(-\dot{m}_{ap} + \dot{m}_{at} + \dot{m}_{EGR}) \qquad (6)$$

$$\dot{p}_i = \frac{T_i R}{V_i}(-\dot{m}_{ap} + \dot{m}_{at} + \dot{m}_{EGR} - \Delta l) \qquad (7)$$

where $\dot{p}_i$ is the absolute manifold pressure (bar), $\dot{m}_{at}$ is the air mass flow rate past throttle plate (kg/sec), $\dot{m}_{ap}$ is the air mass flow rate into the intake port (kg/sec), $\dot{m}_{EGR}$ is the EGR mass flow rate (kg/sec). The added term is used to simulate the leakage from the air manifold, which is subtracted to increase the air outflow from the intake manifold. $\Delta l = 0$ represents no air leak in the intake manifold. The air leakage level is simulated as 20% of total air intake in the intake manifold. This fault occurs from the sample number 3750~ 3850 in the faulty data as shown in Fig.4, and was simulated by changing the Simulink model of the MVEM.

### *B. Actuator fault*

For SI engines, the target is to achieve an air–fuel mixture with a ratio of 14.7 kg air to 1 kg fuel. This means the normal value of air fuel ratio is 14.7. Because any mixture less than 14.7 to 1 is considered to be a rich mixture, any more than 14.7 to 1 is a lean mixture. Lean mixture causes the efficiency of the engine reduced, while rich mixture will cause emission increased. The fuel injector is controlled by the controller with correct amount of fuel. If the fuel injector has any fault the injected fuel amount will not be correct and affect the air/fuel ratio. Here, the malfunction of the fuel inject is simulated by reducing the injected fuel amount of 25% of the total fuel mass flow rate between the sample number 2550 and 2650 as shown in Fig.4. This fault is also simulated by changing the Simulink model of the MVEM.

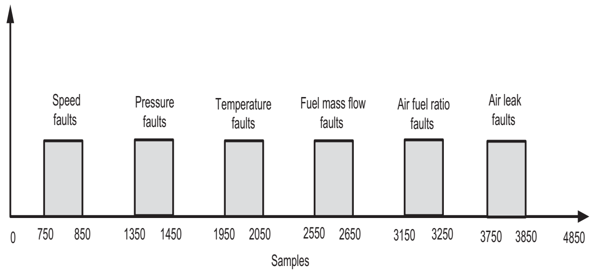

Figure 4. Distribution of the simulated faults

### C. *Sensor fault*

The four sensor faults considered are (10, 15, 10 and 20) % changes superimposed on the outputs of crankshaft speed, manifold pressure, and temperature and air fuel ratio sensors respectively. These faults are simulated from sample numbers 750 to 850, 1350 to 1450, 1950 to 2050 and 2550 to 2650 respectively as shown in Fig.4. The faulty data for the sensors is generated using multiplying factors (MFs) of 1.1, 1.1, 1.15 and 1.2 for the above over-reading faults respectively. Faulty data are generated by the Modified MVEM with throttle angle at different values between 20$^o$ and 60$^o$ for all the fault conditions. The 6 states with their multiplying factors (MFs) are given in table I. The sample time is chosen as 0.02 sec.

## VI. Fault detection

Fig.5 shows the information flow for the fault detection and isolation. Firstly, the 7000 samples data set of random amplitude sequence for throttle angle in the proper range and the outputs of the PID and feed forward controllers are fed into the MVEM under close loop control system. The collected four engine outputs together with the two inputs as well as their delayed values are used to train the RBF model. After training, all the six faults are simulated to the MVEM. Then, with another 4850 set of square signals of throttle angle position (see Fig. 6) and fuel flow which is output of PID and feed forward controller (see Fig. 7) fed into the MVEM under close loop control system, the model prediction error and the filtered residual are generated for fault detection. With the six faults simulated from samples 750 to 3850 as shown in Fig.4.After a low-pass filter is used the filtered prediction errors are shown in Fig.8 (b, c, d & e). The first 500 samples of data set which mean the beginning 10 second of engine operation has been ignored because contain noise signals. The first filtered model prediction error of air fuel ratio is shown in Fig.8, b. The second, third and fourth for air manifold temperature, pressure and engine speed are showed in Figs.8(c, d, e) respectively. In these Figs. the samples 0 to 750 are data without faults. Including them is to show the prediction error is under the selected threshold in "no fault case". Now it is evident that all simulated faults have a significant reflection on the model prediction errors. A threshold is chosen for each prediction error and is also displayed in these Figs. Moreover, Fig. 8, f shows the residual error (*re*) which is generated by (8).

$$re = \sqrt[2]{e_n^{\;2} + e_p^{\;2} + e_t^{\;2}} \qquad (8)$$

Where $e_n$, $e_p$ and $e_t$ are the error vectors of the speed, pressure and temperature respectively between the engine model and the RBF neural network.

TABLE I. THE 6 FAULTS STATES AND MULTIPLYING FACTORS

| No | Fault Name | multiplying factors (MFs) |
|---|---|---|
| 1 | Air Leak 20% | |
| 2 | Injected fuel mass flow 25% | |
| 3 | Speed sensor 10% over reading | 1.1 |
| 4 | Pressure sensor 15% over reading | 1.15 |
| 5 | Temp. sensor 10% over reading | 1.1 |
| 6 | Air fuel ratio 20% over reading | 1.25 |

## VII. Fault isolation

As have been seen in Fig.8, f, though all simulated faults cause a significant deviation in the residual, this can be used to detect fault but cannot be used to isolate fault. When a fault occurs, only its associated output of the fault diagnosis system has a reflection, while all the other outputs should be insensitive to this fault, then the fault can be isolated from the other possible faults. In this research there are 6 possible faults but only four modeling errors. It can be concluded from Fig.8 that if only the first model output (air fuel ratio) goes over the threshold while the other three outputs remain under the thresholds, then it must be air fuel ratio sensor has fault. If second model output (temperature) goes over the threshold while the other three outputs remain under the thresholds, then it must be temperature sensor has fault. Similarly, if only the third model output (pressure) goes over the threshold while the other three outputs remain under the thresholds, then it must be the pressure sensor has fault. Moreover, if only the fourth model output (speed) goes over the threshold while the other three outputs remain under the thresholds, then it must be the speed sensor has fault. If both the first model output (air fuel ratio) and the forth model output (speed) go over the thresholds while the other two outputs remain under the thresholds, then it must be the fuel injector has fault. Finally, If the first, second and third model outputs go over the thresholds while the fourth output remain under the threshold, then it must be the air leak occurs. Therefore, to achieve a clear isolation among all possible faults, another RBF network is employed as a fault classifier. The classifier has four inputs each receiving one of the four modeling errors, and has seven outputs with one representing “no fault case” and the other six representing the six different faults. The classifier is trained in the following way. Collect 7 sets of data with first set without fault and the other six sets each with one fault only. For each data set of the seven, the target of the training for the output corresponding to the contained fault is set to “1”, while the targets for the other outputs set to “0”. Totally 4850 RAS data samples were collected with first 750 without fault and each set of 600 samples with one of the five faults, the last sixth fault occurred during the last set of 1100 samples. These data are fed into the new RBF model and the generated four modeling errors are fed into the RBF classifier to train it, with the targets given as described above. After training, the classifier is tested with the similar arrangement of data, totally 4850 data samples which are the modeling errors obtained from the RBF of fault detection and MVEM under close loop control system (see Fig. 8, b, c, d and e). The first 750 samples are fault-free, followed by six data sets. The first five data sets have 600 samples and having a single fault, the sixth data set has 1100 samples and has the last fault. Between any two of these six faulty data sets insert 500 fault-free samples and the final 1000 samples are fault-free, so that the residual rising time and disappearing time can be observed. The data samples with associated fault types are listed in Table II. Similar to the first RBF network, the centres and widths are also selected using the K-means clustering algorithm and the *P*-nearest centres method respectively. The network weights are trained using the recursive Least Squares algorithm with its parameters set as $\mu$= 1.0, w (0) =1.0×$10^{-6}$×U (nh×6), P (0) =1.0×105×I (*nh*). The number of the hidden layer nodes was tried several numbers and the one giving minimum training error was chosen and was 250. Figs. 9~14 show the test result after filtering. The isolation thresholds are chosen as shown in the Figs.

TABLE II. DATA SAMPLES AND FAULT TYPES

| Data samples | Fault types |
|---|---|
| 1 ~ 750 | No fault |
| 751 ~ 850 | Speed sensor fault |
| 801 ~ 1350 | No fault |
| 1351 ~ 1450 | Pressure sensor fault |
| 1451 ~ 1950 | No fault |
| 1951 ~ 2050 | Temperature sensor fault |
| 2051 ~ 2550 | No fault |
| 2551 ~ 2650 | Fuel injector fault |
| 2651 ~ 3150 | No fault |
| 3151 ~ 3250 | Air fuel ratio fault |
| 3251 ~ 3750 | No fault |
| 3751~3850 | Air leak fault |

## VIII. Discussion of Simulation Results

### A. Training the Neural Network model.

The simulation results of training and testing by using 15 hidden nodes were very good and in general, a good prediction between the engine model output and the RBF neural network output was achieved. From Fig. 3, it can be seen that the mean absolute error between the engine speed output and the RBFNN is very small.

### B. Detection of the Sensor, Component and Actuator Faults.

The Fig. 8 (b, c, d and e) show the test results of the fault detection of air fuel ratio/fuel flow/leakage, temperature/air leak, pressure/air leak, and speed/fuel injection respectively after filtering with 15 hidden nodes. It can be seen from Figs. after filtering operation that all kind of faults were detected clearly. The error values were between 0.05 and -0.1 except the samples in which faults occur. The detection thresholds were chosen as 0.09 for crankshaft speed / fuel injection, (-0.01/+0.08) for manifold pressure/air leak, 0.05 for manifold temperature/air leak and (0/0.06) for air fuel ratio.

### C. Isolation of the Sensor, Component and Actuator Faults.

In this section, another RBFNN called neural classifier were used in order to isolate all kinds of the faults. This neural was received error signals between the MVEM and the RBFNN model outputs. 50, 150 and 250 hidden nodes are used in order to try to obtain good simulation results. From the Figs. of the results, we found 250 hidden nodes after filtering operation were the best case and the simulated faults can be clearly isolated (see Figs. 9~14). The isolation thresholds are chosen as shown in the Figs. in case 250 hidden nodes.

## IX. Conclusions

In this research, the MVEM under close loop control including feed-forward and feed-back controllers was used. Look up table has been used as a feed-forward controller and PID used as feed-back controller. The data of the Look up table were determined by using the MVEM and the data of PID were calculated by Zigler and Nichols methods by using the Matlab software R2009a. The AFR output response of the MVEM close loop control was controlled at 14.7. Four sensor faults (intake manifold pressure, temperature, crankshaft speed and air fuel ratio), one component fault (leakage in the intake manifold) and one actuator fault (injected fuel mass flow) have been simulated. Two RBFNNs were used, the first one to model engine dynamics and the second one to isolate the sensor faults, component fault and actuator fault from the modeling errors. By using *p* – Nearest Neighbours method and K-means algorithm the width in hidden layer nodes of the RBF neural network σ and the centres c are calculated for both RBFNNs. The recursive least square algorithm was applied for training the weights *w* of the RBF neural networks. The proposed method can detect and isolate the faults and from the Figs. of simulation results, it can be seen that the methods were able to detect and isolate the faults.

# A Parameter-free Method for Sensor Fault Detection and Isolation in Bilinear Systems

Assia HAKEM, Komi Midzodzi PEKPE and Vincent COCQUEMPOT

*Abstract*— **This paper is concerned with Fault Detection and Isolation (FDI) and more specifically it focuses on a parameter-free residual generation method. The residual signals are obtained by projecting the measured signals onto the kernel of an extended input matrix, which depends on the structure of the system model. The method was not easily applicable in real-world applications due to a high computational complexity. In that paper, fault indicators are constructed differently, using kernels properties, to avoid this complexity problem. A simulated electromechanical actuator example is taken to illustrate the applicability of the method.**

*Index Terms*— **Fault detection and isolation, data driven methods, bilinear systems, electromechanical actuator.**

## I. Introduction

Real plants are subject to faults, that can affect the process parameters, actuators or sensors. Online fault detection and isolation (FDI) is an important task for human safety and system dependability. Many approaches have been reported in the literature to achieve this task. Two kinds of FDI methods are distinguished [16]. Model-based and model-free methods. Model-based methods consist in comparing the actual system behavior with the one given by an analytical model, i.e. a set of nonlinear differential equations. A signal called residual is used to evaluate this comparison. In the absence of fault and noise, if the process and the model are exactly matched, the residual is zero, otherwise it is different from zero which characterizes fault occurrence. The main common methods for model-based residual generation are:

- observer-based methods [5], [6] and [7]
- analytical redundancy relation (ARR) -based methods [1]
- parameters estimation methods [4], [8]

Unfortunately, the values of the model parameters are unknown in most practical applications. For such case, model-free FDI methods [2], [13] have been proposed. Some of these methods use signal processing techniques to extract special properties of measured signals, these methods are called signal-based methods (see [16] and [17]). Other data driven methods have been proposed recently for switching systems in [10] and [11], for bilinear systems in [11].

The residual generation method that is proposed in that paper is situated between model-based and model-free methods, since the only information we need is the knowledge of the input-output data and of the structure. The values of the model parameters are not needed.

The advantages of the proposed method are as follows:

- The only needed data are inputs and outputs.
- The generated residuals are structured which allows faults isolation.
- Multiple faults may be considered.

The bilinear system is a particular structure of nonlinear systems, this special class of systems has been widely studied in recent years [3]. Many real-world dynamical systems may be represented by a bilinear model and such model can approximate a large class of nonlinear systems. Consequently, bilinear models study is interesting from both theoretical and practical points of view.

The data-projection method for residual generation was extended for bilinear structure models in a previous publication by the authors [15].

The target of this paper is to enhance the parameter-free residual generation method proposed in [15]. The general principle of the method is kept. However, using kernel properties, fault indicators are computed differently, to avoid the computational complexity of method in [15].

The remainder of this paper is organized as follows. A general description of our residual generation method for bilinear models is provided in section 3.The input/output relation is derived in section 3 while the residual expression is derived in section 4. In section 5, simulation results on an electromechanical actuator are presented to show the effectiveness of our method. The final section gives a conclusion.

## II. Overview of the parameter-free residual generation method

Consider known inputs $u_k \in R^m$ and outputs $y_k \in R^\ell$ affected by colored white noise $w_k \in R^\ell$. These input/output signals are supposed to be collected on a physical plant that can be modeled as a discrete-time bilinear system given by:

$$\begin{cases} x_{k+1} = Ax_k + G(x_k \otimes u_k) + Bu_k \\ y_k = Cx_k + Du_k + f_k + w_k \end{cases} \tag{1}$$

where $\otimes$ represents the Kronecker product, and $f_k \in R^\ell$ is the sensor fault vector. It is supposed that the linear dynamic is stable i.e. $\|A\|_2^i \to 0$.

The aim is to detect and to isolate sensor faults when supposing that the only available information is the system structure (bilinear) and input/output data. The system parameters($A \in R^{n\times n}$, $B \in R^{n\times m}$, $C \in R^{\ell\times n}$, $D \in R^{\ell\times m}$, $G \in R^{n\times nm}$) are supposed to be unknown.

The data-based residual generation method for bilinear systems is detailed in the next section. Let us give the general principle of this method. Under the stability conditions, it is possible to express the vector of measured outputs on a given time-window as a function of the inputs. The following expression is thus obtained.

$$Y \cong HM(u, y \otimes u) \tag{2}$$

where $H$ depends on the system parameters, $Y$ is a matrix of outputs collected on a given time-window, $M(u, y \otimes u)$ is a matrix constructed using inputs and the Kronecker product between inputs and outputs. If the chosen time-window is sufficiently large, we can then project equation (2) on the right kernel $\Pi$ of $M(u, y \otimes u)$ $(UM(u, y \otimes u)\Pi = 0)$ and we can derive the relation:

$$Y\Pi = 0 \tag{3}$$

This relation must be verified in absence of disturbances and faults. Consider $Y_{online}$ and $\Pi_{online}$, the $Y$ and $\Pi$ matrices which are computed using online taken values of inputs and outputs signals. In the no fault situation, the signal $\epsilon = Y_{online}\Pi_{online}$, is not exactly null because of the measurement noise. However, it can be proved that $r = E[\epsilon]$ equals 0, with $E[.]$ the mathematical expectation. When a fault occurs, $r = E[Y_{online}\Pi_{online}]$ becomes different from zero. Thus, $r$ can be considered as a fault indicator (residual) to be used for FDI.

It is clear that no system parameter or state estimation is needed for residual computation since $\Pi$ depends only on inputs, which makes residual expression (3) independent on model parameters.

## III. Input-output expression of bilinear systems

The objective of this section is to show how to derive equation (2) from system (1). A general expression of the output $y_k$ is first obtained. Then it is shown that the influence of the state may be neglected under the stability conditions, which leads to equation (2).

A general output expression $y_k$ can be derived, which is given in the following proposition and proved by induction.

*Proposition 1:* The general expression of the output $y_k$ in function of the state $x_{k-i}$, the inputs and system parameters $A$, $B$, $C$, $D$, $G$ is given by:

$$\forall i \geq 0 : y_k = CA^i x_{k-i} + \widetilde{H}_i \overline{z}_{k,i} + \overline{H}_i \overline{u}_{k,i} + f_k + w_k \tag{4}$$

where $\widetilde{H}_i$, $\overline{z}_{k,i}$, $\overline{H}_i$, $\overline{u}_{k,i}$ are given as follows.
a) $\widetilde{H}_i$ and $\overline{H}_i$ depend only on system matrices.

- $\widetilde{H}_i$ depends on the system matrices $C$, $A$ and $G$:

$\widetilde{H}_i = \left[ CA^{i-1}G | \cdots | CAG | CG \right] \in R^{\ell \times nmi}$.

- $\overline{H}_i$ depends on the system parameters $C$, $A$ and $B$:

$\overline{H}_i = \left[ CA^{i-1}B | \cdots | CB | D \right] \in R^{\ell \times m(i+1)}$.
b) $\overline{z}_{k,i}$ and $\overline{u}_{k,i}$ depend on the system states and inputs on a time-window of size $i$.

$\overline{z}_{k,i} = \left[ z_{k-i}^T | \cdots | z_{k-2}^T | z_{k-1}^T \right]^T \in R^{nmi \times 1}$.
with $z_{k-i} = x_{k-i} \otimes u_{k_i}$.
and $\overline{u}_{k,i} = \left[ u_{k-i}^T | \cdots | u_{k-1}^T | u_k^T \right]^T \in R^{m(i+1) \times 1}$.

*Proof:*
Inductive method is used to prove correctness of the general output expression (4), which can be written differently without using matrix representation:

$$\begin{aligned} y_k &= CA^i x_{k-i} + C \sum_{j=0}^{i-1} A^j G.z_{k-j-1} \\ &+ C(Du_k + \sum_{j=0}^{i-1} A^j Bu_{k-j-1}) + f_k + w_k \end{aligned} \tag{5}$$

Expression (5) is verified for $i = 0$ and $i = 1$. Assuming that the proposal holds for $i$, let us prove that it holds for $i + 1$ also:

$$\begin{aligned} y_k &= CA^{i+1} x_{k-i-1} + C \sum_{j=0}^{i} A^j G.z_{k-j-1} \\ &+ C(Du_k + \sum_{j=0}^{i} A^j Bu_{k-j-1}) + f_k + w_k \end{aligned} \tag{6}$$

We replace $x_{k-i} = Ax_{k-i-1} + G.z_{k-i-1} + Bu_{k-i-1}$ into (5), and derive the following equation:

$$\begin{aligned} & y_k = CA^{i+1} x_{k-i-1} + \\ & C(A^i G.z_{k-i-1} + \sum_{j=0}^{i-1} A^j G.z_{k-j-1}) \\ & + C(A^i Bu_{k-i-1} + Du_k + \sum_{j=0}^{i-1} A^j Bu_{k-j-1}) \\ & + f_k + w_k \end{aligned} \tag{7}$$

By identifying expressions (6) and (7), it is straightforward to prove that the proposal for $i+1$ (equation (6)) holds. This ends the proof. ■
Because the linear dynamic is supposed to be stable, i.e. $A^i$ tends to zero for $i$ sufficiently large which results to

$$CA^i x_{k-i} \to 0 \tag{8}$$

As a consequence, for $i$ sufficiently large, the state influence may be neglected in expression (4). This leads to the following approximated expression of the output $y_k$:

$$\begin{aligned} y_k &\cong C \sum_{j=0}^{i-1} A^j G.z_{k-j-1} \\ &+ C(Du_k + \sum_{j=0}^{i-1} A^j Bu_{k-j-1}) \\ &+ f_k + w_k \end{aligned} \tag{9}$$

The matrix representation of expression (9) is given by:

$$\forall i \geq 0 : y_k = \widetilde{H}_i \overline{z}_{k,i} + \overline{H}_i \overline{u}_{k,i} + f_k + w_k \tag{10}$$

## IV. Data-projection residual generation

In this section, a data-based residual $\epsilon_k$ is generated for sensor fault detection and isolation.

By right-multiplying (Kronecker product) the measurement equation of system (1) by $u_k$, and using the following Kronecker product properties:

- $(Q_1 \otimes Q_2)(Q_3 \otimes Q_4)$=$(Q_1\ Q_3) \otimes (Q_2\ Q_4)$
- $(Q_1 \otimes Q_2)$=$(Q_1 \otimes I)Q_2$

where $Q_1$, $Q_2$, $Q_3$ and $Q_4$ are matrices with appropriate dimensions, we can derive the following expression:

$$\begin{aligned} p_k = (C \otimes I_m)z_k + (D \otimes I_m)q_k + \\ (f_k \otimes u_k) + (w_k \otimes u_k) \end{aligned} \tag{11}$$

where $I_m$ is the identity matrix of dimension $m \times m$ and

$$\begin{cases} z_k = x_k \otimes u_k \\ p_k = y_k \otimes u_k\ . \\ q_k = u_k \otimes u_k \end{cases}$$

Consider an integer $L$, which is chosen such that $L > mi + \ell$. The following subsequent vectors and matrices are introduced:

$$s_k = \begin{bmatrix} p_k \\ q_k \end{bmatrix} = \begin{bmatrix} y_k \otimes u_k \\ u_k \otimes u_k \end{bmatrix} \in R^{(\ell+m)m \times 1}$$

$$\overline{s}_{k,i} = \left[ s_{k-i}^T | \cdots | \, s_{k-2}^T | \, s_{k-1}^T \right]^T \in R^{(\ell+m)mi \times 1}.$$

$$S_k = \left[ \overline{s}_{k-L+1,i} \cdots \overline{s}_{k-1,i}\, \overline{s}_{k,i} \right] \in R^{(\ell+m)mi \times L}.$$

$$Z_k = \left[ \overline{z}_{k-L+1,i} \cdots \overline{z}_{k-1,i}\, \overline{z}_{k,i} \right] \in R^{nmi \times L}.$$

$$\begin{aligned} \overline{f}_{k,i} = \left[ (f_{k-i} \otimes u_{k-i})^T | \cdots | \, (f_{k-2} \otimes u_{k-2})^T | \right. \\ \left. (f_{k-1} \otimes u_{k-1})^T \right]^T \in R^{\ell mi \times 1}. \end{aligned}$$

$$\overline{F}_k = \left[ \overline{f}_{k-L+1,i} \cdots \overline{f}_{k-1,i}\, \overline{f}_{k,i} \right] \in R^{\ell mi \times L}.$$

$$\begin{aligned} \overline{w}_{k,i} = \left[ (w_{k-i} \otimes u_{k-i})^T | \cdots | \, (w_{k-2} \otimes u_{k-2})^T | \right. \\ \left. (w_{k-1} \otimes u_{k-1})^T \right]^T \overline{w}_{k,i} \in R^{\ell mi \times 1}. \end{aligned}$$

$$\overline{W}_k = \left[ \overline{w}_{k-L+1,i} \cdots \overline{w}_{k-1,i}\, \overline{w}_{k,i} \right] \in R^{\ell mi \times L}.$$

$$M_i = \begin{bmatrix} C \otimes I_m & 0_{\ell m \times nm} & \cdots & 0_{\ell m \times nm} \\ 0_{\ell m \times nm} & C \otimes I_m & \ddots & \vdots \\ \vdots & \ddots & \ddots & 0_{\ell m \times nm} \\ 0_{\ell m \times nm} & \cdots & 0_{\ell m \times nm} & C \otimes I_m \end{bmatrix} \in R^{\ell mi \times nmi}.$$

$$K_i = \begin{bmatrix} \left[ I_{\ell m} | \, D \otimes I_m \right] & 0_{\ell m \times (\ell m + m^2)} & \cdots & 0_{\ell m \times (\ell m + m^2)} \\ 0_{\ell m \times (\ell m + m^2)} & \left[ I_{\ell m} | \, D \otimes I_m \right] & \ddots & \vdots \\ \vdots & \ddots & \ddots & 0_{\ell m \times (\ell m + m^2)} \\ 0_{\ell m \times (\ell m + m^2)} & \cdots & 0_{\ell m \times (\ell m + m^2)} & \left[ I_{\ell m} | \, D \otimes I_m \right] \end{bmatrix}$$

where $K_i \in R^{\ell mi \times (\ell+m)mi}$.

By putting the terms dependent on the system input and output on the left side of equality (11), the rest of the terms are put on the right side, the following expression is derived at time $k$:

$$\begin{aligned} \left[ I_{\ell m} | \, D \otimes I_m \right] s_k = \\ (C \otimes I_m)z_k + (f_k \otimes u_k) + (w_k \otimes u_k) \end{aligned} \tag{12}$$

Expression (12) at $k-1$ is given similarly as follows:

$$\begin{aligned} \left[ I_{\ell m} | \, D \otimes I_m \right] s_{k-1} = \\ (C \otimes I_m)z_{k-1} + (f_{k-1} \otimes u_{k-1}) + (w_{k-1} \otimes u_{k-1}) \end{aligned} \tag{13}$$

Equation (13) can be rewritten differently as follows:

$$\begin{aligned} 0_{\ell m \times (\ell m + m^2)} s_{k-i} + \cdots + 0_{\ell m \times (\ell m + m^2)} s_{k-2} + \\ \left[ I_{\ell m} | \, D \otimes I_m \right] s_{k-1} = 0_{\ell m \times nm} z_{k-i} + \cdots + 0_{\ell m \times nm} z_{k-2} \\ + (C \otimes I_m)z_{k-1} + (f_{k-1} \otimes u_{k-1}) + (w_{k-1} \otimes u_{k-1}) \end{aligned} \tag{14}$$

By writing expression (12) at $k-2$

$$\begin{aligned} \left[ I_{\ell m} | \, D \otimes I_m \right] s_{k-2} = \\ (C \otimes I_m)z_{k-2} + (f_{k-2} \otimes u_{k-2}) + (w_{k-2} \otimes u_{k-2}) \end{aligned} \tag{15}$$

Equation (15) can be rewritten differently as follows:

$$\begin{aligned} 0_{\ell m \times (\ell m + m^2)} s_{k-i} + \cdots + 0_{\ell m \times (\ell m + m^2)} s_{k-3} + \\ \left[ I_{\ell m} | \, D \otimes I_m \right] s_{k-2} + 0_{\ell m \times (\ell m + m^2)} s_{k-1} = \\ 0_{\ell m \times nm} z_{k-i} + \cdots + 0_{\ell m \times nm} z_{k-3} + (C \otimes I_m)z_{k-2} + \\ 0_{\ell m \times nm} z_{k-1} + (f_{k-2} \otimes u_{k-2}) + (w_{k-2} \otimes u_{k-2}) \end{aligned} \tag{16}$$

By following the same procedure till $k-i$, the common matrix representation of all the obtained equations is given by:

$$K_i \overline{s}_k = M_i \overline{z}_k + \overline{f}_k + \overline{w}_k \tag{17}$$

By concatenating equation (17) over columns on a time-window of size $L$, we can derive the following equation:

$$K_i S_k = M_i Z_k + \overline{F}_k + \overline{W}_k \tag{18}$$

The derived equation (18) and following theorems will be useful in the sequel. We are now ready to express the main results of our paper as Theorem 4.2 and Proposition 2.

*Theorem 4.1:* If the number of independent rows of the matrix $C$ is equal or greater than the number of independent columns of $C$, then the matrix $M_i$ is left invertible. In other words, it exists a matrix $V_i$ such that the following relation holds:

$$V_i M_i = I_{i\alpha} \tag{19}$$

where $\alpha$ is the number of independent rows of the matrix $C$. If the number of independent rows of the matrix $C$ is equal to the number of independent columns of $C$, then
$V_i = M_i^{-1}$.

If the number of independent rows of the matrix $C$ is greater than the number of independent columns of $C$, then
$V_i = (M_i^T M_i)^{-1} M_i^T$.

*Theorem 4.2:* If $\Gamma \in R^{\cdot \times L}$ is a matrix, where the number of independent rows is equal or less than the number of independent columns, then the right kernel of $\Gamma$ is given by:

$$\Pi_{\Gamma} = I_L - \Gamma^T(\Gamma\Gamma^T)^{-1}\Gamma \in R^{L\times L} \qquad (20)$$

where $\Pi_{\Gamma}$ is the right projection matrix of $\Gamma$, and consequently we have:

$$\Gamma\Pi_{\Gamma} = 0 \qquad (21)$$

Using left invertibility property of $M_i$, and by left multiplying equation (18) by $V_i$, matrix $Z_k$ is given by

$$Z_k = V_i K_i S_k - V_i\overline{F}_k - V_i\overline{W}_k \qquad (22)$$

Right projecting matrix $Z_k$ on the right kernel matrix $\Pi_{\left[\begin{smallmatrix} S_k \\ U_k \end{smallmatrix}\right]}$ of $\begin{bmatrix} S_k \\ U_k \end{bmatrix}$, the equation (22) becomes:

$$Z_k\Pi_{\left[\begin{smallmatrix} S_k \\ U_k \end{smallmatrix}\right]} = -V_i\overline{F}_k\Pi_{\left[\begin{smallmatrix} S_k \\ U_k \end{smallmatrix}\right]} - V_i\overline{W}_k\Pi_{\left[\begin{smallmatrix} S_k \\ U_k \end{smallmatrix}\right]} \qquad (23)$$

where $U_k = \left[\overline{u}_{k-L+1,i}|\cdots|\,\overline{u}_{k-1,i}|\,\overline{u}_{k,i}\right] \in R^{m(i+1)\times L}$.

*Proposition 2:* The proposed parameter-free residual is defined as follows:

$$\epsilon_k = Y_k\Pi_{\left[\begin{smallmatrix} S_k \\ U_k \end{smallmatrix}\right]} \qquad (24)$$

where $Y_k = \left[y_{k-L+1,i}|\cdots|\,y_{k-1,i}|\,y_{k,i}\right] \in R^{\ell\times L}$.

The mathematical expectation of $\epsilon_k$,$r = E[\epsilon_k]$ is used for fault detection.

*Proof:*

By concatenating equation (10) over columns on a time-window of size $L$, we can derive the following equation:

$$\forall i \geq 0 : Y_k = \widetilde{H}_i Z_k + \overline{H}_i U_k + F_k + W_k \qquad (25)$$

where $F_k$ and $W_k$ are constructed similarly as $Y_k$.

1) If there is no sensor fault ($f_k = 0$): [we will prove in this case that $E[\epsilon_k] = 0$]

   By concatenating the output in equation (4) on a time-window of size $L$, the evaluation form of the proposed parameter-free residual is given by:

$$\epsilon_k = Y_k\Pi_{\left[\begin{smallmatrix} S_k \\ U_k \end{smallmatrix}\right]} \cong \widetilde{H}_i Z_k\Pi_{\left[\begin{smallmatrix} S_k \\ U_k \end{smallmatrix}\right]} + W_k\Pi_{\left[\begin{smallmatrix} S_k \\ U_k \end{smallmatrix}\right]} \qquad (26)$$

   where $W_k$ and $F_k$ are constructed similarly as $Y_k$. By replacing (23) into (26), and knowing that $\Pi_{\left[\begin{smallmatrix} S_k \\ U_k \end{smallmatrix}\right]}$ is a right kernel of $U_k$, we get:

$$\epsilon_k \cong -\widetilde{H}_i V_i\overline{W}_k\Pi_{\left[\begin{smallmatrix} S_k \\ U_k \end{smallmatrix}\right]} + W_k\Pi_{\left[\begin{smallmatrix} S_k \\ U_k \end{smallmatrix}\right]} \qquad (27)$$

   The evaluation form (27) of the proposed residual is a linear combination of a centered noise $w$, which implies that $E[\epsilon_k] = 0$ when there is no sensor fault.

2) If there is a sensor fault: [we will prove in this case that $E[\epsilon_k] \neq 0$]

   From equation (27), the evaluation form of the proposed parameter-free residual is given by:

$$\begin{aligned}\epsilon_k \cong{} & -\widetilde{H}_i V_i\overline{F}_k\Pi_{\left[\begin{smallmatrix} S_k \\ U_k \end{smallmatrix}\right]} - \widetilde{H}_i V_i\overline{W}_k\Pi_{\left[\begin{smallmatrix} S_k \\ U_k \end{smallmatrix}\right]} + \\ & W_k\Pi_{\left[\begin{smallmatrix} S_k \\ U_k \end{smallmatrix}\right]} + F_k\Pi_{\left[\begin{smallmatrix} S_k \\ U_k \end{smallmatrix}\right]}\end{aligned} \qquad (28)$$

   Following the same procedure as in the no fault case to get the equation (27), the evaluation form of the mathematical expectation of the proposed (28) parameter-free residual becomes:

$$\begin{aligned}E[\epsilon_k] \cong{} & -E[\widetilde{H}_i V_i\overline{F}_k\Pi_{\left[\begin{smallmatrix} S_k \\ U_k \end{smallmatrix}\right]}] + \\ & E[F_k\Pi_{\left[\begin{smallmatrix} S_k \\ U_k \end{smallmatrix}\right]}]\end{aligned} \neq 0 \qquad (29)$$

   which shows the sensitivity of the mathematical expectation of the proposed residual to sensor faults.

### A. Sensor fault isolability

As shown previously the sensor fault is detectable, in addition to that an important process is to isolate this fault which means the decision on which sensor is in faulty case. To achieve this process we distinguish two cases, when the sensor fault is a constant bias fault at least during the time window of $L + i + 1$ and when it is not.

When the sensor fault is a constant bias fault at least during the time window of $L+i+1$, we have the following expression:

$$-\widetilde{H}_i V_i\overline{F}_k\Pi_{\left[\begin{smallmatrix} S_k \\ U_k \end{smallmatrix}\right]} = 0 \qquad (30)$$

As a result the expression (28) becomes:

$$\epsilon_k \cong -\widetilde{H}_i V_i\overline{W}_k\Pi_{\left[\begin{smallmatrix} S_k \\ U_k \end{smallmatrix}\right]} + W_k\Pi_{\left[\begin{smallmatrix} S_k \\ U_k \end{smallmatrix}\right]} + F_k\Pi_{\left[\begin{smallmatrix} S_k \\ U_k \end{smallmatrix}\right]} \qquad (31)$$

Following the same procedure as in the no fault case to get the equation (27), the evaluation form of the mathematical expectation of the proposed (31) parameter-free residual becomes:

$$E[\epsilon_k] \cong F_k\Pi_{\left[\begin{smallmatrix} S_k \\ U_k \end{smallmatrix}\right]} \qquad (32)$$

which shows that the mathematical expectation of the proposed residual is structured, which means that the first row of $E[\epsilon_k]$ is dedicated for the first sensor, the second row of $E[\epsilon_k]$ is dedicated for the second sensor and so on, in this case only the corresponding mathematical expectation of the residual is not zero when the corresponding sensor is in a faulty case.

If the fault fluctuates instantaneously and $\widetilde{H}_i V_i = 0$, it is the same case as for constant bias sensor faults.

But if the fault fluctuates instantaneously and $\widetilde{H}_i V_i \neq 0$, a more convenient decision algorithm should be developed and this case is not treated in this paper for brevity reasons (for signature table the reader is referred to [20] and [21]).

■

## V. Example and simulation

An electromechanical actuator [19] is used to show the effectiveness of the proposed residual generation method for sensor fault detection and isolation.

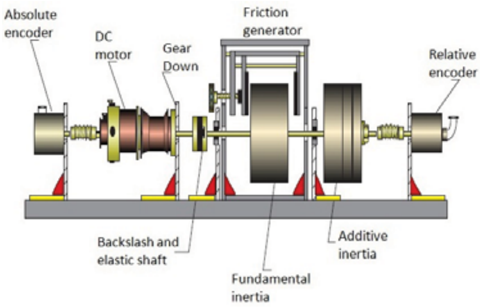

Fig. 1. Electromechanical actuator

This plant may be modeled by a bilinear state-space model:

$$\begin{cases} x_{k+1} = Ax_k + G(x_k \otimes u_k) + Bu_k \\ y_k = Cx_k + Du_k + f_k + w_k \end{cases} \tag{33}$$

with

$$A = \begin{pmatrix} -\frac{R_a}{L_a} & 0 & 0 & 0 \\ 0 & -\frac{F_m}{J_m} & -\frac{k_r}{NJ_m} & 0 \\ 0 & \frac{1}{N} & 0 & -1 \\ 0 & 0 & \frac{k_r}{J_c} & -\frac{F_c}{J_c} \end{pmatrix},$$

$$G = \begin{pmatrix} 0 & 0 & -\frac{k_a}{L_a} & 0\,0\,0\,0\,0 \\ \frac{k_a}{J_m} & 0 & 0 & 0\,0\,0\,0\,0 \\ 0 & 0 & 0 & 0\,0\,0\,0\,0 \\ 0 & 0 & 0 & 0\,0\,0\,0\,0 \end{pmatrix}, \; B = \begin{pmatrix} 0 & \frac{1}{L_a} \\ 0 & 0 \\ 0 & 0 \\ 0 & 0 \end{pmatrix},$$

$$C = \begin{pmatrix} 1\,0\,0\,0 \\ 0\,0\,0\,1 \end{pmatrix}, \; D = \begin{pmatrix} 0\,0 \\ 0\,0 \\ 0\,0 \\ 0\,0 \end{pmatrix}$$

The model parameters are defined in table 1, these parameters are not used for residuals generation but they are used to simulate the model and to generate output data.

| Parameter | Description | Value | Unit |
|---|---|---|---|
| $T_e$ | sampling time | 0.03 | $[sec]$ |
| $J_m$ | motor shaft inertia | $2.4e-4$ | $[m^2kg]$ |
| $J_c$ | load shaft inertia | 0.0825 | $[m^2kg]$ |
| $F_m$ | motor viscous friction | 0.0032 | $[m^2kg/sec]$ |
| $F_c$ | load viscous friction | 0 | $[m^2kg/sec]$ |
| $k_a$ | motor torque constant | 0.156 | $[m^2kg/sec^2]$ |
| $k_r$ | coupling rigidity coefficient | 37.7 | $[m^2kg/sec^2]$ |
| $R_a$ | motor resistance | 1 | $[\Omega]$ |
| $L_a$ | motor inductance | 0.05 | $[H]$ |
| $N$ | gear ratio | 20 | |
| $i$ | time-window | 16 | |
| $L$ | time-window | 339 | |

Table 1

The 4 states are given in table 2:

| State | Description |
|---|---|
| $i_a$ | armature current |
| $w_m$ | motor shaft velocity |
| $\Delta$ | angular rotation |
| $w_c$ | load shaft angular velocity |

Table 2

The input vector is plotted in Fig.2:

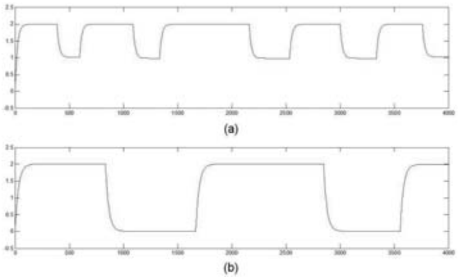

Fig. 2. (a): $u(1,:) = i_e$ is the stator current, (b): $u(2,:) = v_a$ is the armature voltage

The two outputs are plotted in Fig.3:

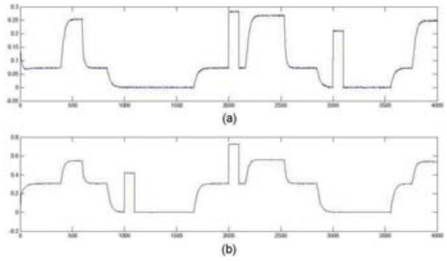

Fig. 3. (a): $y(1,:)$ is the armature current, (b): $y(2,:)$ is the angular velocity

There are two calculated residuals since the number of sensors is 2, the calculated residuals using the proposed method are presented in Fig.4.

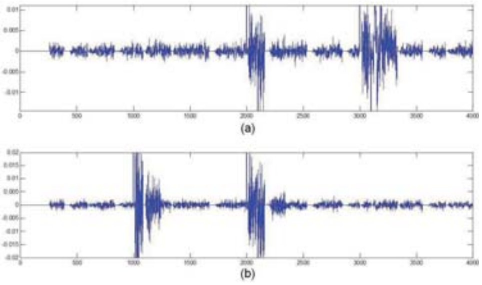

Fig. 4. (a): $\epsilon_k(1)$ is the first residual, (b): $\epsilon_k(2)$ is the second residual

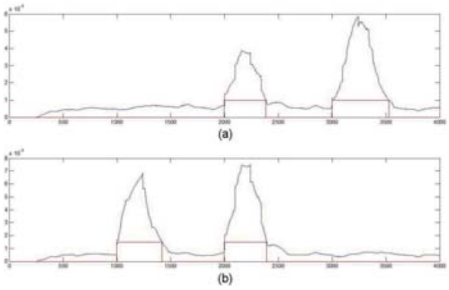

Fig. 5. Blue:(a): $E[\epsilon_k(1)]$, (b): $E[\epsilon_k(2)]$, Red: Thresholding the finite moving average of the proposed residual

In Fig. 5, the blue curve represents the mathematical expectation of the proposed residuals, this mathematical expectation is calculated in a moving time-window of size 339. The red curve represents the result of the decision procedure called Finite Moving Average (FMA) [22] (see the FMA algorithm in Fig. **??**), this is due to the fault sensitivity of the residual mean, which seems to be well dedicated to decide whether there is a fault or not, a good choice of the threshold is needed which can be achieved offline using a healthy database, where the threshold is chosen greater than the maximum value of $E[\epsilon_k]$, for this example the threshold is equal to $0.001$ for the first sensor and $0.0015$ for the second sensor. Moreover, the FDI can be realized if multiple faults occur simultaneously.

## CONCLUSION

A data-projection residual generation method is presented for bilinear systems, where an output matrix is projected on the input right kernel matrix. A new way for input-output matrices construction is proposed to avoid complexity problem of the method presented in paper [15]. The online diagnosis is then easily implemented. Simulation results of an electromechanical actuator show the effectiveness of the proposed method.

*Abstract*—**In this paper a new design method is presented for reconfigurable fault tolerant control of multivariable nonlinear time delay systems. The control reconfiguration algorithm comprises two main parts: fault detection and diagnosis and model reference adaptive control. First, a combination of generic residual generation method and its Laguerre approximation is proposed due to the problem of residual similarity in fault diagnostic process. Second, a novel approach for adaptive reconfigurable control synthesis is proposed using a nonlinear system identification approach based on the approximation of systems via Laguerre series. The Laguerre-based reconfiguration method is implemented and tested on a time delay form of COSY benchmark model as a preliminary study of reconfigurable control applied to a nonlinear time-delayed model. Actuator faults have been implemented in the COSY benchmark and used to evaluate the control reconfiguration schemes. Simulation results showed acceptable level of fault tolerance.**

***Keywords-Fault tolerant control systems, fault detection and diagnosis, residual generation, model reference adaptive control, Laguerre series.***

## I. Introduction

Fault Tolerant Control Systems (FTCS) design is becoming the key issue in technical systems due to rapidly increasing demands for higher system performance, product quality, productivity and cost efficiency. As it is well-known, FTCSs are control systems that possess the ability of accommodating system component failures automatically. In General, FTCSs can be classified into two types: Passive Fault Tolerant Control Systems (PFTCS) and Active Fault Tolerant Control Systems (AFTCS). The design objective of AFTCS is to 1) design a Fault Detection and Diagnosis (FDD) scheme providing as precise as possible information about a fault and 2) design a new reconfigurable controller in response to and compensating for the fault-induced changes in the system, such that the stability and acceptable close-loop system performance can be maintained.

A successful control system reconfiguration relies on a real-time FDD scheme to provide the most up-to-date information about the system. Model-based methods of fault-detection can be used in presence of input and output signals and applying dynamic process models. These methods are based, e.g., on parameter estimation, parity equations or state observers [1,2]. The goal of fault detection is to generate several symptoms indicating the difference between nominal and faulty status. Based on different symptoms, fault diagnosis procedure follows, determining the fault by applying classification or inference methods. In the FDD module, both the fault parameters and the system state variables need to be estimated online in real time. In the case of nonlinear systems one approach is to linearize nonlinear model using system identification methods. Several fault diagnosis methods have been proposed for systems linearized around an operating equilibrium point (see [3] and [4]). Some of these techniques have also been extended to nonlinear systems. In [5] nonlinear observers are synthesized to detect tank leakage.

The strategy of reconfigurable control is based on inherent information of nominal and faulty systems so as to make these systems consistent in some proper sense. This strategy fits the model following/matching scheme well if we regard the nominal systems as the reference models. Model Reference Adaptive Control (MRAC) is a mathematical approach which can be used to design a model-based reconfigurable control. Research on the application of adaptive methods to reconfigurable control has been extensively studied during past years. Poirot and co-authors in [6] have proposed a framework for constructing adaptive and reconfigurable control system based on the control loop paradigm. In [7] three adaptive algorithms for multivariable model reference control in flight control applications have been compared. A Failure Detection and Identification (FDI) and Adaptive Reconfigurable Control (ARC) procedure based on a decentralized FDI-ARC scheme integrating separate modules for aerospace applications has been carried out by Boskovic and co-authors in [8]. They also have done an adaptive fault tolerant control based on the estimation of damage-related parameter and switching among multiple controllers for flight control in [9]. Furthermore, Boskovic and co-authors proposed a new failure parameterization that models a large class of failures in terms of a single parameter in [10]. In order to accomplish the model following /matching scheme, MRAC is an appropriate approach. A number of investigators have proposed MRAC techniques for nonlinear systems [11], [12] and [13].

In practice, systems with time delays are frequently encountered (e.g., process control systems). Time-delayed linear systems have been intensively investigated in [14]. Lyapunov design has been proven to be an effective tool in controller design for nonlinear systems. Adaptive control has also proven its capability in controlling nonlinear time-delayed

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

systems [15], [16], [17]. The FDD problem in time delay systems has also been investigated recently in [18] and [19].

A common topic that has been gaining interest is nonlinear systems. Model linearization is the key issue in the case of nonlinear systems. The idea we used in this paper is approximation of systems via basis functions. This representation is much more parsimonious than the FIR or IIR ones, but contrary to the transfer function model does not require assumptions about the order and time delay of the process. Although it is implemented in a state-space form, it is straightforward to use in system identification. Furthermore, orthogonal polynomials can be used to make the polynomial coefficients uncorrelated, to minimize the error of approximation, and to minimize the sensitivity of calculations to round-off error. Laguerre models suggested here provide feasibility and stability for the closed-loop system. Laguerre lattice filter identifier counts for 1) the identification of the system's dynamics, that are mapped into the filter's structure through the utilization of estimated reflection coefficients and 2) the system's order identification. In [20] the usage of Laguerre parameterization of input sequences in model predictive control has been investigated. Also application of Volterra series to the modeling of static and dynamic nonlinear systems is investigated in [21]. A model predictive control strategy based on Laguerre functions has also been proposed in [22].

This paper looks at the problem of reconfigurable fault tolerant control systems in time-delayed nonlinear systems using Laguerre series in case that system is noise free and disturbances are dispensable. This work on the reconfigurable control synthesis is under assumption that the faulty system information is known by using Laguerre model. After achieving Laguerre model, MRAC is applied on the basis of this linearized model to have better control. At next step, in order to have an accurate FDD, we suggest a novel approach to the problem of residual similarity. A combination of residual generation methods and parameter estimation using Laguerre series would simplify decision making. We employed this concept to generate more detailed residuals. However, because increasing residual signals may leads to diagnosis complexity, classification methods will be helpful. The effectiveness of the Laguerre-based MRAC has been shown via simulation results on a time delay form of COSY benchmark.

## II. Problem Statement

Let us consider the following nonlinear multivariable system subjected to input delay

$$\begin{aligned}\dot{X}(t) &= f_1(X(t), U(t-\tau), F(t), d(t), w(t))\\ Y(t) &= f_2(X(t), U(t-\tau), F(t), d(t), w(t)).\end{aligned} \tag{1}$$

in which $X \in \mathcal{R}^N$ , $U \in \mathcal{R}^m$ and $Y \in \mathcal{R}^N$ are state vector, input and output signals respectively, $\tau \in \mathcal{R}^+$ is the known input delay , $F_{1\times nf}$ is the vector of occurred faults (nf is the number of faults), $d_{1\times nd}$ is the disturbance vector and $w_{1\times nw}$ represents uncertainty or noise vector.

We can approximate (1) using an Nth order Laguerre model

$$\begin{aligned}Y(t) = &\sum_{i=1}^{N} C_i(f)L_i(q,\alpha)U(t)\\ &+\sum_{i=1}^{N} d_i(f)L_i(q,\alpha)Y(t)\end{aligned} \tag{2}$$

where

$$L_i(q,\alpha) = \frac{\sqrt{1-\alpha^2}}{q-\alpha}\left(\frac{1-\alpha q}{q-\alpha}\right)^{i-1} \qquad i = 1,2,\dots, \tag{3}$$

$|\alpha| < 1$ is Laguerre parameter and Laguerre coefficients $C_i(f)$ and $d_i(f)$ could be calculated using recursive least square algorithm. For complicated systems, high orders of Laguerre polynomials give a simple realization of the system and would decrease the approximation error.

Assuming $d(t) = w(t) = 0$ - the system is noise free and disturbances are dispensable - we propose the MRAC scheme for multivariable plant model

$$Y(t) = C(f)L(q,\alpha)\, U(t) \tag{4}$$

where$Y(t) \in \mathcal{R}^N$ and $U(t) \in \mathcal{R}^N$ are output and control input vectors. Moreover

$$L(q,\alpha) = \begin{bmatrix} L_1(q,\alpha) & 0 & 0\\ \vdots & \vdots & \vdots\\ L_p(q,\alpha) & 0 & 0\\ 0 & L_1(q,\alpha) & 0\\ \vdots & \vdots & \vdots\\ 0 & L_p(q,\alpha) & 0\\ 0 & 0 & 0\\ \vdots & \vdots & \vdots\\ \vdots & \vdots & L_1(q,\alpha)\\ \vdots & \vdots & \vdots\\ 0 & 0 & L_p(q,\alpha)\end{bmatrix}_{np\times n} \tag{5}$$

is Laguerre matrix and

$$C(f)_{n\times np} = \begin{bmatrix} C_{111}(f) & \dots & C_{1p1}(f) & \cdots & C_{n11}(f) & \dots & C_{np1}(f)\\ & & \vdots & \ddots & & & \vdots\\ C_{11n}(f) & \dots & C_{1pn}(f) & \cdots & C_{n1n}(f) & \dots & C_{npn}(f)\end{bmatrix}_{n\times np} \tag{6}$$

is Laguerre coefficients matrix under the effect of fault .

The problem is to design an adaptive reconfigurable fault tolerant controller for this system such that all signals of the closed-loop system are bounded and the plant output $y(t)$, asymptotically exact, follows the output $Y_m(t)$ of the reference model

$$Y_m(t) = W_m(s)r = C_m L(q,\alpha)\, r \tag{7}$$

where $W_m(s) \in \mathcal{R}^{N\times N}$ is a stable rational transfer matrix, $r \in \mathcal{R}^N$ is a bounded reference input signal and $C_m$ is Laguerre coefficients matrix.

Let us write (4) as

$$Y_P = G(s)U_p \tag{8}$$

where $G(s) = C(f)L(q, \alpha)$ is the transfer matrix of the linear system. It should be noted that since the relative degree of the Laguerre model is $n^* = 1$

$$\mathrm{L_i}(\mathrm{s}, \alpha) = \frac{\sqrt{2\alpha}}{\mathrm{s} + \alpha}\left(\frac{\mathrm{s} - \alpha}{\mathrm{s} + \alpha}\right)^{\mathrm{i}-1} \tag{9}$$

the relative degree of $\mathrm{G(s)}$ is also $\mathrm{n}^* = 1$.

To meet the control objective the following assumptions are made about $\mathrm{G(s)}$[23]:

(A1): $\mathrm{G(s)}$ is strictly proper and has full rank.

(A2): The transmission of zeros of $\mathrm{G(s)}$ have negative real parts.

(A3): An upper bound $\bar{\nu}_0$ on the observability index $\nu_0$ of $\mathrm{G(s)}$ is known.

(A4): There exists a known matrix $\mathrm{S_p(f)}$ such that $\mathrm{K_p(f)\ S_p(f)} = (\mathrm{K_p(f)S_p(f)})^{\mathrm{T}} > 0$.

In (A4), the high frequency gain matrix $K_p(f)$ of the model is defined as

$$\mathrm{K_p(f)} = \mathrm{C_p(f)\ C_m}^{-1} \tag{10}$$

which is finite and nonsingular. It should be noted that the system dynamics may have some inputs which are not control inputs, but only play a leading role in modeling. In this situations, to achieve appropriate $\mathrm{K_p(f)}$ , matrixes $\mathrm{C_p(f)}$ and $\mathrm{C_m}^{-1}$ must be defined such that all of their elements refer to control inputs.

Without loss of generality, it is assumed that the transfer function of the reference model is diagonal SPR and of the form

$$\mathrm{W_m(s)} = \mathrm{diag}\left[\frac{1}{\mathrm{s} + \mathrm{a_{ri}}}\right], \mathrm{a_{ri}} > 0, i = 1, \dots, N \tag{11}$$

## III. FAULT DETECTION AND DIAGNOSIS METHOD

Early fault detection, which reduces the possibility of catastrophic damage, is possible by comparing the measured signals with a database that contains characteristic signals for machines operating with or without faulty conditions. To obtain the most up-to-date and comprehending database for fault diagnosis simplicity, we need to consider all possible conditions such as types and severities of faults.

In some cases, decision making is difficult because of similarly behaved residuals resulted from faults with different types or different severities. This is the motivation to search more residuals to distinguish these faults. Hence, a combination of residual generation approaches are suggested to overcome this weakness and to make the database better suited for the FDD. The new approach proposed in this paper, combines residual generation methods with parameter estimation using Laguerre series. In fact, residuals from basic FDD method which are weak to have a good decision are expanded via Laguerre series which results in Laguerre coefficients. These coefficients can be used as supplementary residuals to have a well-informed database and to facilitate the decision making easier. This approach is formulized as follows. Let

$$\mathrm{Residue(t)} = \sum_{\mathrm{i}=1}^{\mathrm{n}} \mathrm{r(i,q)\ Residue(t-i)} \tag{12}$$

be the expansion of resulting residuals from basic FDD method where q, $\mathrm{r(i,q)}$ and n denote respectively delay operator, coefficients and model order. Coefficients can be expanded in Laguerre model

$$\mathrm{r(i,q)} = \sum_{\mathrm{j}=1}^{\mathrm{p}} \mathrm{a_{ji}L_j}(\mathrm{q}, \alpha) \tag{13}$$

which leads to

$$\mathrm{Residue(t)} = \sum_{\mathrm{i}=1}^{\mathrm{n}}\sum_{\mathrm{j}=1}^{\mathrm{p}} \mathrm{a_{ji}L_j}(\mathrm{q}, \alpha)\ \mathrm{Residue(t-i)} \tag{14}$$

resulting in Laguerre coefficients $\mathrm{a_{ji}}'\mathrm{s}$ which can be used as supplementary residuals to make an easier fault detection.

Reconfigurable controller

In general, the existing reconfigurable controller design methods fall into one of the following approaches: Linear quadratic regulator, Eigen structure assignment, multiple-model, adaptive control, pseudo-inverse, perfect model following and feedback linearization [22]. Our objective is to design a reconfigurable control strategy to accommodate system component faults.

In this paper, a nonlinear MRAC strategy based on Laguerre model is presented. A Laguerre model is used to synthesize a linear controller that provides a satisfactory closed-loop performance near the nominal operating point.

The proposed control law is considered as

$$\mathrm{U} = \theta_1^{*\mathrm{T}}\mathrm{w_1} + \theta_2^{*\mathrm{T}}\mathrm{w_2} + \theta_3^*\mathrm{r} = \theta^{*\mathrm{T}}\mathrm{w} \tag{15}$$

where

$$\theta^{*\mathrm{T}} = \left[\theta_1^{*\mathrm{T}} \quad \theta_2^{*\mathrm{T}} \quad \theta_3^*\right], \tag{16}$$

$$\mathrm{w} = [\mathrm{w_1}^{\mathrm{T}} \quad \mathrm{w_2}^{\mathrm{T}} \quad \mathrm{r}^{\mathrm{T}}]^{\mathrm{T}}, \tag{17}$$

$$\mathrm{w_1} = \frac{\mathrm{A(s)}}{\Lambda(\mathrm{s})}\mathrm{U} \quad , \quad \mathrm{w_2} = \frac{\mathrm{A(s)}}{\Lambda(\mathrm{s})}\mathrm{Y}, \tag{18}$$

$$\mathrm{A(s)} = [\mathrm{Is}^{\bar{\nu}_0 - 1} \quad \mathrm{Is}^{\bar{\nu}_0 - 2} \quad \dots \quad \mathrm{Is} \quad \mathrm{I}]^{\mathrm{T}} \tag{19}$$

and $\Lambda(\mathrm{s})$ is a monic Hurwitz polynomial of degree $\bar{\nu}_0$ (A3).

**Proposition1**: Consider the system (1) with the assumptions (A1) – (A4) and the reference model (7). Then the adaptive control (15) with update laws

$$\dot{\theta}^{\mathrm{T}} = -\Gamma_{\mathrm{p}}(\mathrm{f})\epsilon\,\mathrm{w}^{\mathrm{T}} \tag{20}$$

assures that all closed-loop signals are bounded and the tracking error $\mathrm{e_1} = \mathrm{Y_p} - \mathrm{Y_m}$ converges to zero asymptotically. ■

In equation (20) $\epsilon = Y(t) - D_p(f) L(q, \alpha)\, \hat{\theta}^{*T} w$ is the output error, $Y(t) = D_p(f)\, L(q, \alpha)\, U(t)$ and $\hat{Y}_f(t) = D_p(f)\, L(q, \alpha)\, \hat{\theta}^{*T} w$ are output vector and its estimate, respectively.

## IV. Simulation Study

A time delay form of the COSY benchmark is considered for simulation studies. The benchmark is composed of three identical tanks with identical area of cross section. The measured variables are the levels of the first tank($h_1$), second tank ($h_2$) and third tank ($h_3$) respectively. Inflows of the first tank ($q_{in1}$) and third tank ($q_{in2}$) are chosen as known inputs. Inflows vary between 0 and 1 and the status of inter connecting pipes switches between 0 and 1, therefore the system can be considered as a hybrid system [4].

When the valve $V_{12}$ operates with delay $T = 10$ seconds, the objective is to control levels of the first and second tanks. The third tank is hardware redundant which may be used in the presence of faults. Control inputs are Inflow of first tank $q_{in1}$ and status of main inter connecting pipe $V_{12}$.

COSY benchmark without time delay has been investigated by many researchers [25]. But in order to apply Proposition1 to its time delay form, the nonlinear model is linearized via Laguerre series with sampling time $T_s = 0.1$ seconds.

### A. FDD method

In this paper the preliminary FDD approach considered is parity equations. A straightforward model-based method of fault detection is to take fix model $G_m$ and run it parallel to the process, thereby forming an output error [1]

$$r(t) = [G_P(s) - G_m(s)]u(t) \tag{21}$$

Since the modeling approach is system identification using Laguerre series, the parity equation approach would follow

$$r(t) = y(t) - \sum_{i=0}^{i=N} C_i(\alpha) L_i(z, \alpha)\, u(t). \tag{22}$$

Two main residuals used in our work are

$$residue1(t) = h_1(t) - \sum_{i=0}^{i=2} C_i(\alpha) L_i(z, \alpha)\, u_1(t) \tag{23}$$

and

$$residue2(t) = h_2(t) - \sum_{i=0}^{i=2} C_i(\alpha) L_i(z, \alpha)\, u_2(t). \tag{24}$$

When faults occur with similar residuals, Laguerre model of order 4 is used to derive Laguerre coefficients of residuals (output errors) to obtain secondary residuals. Preliminary residuals are expanded as

$$Residue1(t) = \sum_{i=1}^{4} a_{1i} L_i(q, \alpha)\, Residue1(t-1) \tag{25}$$

and

$$Residue2(t) = \sum_{i=1}^{4} a_{2i} L_i(q, \alpha)\, Residue2(t-1). \tag{26}$$

The difference between these coefficients ($a_{ji}$) and those of normal condition ($a_{jiN}$)

$$e_{ji} = a_{ji} - a_{jiN}. \tag{27}$$

are used as supplementary residuals.

For diagnosis, classification methods such as Artificial Neural Networks, Fuzzy clustering, Rule-based reasoning and Statistical methods are widely used [2]. The rule-based reasoning method is the one selected for this paper.

### B. Case one: Normal operation

We first start our study by considering the Laguerre-based MRAC strategy in the case with no faults. Hence we simulated the three tank model with $V_{23}(t) = 0$ , which means that the third tank is not under control. The resulting response is shown in Fig.1.

Leakage in first tank and blockage of main pipe between first and second tank are two common kinds of faults considered in three tank system. The severity of these faults can also be an important factor to take a proper action. Here we simulate blockage fault to show how severity of the fault affect decision making.

### C. Case Two: Blockage Fault Occurrence

Next, we simulate the system by assuming that the inter-connecting pipe $V_{12}$ is blocked completely. Responses of $h_1$ and $h_2$ in this case are shown in Fig. 2. Blocking $V_{12}$ results in an undesirable response, which emphasizes the necessity of control reconfiguration. In this situation the third tank enters as a hardware redundancy. The above fault can be easily detected by means of two preliminary residuals. The resulting responses are shown in Fig.3. Fig.4 also shows residuals. In this case to detect blockage we have no problem using these residuals; but when partial blockage occurs, the residuals would be as shown in Fig.5. As it is clear, it is somehow difficult to detect the right fault from difference between Fig.4and Fig.5. Therefore, supplementary residuals $e_{ji}$ shown in Fig.6-9 would be helpful.

## V. Conclusions

In this paper, we employed the concept of parameter estimation based on Laguerre series to solve the problem of reconfigurable fault tolerant control of nonlinear time delay systems. To achieve fast and reliable fault detection, diagnosis and correct reconfiguration, a new parameter estimation method using Laguerre series has been proposed and is combined with other residuals generation approaches. For this purpose, a model reference adaptive fault tolerant control based on Laguerre model for nonlinear time delay systems is proposed. Simulation results for a time delay form of COSY benchmark system in the presence of blockage fault has shown the effectiveness of proposed Laguerre-based FDD-FTCS approach. Note that, the proposed method is also simulated for the leakage and the other faults. Although the obtained simulation results show again its effectiveness, but these simulation results have been omitted due to the lack of space.

However, the robustness of the proposed method to parameter uncertainty and/or its extension for real-world case will be investigated in our future works.

***Abstract*—Cryopumping systems provide an essential function in most magnetic confinement nuclear fusion experiments. The maintenance of an ultra-high vacuum in a magnetic confinement vessel is required for experiments to be conducted, without exception, and cryopumping systems are widely used to achieve this. As such, the availability of this type of nuclear fusion experiment depends in part upon the availability of its vacuum system. In order to reduce experimental time lost to unplanned maintenance, investigation and avoidable failures, a condition monitoring scheme targeted on a cryopumping vacuum system is proposed. A model of the cryopumping system deployed on the Joint European Torus is presented. The model is supported by a first principles derivation and is validated using historical data. Its application to a condition monitoring scheme is discussed. This paper contributes to the wider nuclear fusion development programme by addressing a key maintenance and reliability issue, which is an important step on the road to commercial fusion energy.**

***Index Terms*—Condition Monitoring, Cryopumping, Dynamic Modelling, Two Phase Systems**

## I. Introduction

All nuclear fusion experiments using magnetic confinement techniques rely on the maintenance of an ultra-high vacuum inside the reaction vessel. This includes all the other vessels with which it shares an atmosphere. Any event that causes a disruption or loss of vacuum will result in the experiment being stopped while the vacuum is regenerated and the cause of the event mitigated. At the leading nuclear fusion experiment, the Joint European Torus (JET), and indeed at most others, loss of vacuum events and disruptions to the vacuum pumping system are identified, diagnosed and isolated manually. This process can be lengthy, requiring many man hours of labour. Time expended on maintenance is a significant burden, and as such there is a strong motivation for its reduction. Condition monitoring techniques have been used successfully in many applications, and it is proposed that such a condition monitoring scheme would be a very useful tool for the engineering team at JET. Historically, most disruptive and loss of vacuum events have occurred in the neutral beam heating systems, therefore a condition monitoring scheme focused on this area would be useful. In this paper we discuss a model of the cryopumping system deployed in the neutral beam heating devices at JET and how it can be used in the development of a condition monitoring scheme.

The neutral injection box (NIB) cryopump can be considered to be a two phase system. Two excellent examples of modelling two phase systems can be found in T Phillip's book on modelling and simulation[1] and in KJ Astrom's paper on drum boiler dynamics[2]. The novel model presented here is inspired by these examples. G Duesing's 1987 paper[3] is often referred to in discussions of neutral beam injection systems, and more recently, Ciric[4] and Ciric et al[5] wrote about recent developments in JET's NIB cryopumping scheme. These sources, in addition to design documentation available from CCFE, provide detailed information on the system discussed here. For information on cryogenic and vacuum systems in general, R Barron's book[6], WM Rohsenow's comprehensive book[7] and DJ Hucknall's book[8] are all excellent sources. A two phase model of a cryopumping system, however, has not yet been presented in literature. Using sources together has allowed us to develop a novel analytical model of the JET NIB cryopumping system which can serve both as tool for the design of a condition monitoring scheme and simulating faults.

This paper is split into four sections. The second section describes the physical system with which we are concerned. A justification of the selection of the target subsystem is provided, and its important features are discussed. The third section goes through the analytical model of the NIB cryopumping system and the fourth section presents the a result of a simulation of the model compared to historical data. The final section summarises the key information presented in this paper and notes its future application to condition monitoring.

## II. The Physical Cryopump

Cryopumping reduces the pressure inside a vacuum vessel by condensing gasses onto very cold surfaces. There are several ways to achieve this; RA Haefer describes some in his 1989 book[9]. The NIB cryopumping system at JET works by cooling a series of extruded aluminium surfaces inset with capillaries with cryogenic fluid. Each NIB has ten cryopump elements on each side of the vessel. Fig. 1 is a plan view illustration of a single cryopump element.

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

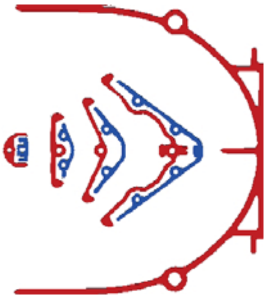

Fig. 1. A single cryopump element

Each cryopump element contains two types of surface: nitrogen surfaces and helium surfaces. The nitrogen surfaces are cooled to around 77K using liquid nitrogen. Similarly, the helium surfaces are cooled to around 4.2K, using liquid helium. In Fig. 1, the nitrogen surfaces have been drawn in red, the helium surfaces in blue. The purpose of the nitrogen surfaces is to shield the helium surfaces from thermal radiation and to pre-cool gas particles. The helium panels condense the majority of the gas. The capillaries embedded in the helium panels are filled from the bottom, and on the top they are tied-off onto a horizontal manifold and phase separator assembly.

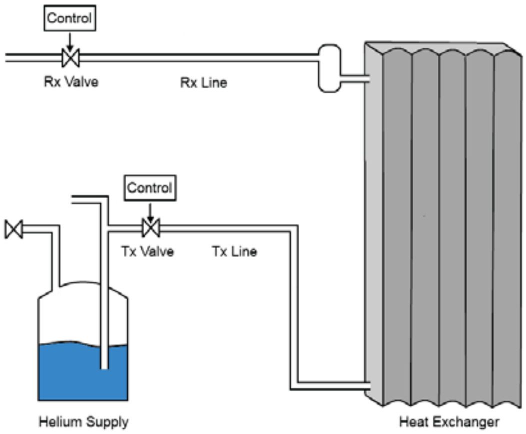

Fig. 2. Illustration of the NIB helium loop

Fig. 2 is a schematic of the NIB helium loop. The heat exchanger represents the two cryopumping walls. Also shown are the fluid/gas transmission and return line (labelled Tx and Rx lines), the transmission and return valves (labelled Tx and Rx valves), and the helium supply tank. The system boundaries are the helium source from which the helium tank is filled, and the helium return valve box, where gaseous helium evolved from the heat exchanger is diverted to either the helium liquefiers or helium collection balloons.

The helium transmission and return lines are part of the same assembly. Liquid helium, liquid nitrogen, gaseous helium and gaseous nitrogen are all carried in a single transmission line, comprised of several concentric cylinders. Together with a vacuum jacket, the cylinders are arranged in such a way as to minimise thermal losses. Between the helium supply tank and the helium return valve box are two valves: the helium supply and return valves. Each valve is designed to minimise thermal losses. They act as control valves, each with a standard feedback PI scheme. The control variable for the supply valve is the level of fluid in the phase separator and the control variable for the return valve is the (absolute) pressure in the helium return line. The helium supply tank is periodically filled, according to the fluid level. Helium inside the tank is distributed to four places: the two NIBs, a cooling system in the supply valve box and to a helium liquefier (to deal with tank losses). Helium inside the tank is maintained at a constant pressure.

A list of measured process variables on the helium loop is presented in Table I. While each of these process variables is available in real time, a recording is only made once an unscaled variable deviates two percent from its previously recorded value.

| Process variable | Unit |
|---|---|
| Phase separator level | % |
| Supply & return valve position | % |
| Supply & return line pressure | BarA and BarG |
| Capillary delta pressure | mBar |
| Helium supply temperature | K |
| Helium return temperature | K |
| Helium tank fill level | % |
| Helium tank fill volume | l |

TABLE I
LIST OF MEASURED PROCESS VARIABLES

The specific (latent) heat capacity of liquid helium is low and the helium panels are sensitive to heat load. This, in addition to the high level of instrumentation on the helium panel support system (the helium loop), means that information about the state of the NIB vacuum can be deduced from examination of the state of the helium loop. Furthermore, historically, the helium loop has experienced more maintenance issues than the nitrogen loop, and several (potential) loss of vacuum events relating to faults in the helium line were identified in a simplified FMEA process. For these reasons, it was decided that the initial focus for the condition monitoring scheme should be on the helium loop. It should also be noted that the cryopump has several operational modes. The mode focused on here is the “full cooldown” mode, which the pumping system is set to during regular operation (i.e. Most of the time outside of scheduled maintenance periods).

## III. The Model Cryopump

The mathematical model of the helium loop in the cryopumping system is split into nine component models, roughly corresponding with the components depicted in Fig. 2. In order to provide structure to the model, the component models have been categorised as either storage or resistive components, allowing a common interface between them and simplifying their analysis. Specifically, the storage components have a pressure associated with them; the resistive components, a flow rate. Fig. 3 is an illustration of this structure. A description of each of these blocks is presented below, starting with the supporting blocks and moving on to the main block, the heat exchanger.

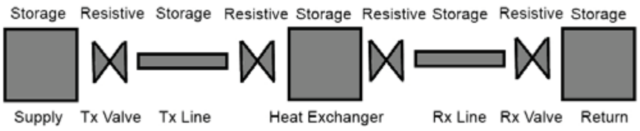

Fig. 3. Model structure

### A. Supporting Blocks

Starting with the supply and return (boundary) blocks, the following assumptions were made:

(a) The helium tank is always refilled at the appropriate times
(b) When the tank is being refilled, it is refilled at a constant, uninterrupted rate
(c) The pressure on the return side of the return valve is controlled and constant
(d) The helium supply pressure and temperature is constant
(e) The helium consumption in both NIBs is similar and converges with time
(f) Helium tank losses (and hence the amount of material sent to the liquefier) are negligible

Given these assumptions, the following equation described the the helium tank fluid volume:

$$\frac{dV_{ht}}{dt} = K_{kl}q_{tf} - K_{kl}\left(q_{sc} + q_{ts} + 2q_{tl}\right) \tag{1}$$

where $V_{ht}$ is the fluid volume in the helium tank, $q_{tf}$ is the helium tank fill rate, $q_{sc}$ is the flow rate to the valve box subcooler, $q_{ts}$ is the flow rate of tank losses, and $q_{tl}$ is the flow rate to the (single) NIB transmission line.

The transmission and return control valves are treated independently, because the former controls the flow of a (relatively, compared to helium gas) incompressible fluid and the latter, compressible helium gas. They are both resistive components. The flow rate through the transmission valve is described by:

$$q_{fl} = Y_{tx}C_v\sqrt{\frac{\Delta p}{v_i}} \tag{2}$$

where $C_v$ is the valve conductance, $\Delta p$ is the differential pressure across the valve, $Y_{tx}$ is the proportion the valve is open, normalised between zero and unity, and $v_i$ is the specific volume of the fluid at the valve inlet.

The return valve is described using an equation for valves transmitting compressible gasses referred to by Baumann[10]:

$$q_{rl} = Y_{rx}C_v 3.22\sqrt{\Delta p\left(p_1 + p_2\right)G_g} \tag{3}$$

where, with care to use US units for all the terms and converting afterwards, owing to the empirical scaling factor, $q_{rl}$ is the return valve flow rate and $G_g$ is the specific gravity of the gas.

The transmission lines are storage components. They are assumed to be of fixed volume, regardless of pressure (historically, pressure deviates no more than 10% from its mean). For the return line, making ideal gas assumptions, the pressure is given by the well known equation:

$$p_{rl} = \frac{nRT_{rl}}{V_{rl}} \tag{4}$$

where the subscript $rl$ referes to the return line.

The supply line pressure is given by:

$$p_{tl} = \int\left(q_{tl} - q_f\right)\frac{B}{V_{tl}} + p_{hyd} \tag{5}$$

where the subscript $tl$ refers to the transmission line, $B$ is the bulk modulus of the helium fluid. $p_{hyd}$ represents hydrostatic pressure, which is given by:

$$p_{hyd} = h\rho g \tag{6}$$

where $h$ the height of the fluid in the heat exchanger capillaries and phase separator and $g$ is acceleration due to gravity.

It should be noted that, whilst liquid helium is more compressible than many other fluids (with commonly assumed bulk modulus of 268 Bar[11], although this varies with temperature), a high pressure change (in the context of this system) is required to significantly reduce its volume. Under normal conditions, helium is typically compressed no more than 1%. Hemce it can be assumed that the pressure in the transmission line is equivalent to the pressure inside the heat exchanger plus the hydrostatic pressure component.

In Fig. 3, two resistive blocks are set either side of the storage component of the heat exchanger. These blocks are treated the same as the valve blocks described in (2) and (3), with $Y$ set to unity and a conductance representative of the constriction between the transmission line and heat exchanger.

### B. Heat Exchanger

Finally, the heat exchanger block is considered. This block requires a more in depth analysis for its behaviour to be described in sufficient detail. There are several different ways to model this section of the system; the technique used here is to take a mass and energy balance across this section's boundaries.

Fig. 4 is an illustration of the capillaries and phase separator as modelled. The top section of the diagram represents the phase separator, with the horizontal return manifold attached, the bottom section represents the capillaries. The distribution of the cryogenic fluid between the capillaries is not relevant and so the capillaries are treated as a lumped element. $Q$, $q_f$ and $q_s$ are the main inputs and outputs to the system. They are, respectively, heat load, fluid flow rate into the capillaries and vapour flow rate. The fluid level in the phase separator is labelled $l$ and the system pressure and temperature are represented by $T$ and $P$.

The following assumptions have been made: The capillaries (risers) are treated as a lumped construction, this entire

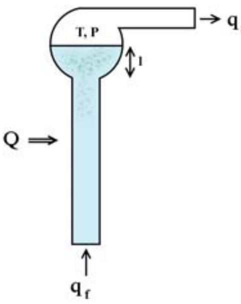

Fig. 4. Phase separator and capillary layout

section is in thermal equilibrium, and the phase separator contains a saturated vapour-fluid mixture. These assumptions are supported by historical process data and represent that real working of the system well. In the coming analysis, the terms $Q$, $q$, $h$, $V$ and $\rho$ represent, heat, flow rate, specific enthalpy and volume respectively. The subscripts '$s$', '$f$', '$w$' and '$t$' refer to vapour, feed, fluid and total respectively. SI units are used unless otherwise stated. This portion of the model is derived as follows.

*1) Global Mass and Energy Balance:* To begin with, the global mass balance of the system is described by:

$$\frac{d}{dt}\left[\rho_s V_{st} + \rho_w V_{wt}\right] = q_f - q_s \tag{7}$$

And the energy balance of the system is:

$$\frac{d}{dt}\left[\rho_s V_{st} u_s + \rho_w V_{wt} u_w + m_t C_p t_m\right] = Q + q_f h_f - q_s h_s \tag{8}$$

Now, the well known relationship between specific enthalpy and specific energy

$$u = h - \frac{p}{\rho} = h - pV \tag{9}$$

is substituted into equation 8 to give a global energy balance:

$$\begin{aligned}&\frac{d}{dt}\left[\rho_s V_{st} h_s + \rho_w V_{wt} h_w + m_t C_p t_m - pV_t\right]\\&= Q + q_f h_f - q_s h_s\end{aligned} \tag{10}$$

*2) Local Mass and Energy Balances:* To describe the distribution of vapour of fluid in the phase separator we start with the relationship between their volumes:

$$V_t = V_{st} + V_{wt} \tag{11}$$

And condensation enthalpy is represented by $h_c$.

With this property defined, the next step is to examine the mass and energy balance in the capillaries. In the analysis of other two-phase boiler systems (for example, power plant boilers), often the term "steam quality" is used to describe the proportion of vapour to fluid at a given location.

The mass fraction of vapour in the capillaries (steam quality) here is described by:

$$\alpha_m = \frac{QA}{qh_c V} z \tag{12}$$

If $\xi$ is the normalised length coordinate along the riser ($0 \leq \xi \leq 1$), then:

$$\alpha_m = \alpha_r \xi \tag{13}$$

Steam slip is a measure of the relative average velocities of liquid and gas phases in two phase flow. In this model it is assumed that steam slip is negligible, as its inclusion significantly increases the complexity of the analysis while not contributing significantly to the output of the model. For similar reasons, it is assumed the the boiling and vapour nucleation process begins at the bottom of the capillary tubes.

The average steam volume ratio in the capillaries is given by:

$$\begin{aligned}\overline{\alpha}_v = \frac{\rho_w}{\rho_w - \rho_s}\Bigg[1 - &\frac{\rho_s}{\left(\rho_w - \rho_s\right)\alpha_r}\\ &\ln\left(1 + \frac{\rho_w - \rho_s}{\rho_s}\alpha_r\right)\Bigg]\end{aligned} \tag{14}$$

Using this relation, the capillary mass balance is given by:

$$\frac{d}{dt}\left[\rho_s \overline{\alpha}_v V_r + \rho_w \left(1 - \overline{\alpha}_v\right) V_r\right] = q_f - q_r \tag{15}$$

Then from this and 9, the capillary energy balance is:

$$\begin{aligned}&\frac{d}{dt}\left[\rho_s h_s \overline{\alpha}_v V_r + \rho_w h_w \left(1 - \overline{\alpha}_v\right) V_r - pV_r + m_r C_p t_s\right]\\&= Q + q_f h_f - \left(\alpha_r h_c + h_w\right) q_r\end{aligned} \tag{16}$$

With the mass and energy balance in the capillaries accounted for, the dynamics of the phase separator and the distribution of vapour within it remain to be analysed.

The volume of vapour in the phase separator under the fluid level is given by:

$$\frac{d}{dt}\left[\rho_s V_{sd}\right] = \alpha_r q_r - q_{sd} - q_{cd} \tag{17}$$

where the condensation flow rate in the phase separator is given by:

$$\begin{aligned}q_{cd} = \frac{1}{h_c}\Bigg[&\rho_s V_{sd}\frac{dh_s}{dt} + \rho_w V_{wd}\frac{dh_w}{dt}\\&- \left(V_{sd} + Vwd\right)\frac{dp}{dt} + m_d C_p \frac{dt_s}{dt}\Bigg]\end{aligned} \tag{18}$$

The flow rate of vapour through the surface is calculated from the velocity and volume of vapour bubbles leaving the risers:

$$q_{sd} = \frac{\rho_s V_{sd}\left[1.53\frac{\sigma g(\rho_w - \rho_s)}{\rho_w^2}\right]^{\frac{1}{4}}}{l} \tag{19}$$

The volume of fluid inside the phase separator is obtained by subtracting the amount of fluid in the capillaries from the total amount of fluid in the system:

$$V_{wd} = V_{wt} - (1 - \overline{\alpha}_v)\, V_r \tag{20}$$

This allows the fluid level in the phase separator to be calculated:

$$\text{level}(\%) = 50 + \left[\arcsin\left(2\frac{V_{wd} + V_{sd}}{V_t}\right) - 1\right]\frac{50}{90} \tag{21}$$

where the trigonometric function is in degrees and the fill level of the phase separator is between 0 and 100 %.

*3) Dynamics of the Capillaries and Phase Separator:* In order to describe the mass flow rates of vapour and fluid through the capillaries and phase separator, first the capillary mass balance described in 15 is multiplied by $-(h_w + \alpha_r h_c)$:

$$\begin{aligned}&\frac{d}{dt}\left[\rho_s\overline{\alpha}_v V_r + \rho_w (1 - \overline{\alpha}_v)\, V_r\right]\left[-(h_w + \alpha_r h_c)\right] \\ &\quad = \left[q_f - q_r\right]\left[-(h_w + \alpha_r h_c)\right]\end{aligned} \tag{22}$$

Then this is added to the capillary energy balance, given in 16:

$$\begin{aligned}&\frac{d}{dt}\left(\rho_s\overline{\alpha}_v h_s V_r\right) - (h_w + \alpha_r h_c)\frac{d}{dt}\left(\rho_s\overline{\alpha}_v V_r\right) \\ &+ \frac{d}{dt}\left(\rho_w h_w (1 - \overline{\alpha}_v)\, V_r\right) \\ &- (h_w + \alpha_r h_c)\frac{d}{dt}\left(\rho_w (1 - \overline{\alpha}_v)\, V_r\right) - V_r\frac{dp}{dt} + m_r C_p\frac{dt_s}{dt} \\ &= Q + q_f h_f - (\alpha_r h_c + h_w)\, q_r - (q_f - q_r)(h_w + \alpha_r h_c) \\ &= Q + q_f h_f - q_f h_w - q_f\alpha_r h_c \\ &= Q + q_f (h_f - h_w - \alpha_r h_c)\end{aligned} \tag{23}$$

This simplifies to:

$$\begin{aligned}&h_c (1 - \alpha_r)\frac{d}{dt}\left(\rho_s\overline{\alpha}_v V_r\right) + \rho_w (1 - \overline{\alpha}_v)\, V_r\frac{dh_w}{dt} \\ &- \alpha_r h_c\frac{d}{dt}\left(\rho_w (1 - \overline{\alpha}_v)\, V_r\right) + \rho_s\overline{\alpha}_v V_r\frac{dh_s}{dt} \\ &- V_r\frac{dp}{dt} + m_r C_p\frac{dt_s}{dt} = Q + q_f (h_f - h_w - \alpha_r h_c)\end{aligned} \tag{24}$$

To derive an equation for the capillary flow rate, $q_r$, 15 is rearranged into terms of $p$ and $\alpha_r$:

$$\begin{aligned}q_r &= q_f - \frac{d}{dt}\left[\rho_s\overline{\alpha}_v V_r + \rho_w (1 - \overline{\alpha}_v)\, V_r\right] \\ &= q_f - V_r\frac{d}{dt}\left((1 - \overline{\alpha}_v)\,\rho_w + \overline{\alpha}_v\rho_s\right) \\ &= q_f - V_r\frac{d}{dp}\left[(1 - \overline{\alpha}_v)\,\rho_w + \overline{\alpha}_v\rho_s\right]\frac{dp}{dt} \\ &\quad + V_r (\rho_s - \rho_w)\frac{d\overline{\alpha}_v}{d\alpha_r}\frac{d\alpha_r}{dt}\end{aligned} \tag{25}$$

The final step is to derive an expression for the dynamics of the vapour in the phase separator. Substituting the mass equations for $q_{cd}$, $q_{sd}$ and $q_r$ (equations 18, 19 and 25) into the vapour balance equation (17) gives:

$$\begin{aligned}&\rho_s\frac{dV_{sd}}{dt} + V_{sd}\frac{d\rho_s}{dt} \\ &= \alpha_r\Big(q_f - V_r\frac{d}{dp}\left[(1 - \overline{\alpha}_v)\,\rho_w + \overline{\alpha}_v\rho_s\right]\frac{dp}{dt} \\ &+ V_r (\rho_w - \rho_s)\frac{d\overline{\alpha}_v}{d\alpha_r}\frac{d\alpha_r}{dt}\Big) \\ &- \frac{\rho_s V_{sd}\left[1.53\frac{\sigma g(\rho_w - \rho_s)}{\rho_w^2}\right]^{\frac{1}{4}}}{l} \\ &- \frac{1}{h_c}\Big(\rho_s V_{sd}\frac{dh_s}{dt} + \rho_w V_{wd}\frac{dh_w}{dt} \\ &- \left[V_{sd} + V_{wd}\right]\frac{dp}{dt} + m_d C_p\frac{dt_s}{dt}\Big)\end{aligned} \tag{26}$$

Which can be rearranged to:

$$\begin{aligned}&\rho_s\frac{dV_{sd}}{dt} + V_{sd}\frac{d\rho_s}{dt} \\ &- \alpha_r\Big(-V_r\frac{d}{dp}\left[(1 - \overline{\alpha}_v)\,\rho_w + \overline{\alpha}_v\rho_s\right]\frac{dp}{dt} \\ &+ V_r (\rho_w - \rho_s)\frac{d\overline{\alpha}_v}{d\alpha_r}\frac{d\alpha_r}{dt}\Big) \\ &+ \frac{1}{h_c}\Big(\rho_s V_{sd}\frac{dh_s}{dt} + \rho_w V_{wd}\frac{dh_w}{dt} \\ &- \left[V_{sd} + V_{wd}\right]\frac{dp}{dt} + m_d C_p\frac{dt_s}{dt}\Big) \\ &= \alpha_r q_f + \left(\frac{\rho_s V_{sd}\left[1.53\frac{\sigma g(\rho_w - \rho_s)}{\rho_w^2}\right]^{\frac{1}{4}}}{l}\right)\end{aligned} \tag{27}$$

*4) Non-linear State Variables:* Using four state variables, a full set of set of state equations that describe this section of the model can be developed. The four state variables are pressure, steam quality at the capillary-phase separator junction, total volume of fluid and volume of vapour under the fluid level ($p$, $\alpha_r$, $V_{wt}$ and $V_{sd}$). The state equations describing the heat exchanger take the following form, where the $e$ terms are found by collecting terms in the equations highlighted below. Saturated steam tables are used to evaluate the thermodynamic terms.

From 7, 10 and 11:

$$e_{11}\frac{dV_{wt}}{dt} + e_{12}\frac{dp}{dt} = q_f - q_s \tag{28}$$

$$e_{21}\frac{dV_{wt}}{dt} + e_{12}\frac{dp}{dt} = Q + q_f h_f - q_s h_s \tag{29}$$

and 24 and 27:

$$e_{32}\frac{dp}{dt} + e_{33}\frac{d\alpha_r}{dt} = Q + q_f (h_f - h_w - \alpha_r h_c) \tag{30}$$

$$e_{42}\frac{dp}{dt}+e_{43}\frac{d\alpha_r}{dt}+e_{44}\frac{dV_{sd}}{dt}=\alpha_r q_f + \left(\frac{\rho_s V_{sd}\left[1.53\frac{\sigma g(\rho_w-\rho_s)}{\rho_w^2}\right]^{\frac{1}{4}}}{l}\right) \tag{31}$$

## IV. Validation

This model is implimented in Matlab/Simulink using a combination of standard blocks and s-functions, and the output of the simulation was compared to data recorded at JET on the NIB4 cryopumping system. The two simulation results presented below are compared to data from the morning of February 21, 2012. The inputs to the simulation were historically measured supply valve position and a heat load corresponding to the experiment shots run that morning. The physical parameters (sizes, masses, conductances and boundary pressures) of the model were set according to design data provided by CCFE.

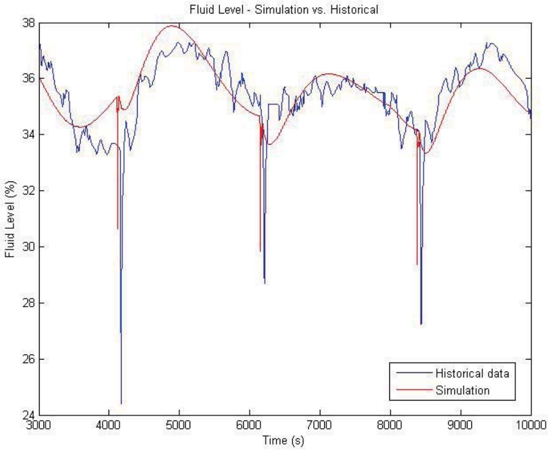

Fig. 5. Phase separator fluid level

Fig. 5 and 6 show the most interesting features of the simulation. The simulation tracks the historical process data to within 1% of the total variable range (1 to 100%) in both cases for most of the time shown. This suggests that the model describes the system well enough to simulate and predict the important system behaviors.

Each of the three salient points corresponds to the occurrence of a shot. A typical shot results in an additional heat load of around 20W on the helium panels for one or two seconds, followed by a lower heat load of around 3W for a further thirty seconds. Both the fluid level and return valve position appear to be sensitive to small heat loads on the cryopumping system, compared to the base load heat from the panel supports and thermal radiation of nearby components of close to 104W. As such, these are potentially useful variables to consider when designing a scheme to detect faults resulting in excessive heat load, such as loss of vacuum events.

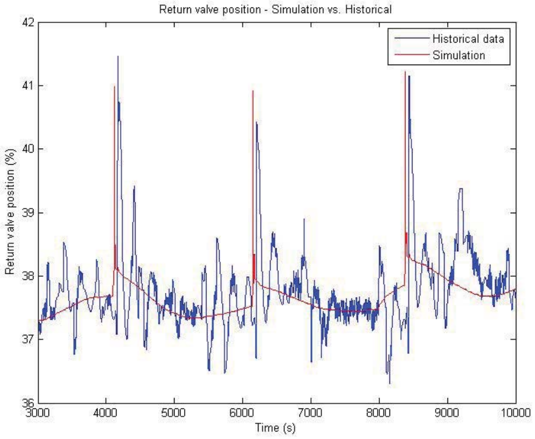

Fig. 6. Return valve position

## V. Conclusion

A novel analytical model of a large two phase cryopumping system has been derived from first principles and validated using historical data. Dividing the cryopump into resistive and storage components is a suitable technique for modelling such systems. From a Matlab/Simulink simulation it was found that phase separator fluid level and return valve position are highly sensitive to extra heat load on the cryopumping system. This suggests that the model could be used in the design of a condition monitoring scheme to detect loss of vacuum events.

Future work will see this model used to design a condition monitoring scheme, making use of the parity equations approach. This model could also be used as a basis for developing simulations of faults and could also be used as part of a model based control design process.

## Acknowledgment

This research is being conducted on behalf of CCFE and is funded by EPSRC, as a CASE studentship.

***Abstract*—On future UAVs it is envisaged that the power requirements of all on-board electrical systems will increase. Whilst, in most flight (mission) situations the installed generation capacity will have adequate capacity to operate the systems, it is possible that during certain abnormal situations the generators on-board may be forced to operate under very high load conditions. The main failure mechanism for a generator is overheating and subsequent disintegration of windings, hence the research problem being addressed here is that of modelling the thermal dynamics of a generator in such a way that the model can be used to predict future temperatures given knowledge of the future mission requirements. The temperature predictions will be used to allow prioritising of the mission actions in order to get the most out of a generator without overheating it.**

**The research presented here shows details the modelling of the generator, and presents some initial validation results showing good correlation between data taken from the rig and the simulation output of the model.**

## I. Introduction

The current trend of increased use of electrical power to run systems on-board an aircraft [1] [2] has lead to much research being undertaken to improve system performance, reliability and maintainability. Flight critical systems previously operated by other means, such as hydraulics or pneumatics, now need to be guaranteed a constant supply of electricity to be considered safe. This aim of this study is to look at power supply within aircraft, focusing particularly on power generation, aiming to develop methods of ensuring more reliable supply of power.

The ability of a generator to supply power is based upon its thermal state, assuming there are no other faults on the system. Under normal circumstances a well designed generator will easily operate within its thermal limits, but certain abnormal situations may force very high loading of the generator which could push it near or above its thermal limits.

The main failure mechanism for a generator is overheating and subsequent disintegration of windings, hence the research problem being addressed here is that of modelling the thermal dynamics of a generator in such a way that the model can be used to predict future temperatures given knowledge of the future mission requirements. The temperature predictions will be used to allow prioratising of the mission actions in order to get the most out of a generator without overheating it.

When looking at the literature available on thermal modelling of electrical machines it became apparent that it was almost exclusively focused on their design, and there was no work using this type of model as part of a health management system. The types and use of thermal models is summarised by Boglietti et.al. [3] in their survey paper.

When choosing the modelling method, the biggest factor in the decision was the execution speed. For the model to be useful in a prediction system it would have to be able to make predictions in real-time, this eliminated computational fluid dynamics (CFD), and finite element analysis (FEA) as possible methods due to their computational intensity. Instead a lumped parameter, thermal network type model was chosen.

Literature is available detailing this type of model. Example include the work of Perrez and Kassakian [4], and the work of Mellor et. al. [5]. This works on the principle that at its most simple an electrical machine is a lump of iron/steel, with copper windings. By modelling the iron parts of the generator as cylinders, parameters can be designed to calculate the average temperature of the various components to a good degree of accuracy, but using a fraction of the computing power of other methods.

The rest of this paper details the design of the thermal model for a generator, specifically one that is part of an experimental rig available to help validate the model. Section II. talks about the experimental rig. Section III. details the model design and choices, as well as the method of simulation. Section IV. details the current results, and section V. concludes the paper.

## II. Experimental Setup

The experimental rig setup is shown in Figure 1.

The rig itself consists of a motor driving the shaft of a 3-phase, 415V, 50Hz generator with a rated power of 5kVA, allowing the shaft speed to be controlled as necessary for any experiments. Table I lists the sensor measurements currently available, although more sensors are to be added in the near future to give a larger range temperature measurements from the generator. These include the temperature of the air flow at the input, output, and in some of the air spaces where possible. Sensors which enable a mass flow reading for the airflow to be determined are also to be installed.

## III. Model Design

The first stage in designing a lumped parameter model is to subdivide the generator into the various section, with each section then being modeled, as a subset of the full model. The subdivisions need to model the generator in sufficient detail that the temperature states of various parts of the generator can be found. This is balanced by the most important requirement, that the model is able to simulate the thermal state in real time so the number of nodes needs to be kept to the minimum possible.

Many authors have made different choices in how they subdivide their model Yangsoo et.al [6] divided the stator and rotor into multiple nodes in order to obtain the best possible accuracy, but this also lead to increased computation time. Kylander [7] showed that a thermal network model can still obtain high accuracy even when subdividing the machine in a modest number of areas. This was also applied by Okoro [8] giving steady state temperatures within ±5°$C$.

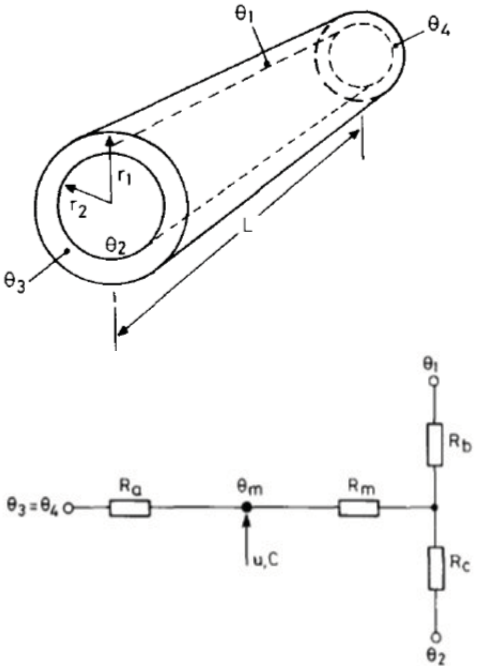

Fig. 2. Standard Cylinder and Thermal Network [5].

### A. Subdivisions within the Model

In the model the generator was broken down into 5 main areas, some of which were further subdivided. The 5 areas were the frame, stator, rotor, shaft and the air within the generator.

Unlike most current literature where the whole motor is considered in the same amount of detail, whether that be high or low, for this model the most important heat paths were identified and modeled in the most detail. These were: the stator, due to the fact that the stator winding will be the hottest part of the motor; and the air in the generator, the high airflow through the machine means that the forced convection created by it needs to be modeled carefully to get the best accuracy.

Two types of heat transfer considered in the model: conduction; and convection. The conductive heat transfer was modeled using a node at the centre representing the average temperature of the section, where any heat input, and the heat storage of the section are introduced, thermal resistance then describe the heat conduction over the component. The general model used to represent a cylinder is shown in Figure 2.

Due to the fact that the stator in the machine is only 54mm long, it was assumed that the axial temperature in the components of the model is constant, this is shown in figure 2 as a single thermal resistance $R_a$ representing the flow of heat from the mean temperature to the ends of the cylinder. Unlike many authors using this approximation though the decision was taken to model the whole length of the machine, not just half. This was due to considerations with the coolant network that are described later. The equations for the network from Mellor et. al. are shown below [5].

$$R_a = \frac{L}{6\pi k_a(r_1^2 - r_2^2)} \tag{1}$$

$$R_b = \frac{1}{2\pi k_r Ls}\left(1 - \frac{2r_2^2 log(\frac{r_1}{r_2})}{r_1^2 - r_2^2}\right) \tag{2}$$

$$R_c = \frac{1}{2\pi k_r Ls}\left(\frac{2r_1^2 log(\frac{r_1}{r_2})}{r_1^2 - r_2^2}\right) \tag{3}$$

$$R_m = \frac{1}{4\pi k_r Ls(r_1^2 - r_2^2)}\left(r_1^2 + r_2^2 - \frac{4r_1^2 r_2^2 log(\frac{r_1}{r_2})}{r_1^2 - r_2^2}\right) \tag{4}$$

Where $R_{a,b,c,m}$ are the resistance shown in Fig. 2, $L$ is the cylinder length, $r_1$ and $r2$ are the outer and inner radius respectively, $k_r$ and $k_a$ are the axial and radial thermal conductances, and $s$ is the stacking factor.

*1) Stator:* As stated earlier the stator is one of the two important areas in the model, and getting the necessary detail to model the winding temperature as well as the iron temperature was necessary. The stator was split into three areas, the stator back iron, stator teeth and stator winding. The stator iron and teeth were modeled as cylinders shown above, with the addition for the stator teeth of a resistance which gave the temperature of the inside of the slot touching the winding.

The stator winding was modeled by using the network for a rod (i.e. inner radius = 0) to represent a single slot, then multiplying this by the number slots on the stator.

*2) Rotor:* The rotor was modeled as a single cylinder, this choice was made because it was less important to have the same detail in the model that the stator has, as it would be much cooler during operation and not liable to overheat. It would also be extremely difficulty to measure the temperature of the rotor during operation making it hard to validate the results accurately, and the extra computation time required to simulate the nodes is unnecessary in this application.

*3) Shaft and Frame:* Both the shaft and frame were modeled as simple two resistance networks, which are more than adequate for this application.

### *B. Coolant Network*

The generator that the model is based upon (Fig. 1) has a large fan attached to the shaft designed to provide a large amount of airflow through the generator. This means that within this model it is not appropriate to assume that most heat transfers from the stator to rotor, or vice versa.

Yangsoo and Kauth [6] researched the modelling of an induction motor with forced cooling, using a two-network solution, one for the motor, one for the cooling. In this case both parts are modeled as a single network in order to maintain greater simplicity. The major difference between radial and axial heat flow is in how the resistance for axial heat flow is defined. Figure 3 shows a diagram of the thermal network for the air gap in the machine.

The thermal resistances $R_{con1}$ and $R_{con2}$ are calculated using the equation for convective heat transfer

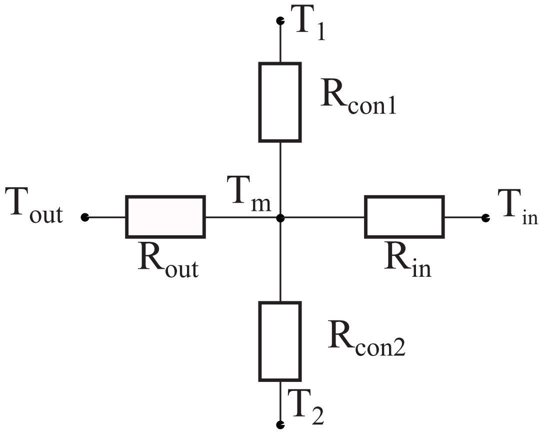

Fig. 3. Network for airflow.

$$R = \frac{1}{h_C A} \tag{5}$$

Where $h_C$ is the convective heat transfer co-efficient, and $A$ is the surface area.

The thermal resistance for $R_{in}$ and $R_{out}$ are based upon the mass flow rate through the air section

$$R = \frac{1}{\dot{m}C_p} \tag{6}$$

Where $\dot{m}$ is the mass flow rate, and $C_p$ is the thermal conductivity. As expected this leads to very low resistance values for axial heat flow through the air sections as expected with forced convection.

This thermal network is used to model the four air sections in the generator, the air gap, the two end air sections, and finally the air in the gap between the stator and the frame. The air flows into the end air at one side, splits between the air gap and top air, then re-combines on the other side. The size of the gap between stator and the frame is much larger than the stator/rotor air gap meaning the large proportion of the air flows through it cooling the stator and transferring some heat to the frame.

### *C. Solving the Thermal Network*

Figure 4 shows the complete thermal network of the generator, with Table II showing what each number in the diagram represents. From this a heat balance equation can be obtained for each node in the model, the equation for the central node of the stator iron is shown below

$$C_{si}\frac{d\theta_{sim}}{dt} = \frac{1}{R_{sia}}(\theta_{sia} - \theta_{sim}) + \frac{1}{R_{sir3}}(\theta_{sim'} - \theta_{sim}) + U_{si} \tag{7}$$

Where the subscript $si$ denotes that the value is from the stator back iron, with the letters $a$ and $r$, denoting axial and radial directions respectively, $R_{sia}$ for example is the stator iron axial resistance. $C_{si}$ is the heat storage for the stator back iron, $\theta_{sim}$ is the average temperature of the part, $U_{si}$ is the heat

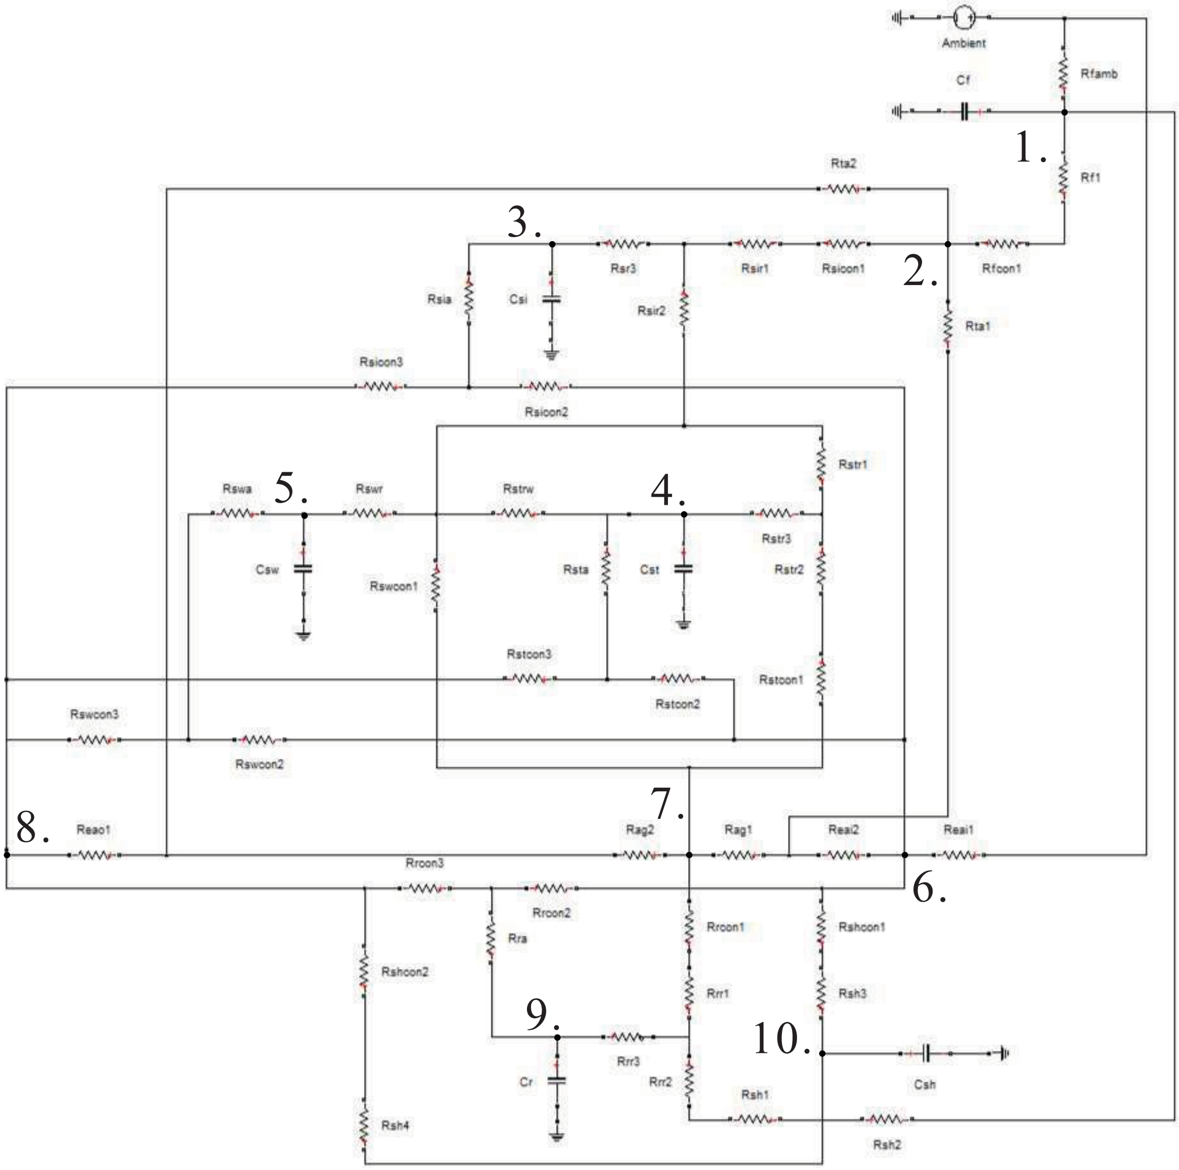

Fig. 4. Complete thermal network.

TABLE II
MODEL SUBDIVISIONS

| Fig. 4 No. | Generator Part |
|---|---|
| 1 | Frame |
| 2 | Top Air |
| 3 | Stator Back iron |
| 4 | Stator Teeth |
| 5 | Stator Winding |
| 6 | End Air In |
| 7 | Air Gap |
| 8 | End Air Out |
| 9 | Rotor |
| 10 | Shaft |

input to the stator iron. $\theta_{sia}$ and $\theta_{sim'}$ are the temperatures at the adjacent nodes, with $R_{sia}$ and $R_{sir3}$ being the thermal resistance between them.

Each node can be expressed in a similar manner to Eq. 7, these equations can then be expressed in matrix form

$$[C]\frac{d[\theta]}{dt} = [G][\theta] + [u] \tag{8}$$

where $[C]$ is a square matrix of thermal heat storage values, $[G]$ is a square matrix of thermal conductance between nodes, $[\theta]$ is the node temperature states, and $[u]$ is a column matrix of heat sources. The above differential equations allow the network to be solved for transient conditions.

TABLE III
SIMSCAPE EQUIVALENT COMPONENTS

| Electrical Component | Thermal Equivalent |
|---|---|
| Resistor | Thermal Resistance |
| Capacitor | Heat Storage |
| Current Source | Heat Input |
| Voltage Source | Constant Temp |

### D. Simulation in Simscape

When the initial work was undertaken to create this model, the first iterations were kept simple with few nodes to test the concept, complexity was then increased through iterations, with the addition of nodes. It was found that while it was easy to update the various resistances within the model using a simple Matlab script, the addition of nodes meant that often equations completely changed, as well as new ones added, and this meant that the system of equations would have to constantly be re-written, and then condensed, taking a lot of time.

In order to speed up the process, to avoid having to re-calculate the the matrices for Eq. 8 every time changes to the number of nodes are made, the Simscape package in the Matlab Simulink environment was used. Specifically the electrical component libraries. The electrical library was used instead of the thermal library due to the fact the thermal library doesn't have the flexibility required to simulate the cylindrical components used, nor can some of the interactions be modeled sufficiently between certain sub-divisions within the model.

The electrical components within the model are easily related to the equivalent thermal ones, Table III list the components and what they represent.

## IV. VALIDATION

Some initial data was collected from the alternator rig and was used to show that the model performed as expected. Currently it was only possible to extract temperature data for stator windings, as more temperature sensors are yet to be installed, but the results still give a good indication of the accuracy of the model until full validation is finished.

The temperatures were measured using PT 100 type platinum resistance thermometers (PRT) placed within each of the stator windings. The PRTs conform to the class B specification in BS 1904 : 1984 [9], the probes are 35mm long, and 4.8mm diameter, with a thin film core. The three measurements taken were then combined to give an average temperature of the stator windings as a whole.

Figure 5 shows a comparison of the measured stator winding temperature to the simulated one. The results show that the model simulates the final steady state temperature with good accuracy, but as is seen in work by others [8] the time constant of the model is faster than the actual system, while this doesn't lead to huge inaccuracy matching the time constant more accurately will provide better performance during rapid load transitions. Further data needs to be collected, giving information on other areas of the generator. Tests need to be undertaken which show the model simulating multiple steps for increasing power output, and finally tests which show the model performance during a cooling cycle.

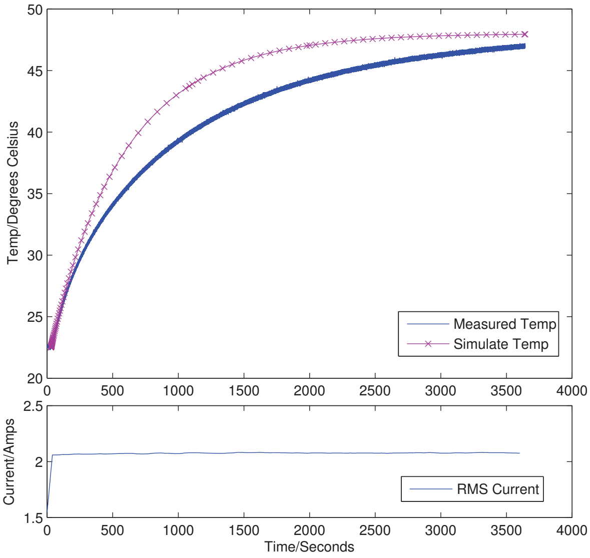

Fig. 5. Initial comparison of model to stator winding temperature.

Also included are graphs showing the simulated temperatures for the rest of the generator (Figures 6 and 7). Looking at the graph it can be seen that the simulation results meet some basic expectation. The stator winding and teeth are the hottest parts of the generator as expected, followed by the stator iron. It also shows that the heat flow in the air is modeled correctly, with the input air temperature much lower than the output air temperature.

## V. FURTHER WORK

The work described here covers just the initial modelling of the generator, with some initial validation work completed. The next stage is to complete the validation process, with the expectation of increasing the accuracy of the model further, especially refining the most important heat paths in the model around the stator and its winding, as well as the airflow through the generator.

There is also the second stage of the study to complete using the model as a prognostic tool to predict the generator's thermal state over time. This will include designing a system to set the initial model states as accurately as possible before prediction, a method of creating estimated load profiles, and the designing of scenarios to test the system at its limits.

## VI. CONCLUSION

This paper has presented the thermal model for a 3-phase generator. The execution is very fast, simulating 3614 seconds of operation in 2.59 seconds, therefore easily fulfilling the

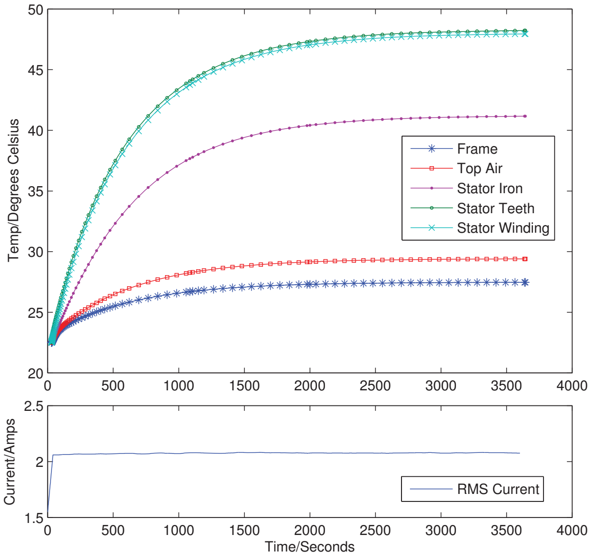

Fig. 6. Stator, Frame and Top Air temperatures with current over time.

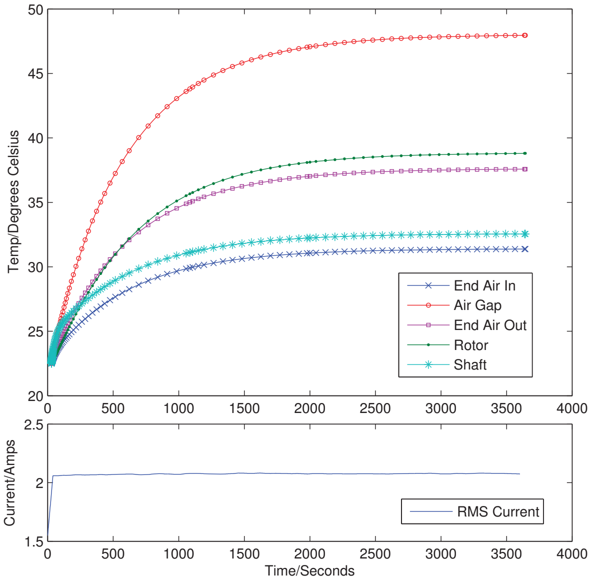

Fig. 7. Air and Rotor temperatures with current over time.

most important requirement of the model, to operate in real-time or faster.

Initial validation results show that the model is able to achieve a good degree of accuracy as well, simulating transient operation. Although there is still more testing to be undertaken with extra sensors added to test if this accuracy is maintained across all temperature states of the model.

## VII. Acknowledgments

The authors work like to thank the Engineering and Physical Sciences Research Council (EPSRC) for the case award for this work, as well as BAE Systems for the additional support provided.

*Abstract—***This paper investigates the use of time domain vibration features for detection and diagnosis of different faults from a multi stage reciprocating compressor. Principal Component Analysis (PCA) is used to develop a detection and diagnosis framework in that the effective diagnostic features are selected from PCA of 14 potential features and a PCA model based detection method using Hotelling's $T^2$ and Q statistics is subsequently developed to detect various faults including suction valve leakage, inter-cooler leakage, loose drive belt, and combinations of discharge valve leakage with suction valve leakage, suction valve leakage with intercooler leakage and discharge valve leakage with intercooler leakage. A study of Q -contributions has found two original features: Histogram Lower Bound and Normal Negative log-likelihood which allow full classification of different simulated faults.**

***Keywords; Fault detection, Vibration, Reciprocating compressor, Principles component analysis, contribution plots.***

## I. INTRODUCTION

Principal component analysis (PCA) has been applied successfully in condition monitoring systems[1]. Statistical techniques for extracting process information from massive data sets and interpreting this information have been developed in various fields [2, 3] and PCA has been widely used to reduce the dimensionality of the original dataset by projecting it onto a lower dimensional space. Such a procedure was first proposed in 1933 by Hotelling [4] to solve the problem of de-correlating the statistical dependency between variables in multivariate statistical data derived from exam scores.

In the PCA approach, the first principal component corresponds to the direction in which the projected observations have the largest variance. The second component is then orthogonal to the first and again maximizes the variance of the data points projected on it. One approach that has proved particularly powerful for monitoring and diagnosis is the use of PCA in combination with $T^2$ charts, Q charts, and contribution plots [5]. Chemometric techniques for multivariate process monitoring have been described in several review papers [6]. Misra et al., applied PCA techniques to industrial data from a reactor system and compared its performance with that of a multi-scale PCA approach [7]. Some researchers have used different extensions of PCA such as nonlinear, multi-scale or exponentially weighted PCA [8]. Roskovic used PCA to analyse automatic fault detection and identification of process measurement equipment or sensors [9].

In this work, PCA is used not only as an approach for feature space dimensionality reduction but also for contribution plots.

A contribution plot shows the contribution of each process variable to the statistic calculated. A high contribution of a process variable usually indicates a problem with this specific variable. This approach has been used and works successfully in practice [10, 11] as it does not need historical information for the results. Kourti and MacGregor [12] applied contribution plots of quality and process variables to find faulty variables for a high-pressure low-density polyethylene reactor. They remarked that the contribution plots may not reveal the assignable causes of abnormal events; but, the group of variables contributed to the detected events will be identified for further investigation. Kano, et al., [13] presented the contribution of each process variable to the dissimilarity index used in DISSIM which can be used to identify the variables that contribute significantly to an out of control value of the dissimilarity index, and then the effectiveness of the contribution plot is evaluated. Qin et al., [14] decentralized a complex chemical process into several blocks; hierarchically investigating block and variable contributions to isolate faulty variables. Since the monitored variables were arranged into blocks according to the process, the fault isolation tasks were easier to perform than an investigation of all the variables. Yoon and MacGregor [15] comprehensively compared the model-based and data-driven approaches for fault detection and isolation, and concluded that the contribution plots provide for easy isolation of simple faults, but that additional information about the operating process is needed to isolate complex faults. This paper is organized as follows. Section 2 presents an overview of PCA for detection faults of the $T^2$ and Q statistics. In Section 3 the contribution plots Q statistic.

## II. BASIC THEORY

### A. Data Modelling using PCA

A primary objective of PCA is for dimensionality reduction or data compression to achieve efficient data analysis. PCA forms a new smaller set of variables with minimal loss of information, compared with the original data. Based on this unique characteristic, PCA is used for classification of variables and hence early identification of abnormalities in the data structure, i.e. detection of faults.

The PCA creates a covariance matrix (or correlation matrix) by transforming the original correlated variables into a new set of uncorrelated variables. Let the variables describing the machine being investigated be the m–dimensional data set: $X = x1, x2, x3, \dots xm$, the PCA decomposes the observation vector, X, into a set of new directions P as [16]:

$$X = TP^T = t_1{P_1}^T + t_2{P_2}^T + \cdots + t_m{P_m}^T$$
$$= \sum_{i=1}^{m} t_i{P_i}^T \qquad (1)$$

Where $P_i$ is an eigenvector of the covariance matrix of X. P is defined as the principal component loading matrix and T is defined to be the score matrix of the principal components (PCs).

The loading matrix helps identify which of the variables contribute most to individual PCs, whilst the score provides information on sample clustering and identifies transitions between different operating conditions.

The expectation with PCA is that the original variables are sufficiently well correlated that the only a relatively small number of the new variables (PCs) account for most of the variance. In this case no essential information is lost by using only the first few PCs for further analysis and Equation (1) can be expressed as [17]:

$$X = TP^T + E = \sum_{i=1}^{k} t_i{p_i}^T + E \qquad (2)$$

Where E represents a residual error matrix. For example, if only the first three PCs represent a sufficiently large part of the total variance, E will be calculated by:

$$E = X - [t_1{p_1}^T + t_2{p_2}^T + t_3{p_3}^T] \qquad (3)$$

In certain applications such as process monitoring, when a plant malfunctions, original variables have minimal impact on the first few PCs, but dominate the higher orders. Thus in process engineering use of these higher order components may be needed to provide the necessary diagnostic information [16]. In this way $E$ can be very useful to measure these changes.

### B. PCA Model Based Detection

PCA based fault detection is usually based on two detection indices: Hotelling's $T^2$ statistic and Q statistic.

Hotelling's $T^2$statistic is a measure of the major variation of measurement variation and detects new data if the variation in the latent variables is greater than the variation explained by the model or baseline condition. For a new measurement feature vector x, the $T^2$ statistic detection can be found from:

$$T^2 = x^T P \lambda^{-1} P^T x \le T_\alpha^2 \qquad (4)$$

Where the $100(1-\alpha)\%$ control limit for $T_\alpha^2$ is calculated by means of a F-distribution as [18]:

$$T_\alpha^2 = \frac{k(m-1)}{m-k} F(k, m-1; \alpha) \qquad (5)$$

Where $F(k, m-1; \alpha)$ is an F-distribution with k and $(m-1)$ degrees of freedom, with chosen level of significance α, k is the number of PC vectors retained in the PCA model, and m is the number of samples used to develop the model. The Q statistic, also represented as SPE, is the squared prediction error. It is a measure of goodness of fit of the new sample to the model. The Q statistic based detection can be done by:

$$SPE = \|(I - PP^2)x\|^2 \le Q_\alpha \qquad (6)$$

The $100(1-\alpha)\%$ control upper limit $Q_\alpha$[12] is:

$$Q_\alpha = \theta_1 \left[\frac{h_0 c_\alpha \sqrt{2\theta_2}}{\theta_1} + 1 + \frac{\theta_2 h_0 (h_0 - 1)}{\theta_1^2}\right]^{\frac{1}{h_0}} \qquad (7)$$

Where:

$$\theta_i = \sum_{j=a+1}^{m} \lambda_j^i \qquad (8)$$

$$h_0 = 1 - \frac{2\theta_1\theta_3}{3\theta_2^2} \qquad (9)$$

New events (faults) can be detected using the $T^2$or SPE; the Q-contribution plot represents the significance of each variable on the index as a function of the variable number for a certain sample, and can be used to diagnose the fault. When the $T^2$or SPE exceeds the threshold, the contribution of the individual variables to the $T^2$ or SPE can be identified, and the variable making a large contribution to the $T^2$ or SPE is indicated to be the potential fault source. In general, when an unusual event occurs and it produces a change in the covariance structure of the model, it will be detected by a high value of Q.

### C. Contribution Plots of Q Statistic

Once an abnormal factor has been detected, it is important to diagnosis the special event to find its cause. The contribution of the measurement variable and time periods to the deviation observed in the Q statistic can be used to help suggest an assignable cause. Using the distributions, confidence limits for the two statistics can be obtained. For the monitoring of new batches, the process data of the new batch $X_{new}(JK \times 1)$ is projected onto the model.

$$X_{new}^T = t_{new}^T P^T + e_{new}^T \qquad (10)$$

$$t_{new}^{T}P^{T} = X_{new}^{T}P(P^{T}P)^{-1}$$

$$e_{new}^{T} = X_{new}^{T} - t_{new}^{T}P^{T}$$

The $Q$-statistic for the new batch, $X_{new}$ is defined as follows:

$$Q_{new} = \sum_{ik=1}^{JK}(e_{new,jk})^2 \qquad (11)$$

### D. *Contribution of the Process Variables to the Q Statistic*

If, for a specific new batch, a disturbance was detected in the Q-chart of the residuals, then the contribution of the variables to the Q-statistic should be investigated. The contribution $c_{jk}^{Q}$ of process variable j at time k to the Q-statistic for this batch equals:

$$c_{jk}^{Q} = (e_{new,jk})^2 = (x_{new,jk} - \hat{x}_{new,jk})^2 \qquad (12)$$

Where $x_{new,jk}$ is the jkth element of $x_{new,jk}$(JK × 1), $\hat{x}_{new,jk}$ is the part of this element predicted by the model, and $e_{new,jk}$ is the residual. In order to find at disturbance occurred, all contributions $c_{jk}^{Q}$ can be plotted and examined [19].

## III. VIBRATION DATA AND FEATURE CALCULATION

### A. *Vibration Data Acquisition*

Vibration datasets were collected from a two-stage, single-acting Broom Wade TS9 reciprocating compressor, which has two cylinders, designed to deliver compressed air between 0.55MPa and 0.8MPa to a horizontal air receiver tank with a maximum working pressure of about 1.38MPa.

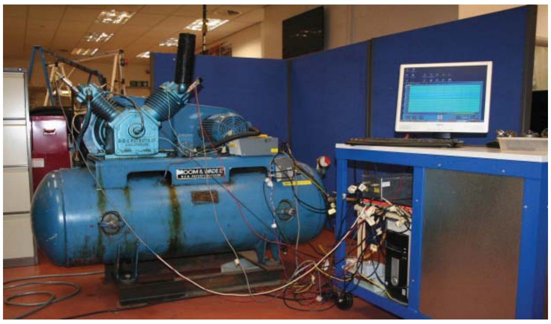

Figure 1 Reciprocating compressor test system.

As shown in Figure 1, the driving motor was a three phase, squirrel cage, air cooled, type KX-C184, 2.5kW induction motor. It was mounted on the top of the receiver and transfers its power to the compressor through a pulley belt system. The transmission ratio is 3.2, which results in a crank shaft speed of 440 rpm when the motor runs at its rated speed of 1420 rpm. The air in the first cylinder is compressed and passed to the higher pressure cylinder via an air cooled intercooler.

For characterising vibrations under different faults, four common faults were seeded into the compressor: a leaky discharge valve in the high pressure cylinder, suction valve leakage, a leaky intercooler, a loose drive belt. Different combinations of these faults were also used; discharge valve leakage combined with suction valve leakage, suction valve leakage combined with intercooler leakage and discharge valve leakage combined with intercooler leakage. In order these faults are denoted: fault 1, fault 2, fault 3, fault 4, fault 5, fault 6 and fault 7. These faults may have little effect on the pressures generated but a faulty compressor will consume more electrical energy than a healthy compressor.

Vibrations of the two-stage compressor were measured using two accelerometers mounted respectively on the low stage and high stage cylinder heads near the inlet and outlet valves. As shown in Figure 2. In addition, the pressures, temperatures and speed were also measured simultaneously for comparisons. The data segment collected is 30642 samples at different discharge pressures ranged from 0.2 to 1.2MPa in steps of 0.1MPa. As the sampling rate is 62.5 kHz, each segment of data includes more than three working cycles of the compressor, which is sufficient for obtaining stable results. In total, 8×11=88 data records were collected for the baseline and seven faults for each discharge pressure.

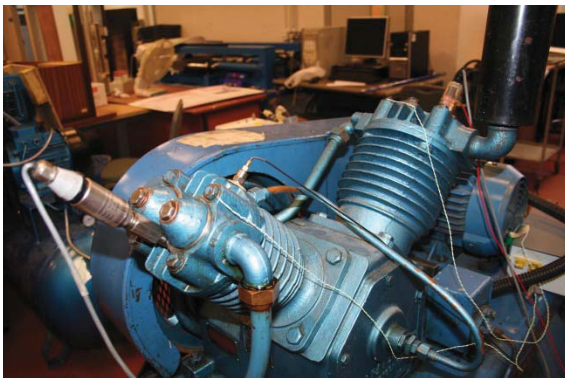

Figure 2 Vibration transducers

### B. *Time Domain Features*

Many features (statistical parameters) can be extracted from the raw vibration signals for fault detection and diagnosis. The parameters used in this study have been proved previously by many researchers as effective representation of vibration signals for CM.

The statistical parameters extracted from the raw vibration signals included, peak factor, RMS, histogram lower bound (HLB), histogram upper bound (HUB), entropy, crest factor, absolute value, shape factor, clearance factor, variance, skewness, kurtosis[20], normal negative log-likelihood value (Nnl) and Weibull negative log-likelihood value (Wnl) [21].

Weibull negative log-likelihood value and normal log-likelihood value were used recently for features extraction from vibration signals [21].

$$-LogL = -Log\prod_{i=1} f\left(a, \frac{b}{x_i}\right)$$

$$= -\sum_{i=1}^{n} log\, f(a,b\backslash x_i) \qquad (13)$$

Where $f(x_i, a, b)$ is the probabilty density function. For Weibull negative log-likelihood function and normal negative log-likelihood function, the *pdfs* are calculated as follows:

$$Weibull\, pdf\ f(x_i\backslash a,b) = \frac{b}{a}\left(\frac{x_i}{a}\right)^{b-1} exp^{-\left(\frac{x_i}{a}\right)^{b}}$$

$$Normal\, pdf f(x_i\backslash \mu,\sigma) = \frac{1}{\sigma\sqrt{2\pi}} exp^{-(x_i-\mu/2\sigma^2)^2}$$

where $\mu$ and $\sigma$ denote the mean and standard deviation respectively.

## IV. DETECTION AND DIAGNOSIS RESULTS

### A. *PCA Model Development*

Figure 3 shows the relative variance of the fourteen variables selected for PCA. It also shows that seven of these account for 99% of the variance, and this means that the subspace composed of those seven PCs contains enough information on the variation of the original features for it to be sufficient to detect the faults in the reciprocating compressor.

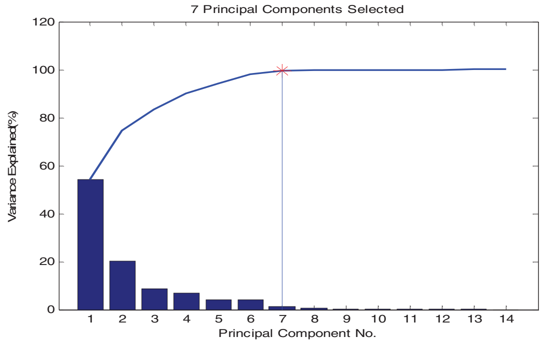

Figure 3 Principal component selection.

### B. *PCA Model Based Detection*

From Figure 4(a) and 4(b) it can be seen that most of both $T^2$ and $SPE$ are within the thresholds but there are three occasions, at samples 2, 30, 45, at which the threshold is exceeded. This can be due to the non-stationary behaviour of the vibration signal and the ability of PCA to detect the change which are acceptable from statistical analysis but means the confidence level is selected appropriately.

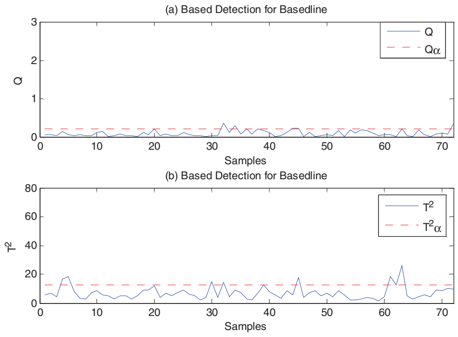

Figure 4 Model evaluation

On the Q-chart in Figure 5(a), there are some points at which the control limit is exceeded, and these indicate false alarms. However, the $T^2$ statistics detected a fault at the same points as shown in Figure 5(b), which shows too many contents reflected by the latent PCs and indicate the presence of a fault.

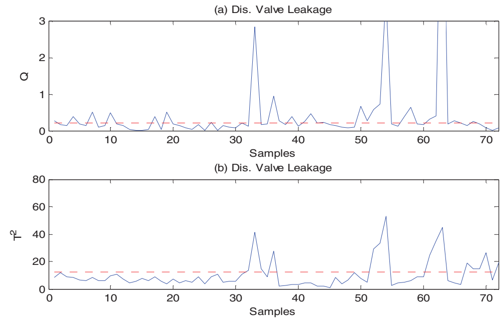

Figure 5 Discharge valve leakage detection by $T^2$ and $Q$statistics.

The performance of the $Q$ method with the leaky suction valve is shown in Figure 6(a). It can be seen that the $SPE$ value exceeds the threshold value many times which indicates the occurrence of major faults while the $T^2$ method crossed the control limits fewer times as can be seen from the Figure 6(b).

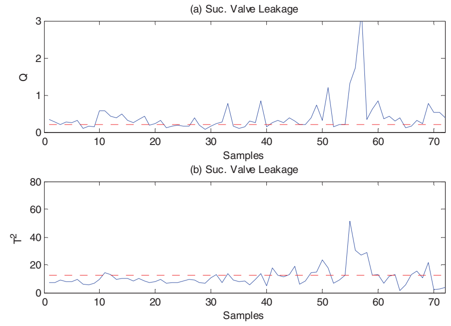

Figure 6 Suction valve leakage detection by $T^2$ and $Q$ statistics.

The result in Figure 7(a, and b) show the $Q$ and $T^2$ statistics for the intercooler leakage fault, and the values at which the threshold is crossed can be clearly seen in both plots but with larger deviation amplitude in the $T^2$ method.

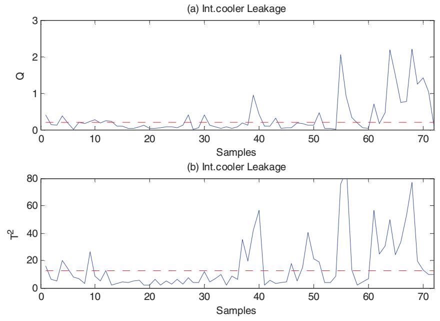

Figure 7 Intercooler detection by $T^2$ and $Q$ statistics.

Figure 8 depicts the performance $T^2$ and $Q$ methods of the loose belt fault. From the obtained result it can be seen that the $SPE$ values cross the threshold many times, which indicates the occurrence of the major faults. While the $T^2$-statistic has crossed the threshold in less points with varying amplitude.

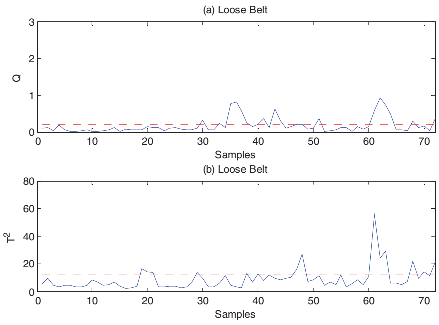

Figure 8 Loose belt detection by $T^2$ and $Q$ statistics.

The performance of $T^2$ and $Q$ statistics models with combined faults was also investigated. Figure 9 shows the results for combined discharge valve leakage and suction valve leakage. It can be seen that with the $\mathrm{T}^2$ method there are a number of occasions when the SPE value exceeds in threshold value. Similarly the $Q$ statistics clearly shown the $SPE$ plot crossed the threshold a large number of times which indicates the occurrence of major faults. This confirms the ability of the $T^2$ method to detect combined faults.

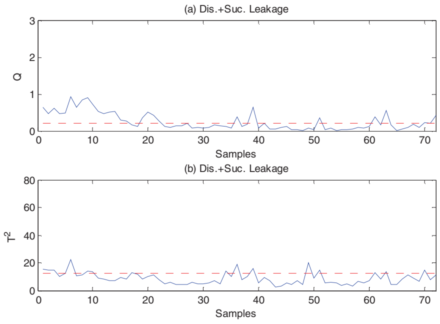

Figure 9 Combined discharge valve leakage and suction valve leakage detection by $T^2$ and $Q$ statistics.

For combined suction valve leakage and intercooler leakage, both $T^2$ and $Q$ statistics detected the faults as shown in Figure 10, where it can be clearly seen that many data points exceeds the threshold. Both models exhibited similar performance for detection of this fault with particularly high deviation amplitudes in the $Q$ statistics.

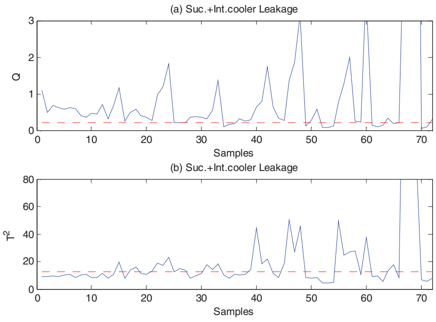

Figure 10 Combined suction valve leakage and intercooler leakage detection by $T^2$ and $Q$ statistics.

From the Figure 11, the combined discharge valve leakage and intercooler leakage provide many data points that exceed the threshold for the both $T^2$ and $Q$ statistics and hence indicate the presence of severe faults.

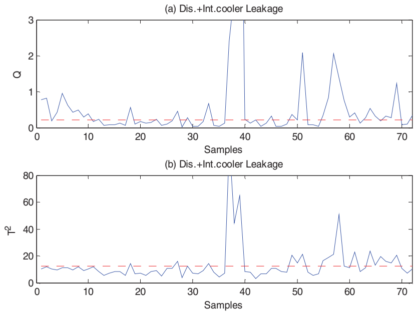

Figure11 Combined discharge valve leakage and intercooler leakage detection by $T^2$ and $Q$ statistics.

### C. PCA Model Based Diagnoses

Once a fault has been detected, it is important to identify an assignable cause. Identification of the source of the fault is facilitated by inspecting the plots showing the contributions of the various measurement variables to the deviations observed in the monitored metric. Such contribution or diagnostic charts can be immediately displayed on line by the system, as soon as the special event is detected. Although they may not provide an unequivocal diagnosis, they should at least clearly indicate the group of variables that are primarily responsible for the detected fault. The contribution plots obtained from the data in different cases as shown in Figure 12, the contribution of each variable is different. The major variables contributing in these deviations were mostly variables 10, 11 and 13 along with variables 2, 3, 4 and 14. The variables contributing most significantly to the Q-statistic are 10 and 13 because they are largest. This result implies that a fault or disturbance related to a pressure in the process occurs. On the other hand, the variables contributing significantly to the dissimilarity are 2, 3, 4, 11 and 14. These variables are slightly different from the variables contributing in the process occurs. Thus, the information obtained from the contribution plots is useful for investigating the cause of the fault.

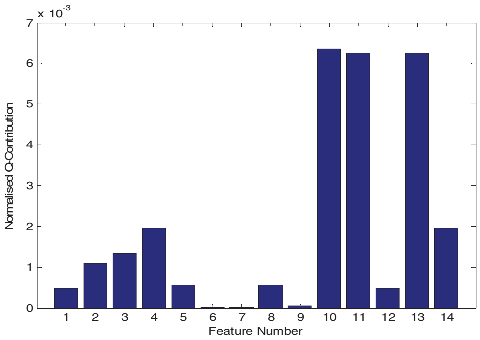

Figure 12 Overall $Q$ contribution charts for 14cases based on PCA model.

The results in Figure 13 show that variable 11 contributes most for the loose drive belt fault and combined discharge valve and suction valve leakage.

Variable 13 also recorded the highest contribution for combined discharge valve and suction valve leakage.

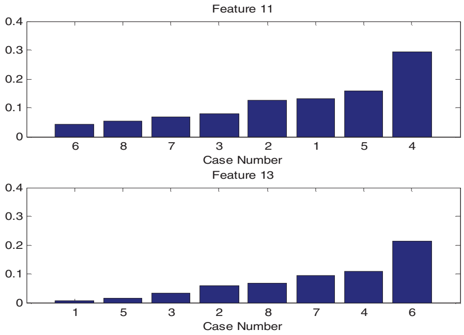

Figure 13 $Q$ contribution charts for fault classification based on feature 11 and 13.

We can therefore represent that faults as combinations of variables. Figure 14 presents a way to achieve separation between the normal operation and operation with any of the given faults. It provides the best combination of variables, with which to detect faults most effectively. It can be shown that the best combination of variables given by the $Q$-plots are variables 11 and 13. This combination gives a direction in the multivariate tool-state variable space, onto which the data can be projected, which can be used for detecting a specific class of fault. This is depicted in Figure 14. For each fault that is classified.

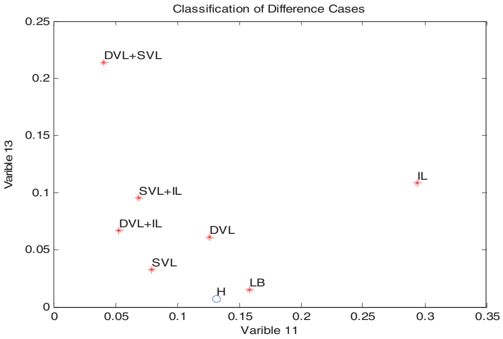

Figure 8 .Fault classifications based on feature 11 and 13 combination

## V. CONCLUSIONS

It has been demonstrated in this study that PCA based approaches allow the detection of single and multiple faults in a reciprocating compressor. The model developed from baseline consists of the seven most important PCs which explain nearly 99% of the variances from 14 original vibration features. The presence of faults can be detected by comparing the feature values from the time domain of the vibration signal with the $T^2$ and $Q$ statistics.

However the $Q$-statistic had better detection ability for all faults investigated. The contribution of the $Q$-plot, was presented in a way which allows it to be used with any latent variable component or regression model to detect a specific progress variable. The $Q$-contributions show that two particular variables, 10 and 13 gave the largest values of the minimum difference between different cases, thus these were used to detect and differentiate the given faults.

# A Robust LPV Fault Detection Approach Using Parametric Eigenstructure Assignment

Fengming Shi and Ron J. Patton
Department of Engineering
University of Hull
Hull, HU6 7RX, UK
shi_fengming@163.com and R.J.Patton@hull.ac.uk

**Abstract --In this paper, an eigenstructure assignment fault detection approach to linear time invariant (LTI) systems is extended to Linear Parameter Varying (LPV) systems. Fault detection filter design algorithms using eigenstructure assignment have been widely studied for LTI systems. However, LPV strategies are very useful for systems which have no unique equilibrium and are difficult to linearize. The parametric eigenstructure assignment approach is used to design an observer as a residual generator by viewing the varying parameters as fixed parameters in the design procedure. The residual observer feedback structure is implemented using a measured scheduling parameter An example is given of actuator fault detection of a two-link manipulator system.**

***Key words:* *Fault detection; LPV systems; Eigenstructure assignment, Fault residual generation***

## I. INTRODUCTION

Safety and reliability are very important in control systems and these demanding requirements must be ensured at a reasonable level. Fault detection (FD) methodologies and techniques are important topics in systems engineering from the viewpoint of improving plant safety and reliability. The FD literature is vast and the topics addressed are essentially related to the different design methodologies proposed to tackle the FD problem [1-4]. Model-based FD techniques are the most popular and are receiving considerable attention. The ideas are to derive a mathematical model of the plant and to compute additional artificial signals that are checked, during the on-line operations, with the corresponding measured quantities. State observers are often considered as the role of on-line residual generation because of the fast detection rate [5].

The eigenstructure assignment approach to robust FD was first demonstrated in [6]. It has been shown that a well-defined residual signal can be completely de-coupled from the disturbance by assigning a suitable eigenstructure to an observer. In this way, robust fault detection is achieved. Parametric eigenstructure assignment approaches [7-14] opened a wide field to use the design freedom of eigenvalue placement to achieve other desired performance, such as structured disturbance decouple. Some optimization approaches were also considered in the FD methods with pole placement [15-17].

Many real systems cannot be modeled by linear models, for example when no unique equilibria exist. A feasible approach to handle the nonlinearity of such systems is to use linear parameter-varying (LPV) models to approximate the dynamic nonlinearity. The LPV strategy was first introduced in [18, 19] and the big advantage of LPV modeling is that powerful linear design tools for stability and performance can be extended and applied [20, 21], LMI methods for multiple-model FD have been studied in [22, 23]. Traditional multi-model eigenstructure assignment approaches use iterative methods based on optimizing the worst case performance and the initial condition is calculated e.g. by a linear quadratic regulator (LQR) or by an H infinity method [24, 25].

In this paper, a non-iterative robust fault detection approach is presented based on a state observer structure within the LPV framework. The LPV fault detection approach is an extension of the approach in LTI case. Using parametric eigenstructure assignment, the varying parameters are viewed as fixed parameters in the design procedure and the observer law is implemented with the varying parameters measured or estimated on line.

The remainder of the paper is organized as follows: Section II recalls the parametric eigenstructure assignment approach to LPV systems and FD approach for LTI system. A design procedure for robust FD is also proposed in this Section; Section III demonstrates the usefulness of the proposed approach by a means of a two-link manipulator example. Conclusions are given in Section IV.

## II. PARAMETRIC EIGENSTRUCTURE ASSIGNMENT TO LPV SYSTEMS

Consider a stable LPV system in the following form:

$$\dot{x}(t) = A\big(\theta(t)\big)x(t) + B\big(\theta(t)\big)u(t) + B_f\big(\theta(t)\big)f(t) + Ed(t) \quad (1)$$

$$y(t) = C\big(\theta(t)\big)x(t) + D\big(\theta(t)\big)u(t), \quad (2)$$

where $x(t) \in R^n, u(t) \in R^r and\ y(t) \in R^m$ are the state vector, the input vector and measured output vector, respectively. And $f(t)$ and $d(t)$ are the fault vector and disturbance signal, respectively. $E$ is a known constant matrix and $A(.), B(.), C(.), D(.), B_f(.)$ are known

This work is sponsored by the Hull China and CSC scholarships awarded to Fengming Shi during 2010-2013

continuous functions of a time-varying parameter vector $\theta(t)$ which satisfies:

$$\theta(t) = \left[\theta_1(t), \cdots \theta_{n_\theta}(t)\right]^T \in \Theta, \forall\, t \geq 0$$

where $\Theta$ is a compact set. Hereafter, the subscript $t$ is omitted without causing confusion.

The observer dynamics used by the residual generator are described by:

$$\left.\begin{array}{l} \dot{\hat{x}} = \big(A(\theta) - K(\theta)C(\theta)\big)\hat{x} + \big(B(\theta) - K(\theta)D(\theta)\big)u + K(\theta)y \\ \hat{y} = C(\theta)\hat{x} + D(\theta)u \\ r = Q(\theta)(y - \hat{y}) \end{array}\right\} \tag{3}$$

where $r \in R^p$ is the residual vector, $\hat{x}$ and $\hat{y}$ are state and output estimation vectors. The matrix $Q(\theta) \in R^{p\times m}$ is the residual weighting factor.

### *A. LPV Parameric Eigenstrucutruer assignent*

Observer design is dual of state feedback controller design. Left Eigenstructure assignment of observer is dual of the right Eigenstructure assignment of state feedback controller. That means if the desired left eigenvector matrix of $A(\theta) - K(\theta)C(\theta)$ is $R^T(\theta)$, then the desired right Eigenvector matrix of $A^T(\theta) - C^T(\theta)K^T(\theta)$ is $R(\theta)$. That is to say the desired left Eigenvector of $A(\theta) - K(\theta)C(\theta)$can be assigned by assigning the right eigenvector of $A^T(\theta) - C^T(\theta)K^T(\theta)$. By the definition, if the right eigenvector matrix of $A^T(\theta) - C^T(\theta)K^T(\theta)$ is $R(\theta)$, the eigenvalue matrix is $F(\theta)$. It follows that:

$$A^T(\theta)R(\theta) - C^T(\theta)K^T(\theta)R(\theta) = R(\theta)F(\theta) \tag{4}$$

Let $K^T(\theta)R(\theta) = W(\theta)$, Equation (4) can be rewritten as

$$A^T(\theta)R(\theta) - C^T(\theta)W(\theta) = R(\theta)F(\theta) \tag{5}$$

Hence, the problem to assign desired closed-loop eigenstructure to a system using a residual generator is to find a solution of (4).

Now, without proof, a theorem of parametric solution of Sylvester equation is introduced, and the proof details can be found in [8, 9, 26].

**Theorem 1**

Let $[A(\theta)\ B(\theta)]$ be controllable, and the matrix $B(\theta)$ be of full-column rank. If the desired closed-loop self-conjugate eigenvalue set be described as $\Lambda = \{\lambda_i(\theta): \lambda_i(\theta) \in \mathbb{C}, i = 1,2,..\tilde{n},\ 1 \leq \tilde{n} \leq n\}$. The algebraic and geometric multiplicities of the eigenvalue $\lambda_i$are denoted by $q_i$and $r_i$, respectively and $p_{ij}$, $q_i$ *and* $r_i$satisfy the relations:

$$\textstyle\sum_{j=1}^{r_i} p_{ij} = q_i, \sum_{i=1}^{\tilde{n}} q_i = n$$

Then all the solutions of the Sylvester matrix equation [10]:

$$A(\theta)R(\theta) + B(\theta)W(\theta) = R(\theta)F(\theta)$$

are given by:

$$\begin{bmatrix} R_{ij}^k \\ w_{ij}^k \end{bmatrix} = \begin{bmatrix} N\big(\theta, \lambda_i(\theta)\big) & \cdots & \frac{1}{(k-1)!}\frac{d^{k-1}}{d\lambda^{k-1}} N\big(\theta, \lambda_i(\theta)\big) \\ M\big(\theta, \lambda_i(\theta)\big) & \cdots & \frac{1}{(k-1)!}\frac{d^{k-1}}{d\lambda^{k-1}} M\big(\theta, \lambda_i(\theta)\big) \end{bmatrix} \begin{bmatrix} f_{ij}^k(\theta) \\ \vdots \\ f_{ij}^1(\theta) \end{bmatrix} \tag{6}$$

$$\mathrm{k} = 1, 2, \ldots., \mathrm{p}_{ij}, \mathrm{j} = 1,2, \ldots.\mathrm{q}_i, \mathrm{i} = 1,2, \ldots.\mathrm{n}'$$

where the $f_{ij}^k \in C^r$ are arbitrarily chosen from parameter vectors. $N\big(\theta, \lambda(\theta)\big)$ and $M\big(\theta, \lambda(\theta)\big)$ are right co-prime matrix polynomials satisfying:

$$[\lambda(\theta)I - A(\theta)]^{-1}B(\theta) = N\big(\theta, \lambda(\theta)\big)M^{-1}\big(\theta, \lambda(\theta)\big) \tag{7}$$

Then the observer gain can be calculated by:

$$K(\theta) = R^{-1}(\theta)W(\theta)$$

From the above theorem, it can be known that the desired eigenvectors and generalized eigenvectors can be parameterized by (6). By specially choosing the free parameters given in (6), solutions with desired properties can be obtained.

### *B. LPV fault detection*

The FD design must ensure that the residuals are close to zero in the fault-free situation whilst suitably deviating from zero in the presence of faults. A necessary condition for achieving disturbance de-coupling design is [4, 14].

$$Q(\theta)C(\theta)E = H(\theta)E = 0$$

If $C(\theta)E = 0$, any residual weighting matrix can satisfy this necessary condition.

The basic principle to assign the left eigenstructure for LTI case is given in [4, 12]. The theorem is introduced here.

**Theorem 2**

The sufficient conditions for satisfying the disturbance de-coupling requirement $G_{rd} = QC(sI - A + KC)^{-1}Ed = 0$ are:

(1) $QCE = 0$

(2) All rows of the matrix $H = QC$ are left eigenvectors of $(A - KC)$ corresponding to any eigenvalues.

A similar result for the LPV case is now given.

**Theorem 3**

The sufficient conditions for satisfying the disturbance de-coupling requirements for the system.

$$G_{rd} = Q(\theta)C(\theta)(sI - A(\theta) + K(\theta)C(\theta))^{-1}Ed(s) = 0$$

are:

(1) $Q(\theta)C(\theta)E = 0$

(2) All rows of the matrix $H(\theta) = Q(\theta)C(\theta)$ are left eigenvectors of $(A(\theta) - K(\theta)C(\theta))$ corresponding to any eigenvalues.

Noting that the above result is intuitively an extension of the LTI case, the proof is omitted here.

### C. Design procedure

Following the previous arguments, a design procedure is proposed to design a robust residual generator to LPV system.

**Step 1**: Select the desired eigenvalues for the observer which can be parametric to obtain more design freedoms.

**Step 2:** Calculate the $N(\theta, \lambda(\theta))$ and $M(\theta, \lambda(\theta))$ using elementary transformation and the rational matrix factorization method.

**Step 3:** Check rank$(\mathrm{C}(\theta)\mathrm{E})$, choose a basis for $LKer(\mathrm{C}(\theta)\mathrm{E})$.

**Step 4:** Check $\mathrm{Q}(\theta)\mathrm{C}(\theta)$, set the desired *left* eigenvectors with some of the eigenvectors in a parametric form to keep the design freedom.

**Step 5:** Project the desired eigenvectors into the achievable subspace to get the achieved eigenvector matrix.

**Step 6:** Calculate the observer gain by $K(\theta) = W(\theta)R(\theta)^{-1}$. To simplify the structure, some parameters are chosen at this step.

**Step 7:** Verify the achieved eigenvalues and eigenvectors, and chose the remaining parameters based on the performance specifications.

## III. AN EXAMPLE

A two-link robotic manipulator is considered to rotate in the vertical plane, whose position can be described by a 2-vector $\varphi = (\varphi_1, \varphi_2)^T$ of joint angles, and whose actuator inputs consist of a vector $u = (u_1, u_2)^T$ of torques applied at the manipulator joints as shown in Fig. 1. Using the vectors $\dot{\varphi}$ and $\ddot{\varphi}$ to denote the joint velocities and accelerations, respectively. The dynamics of this simple manipulator can be written in the more general form [27] as:

$$\Xi(\varphi)\ddot{\varphi} + O(\varphi, \dot{\varphi})\dot{\varphi} + \mathrm{g}(\varphi) = u$$

where: $\Xi(\varphi) \in R^{2\times 2}$ is the manipulator inertia tensor matrix, $O(\varphi, \dot{\varphi})\dot{\varphi} \in R^2$ is the vector function containing the Centripetal and Carioles torques, i.e. $O(\varphi, \dot{\varphi})) \in R^{2\times 2}$ and $\mathrm{g}(\varphi) \in R^2$ are the gravitational torques. The details of equations of motion and physical parameters as outlined in Table I are described in [23].

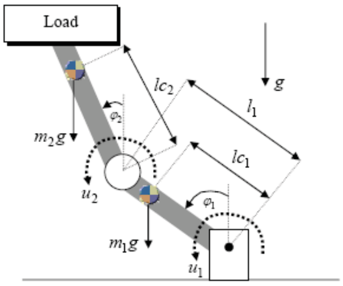

Figure 1. Two-link manipulator structure

TABLE I. PARAMETER VALUES FOR THE TWO LINK MANIPULATOR SYSTEM

| Parameters | $I_1$ | $I_2$ | $l_1$ | $lc_1$ | $lc_2$ | $m_1$ | $m_2$ | g |
|---|---|---|---|---|---|---|---|---|
| Values | 0.833 | 0.417 | 1.0 | 0.5 | 0.5 | 10.0 | 5.0 | 9.80 |
| Units | Kg*$m^2$ | Kg*$m^2$ | m | m | m | Kg | Kg | $m/s^2$ |

### A. LPV model of two link manipulator

A polytopic LPV representation of this model system is used in this example. It is important to note that in this study the quadratic terms $O(\varphi, \dot{\varphi})$ are not considered because they are not bounded. As shown later by the Simulink result, it turns out that the two-link manipulator works well, even if these bounds are not known *a priori*. Considering this limitation the system dynamics can be described as:

$$\Xi(\varphi)\ddot{\varphi} + \mathrm{g}(\varphi) = u$$

where

$$\Xi(\varphi) = \begin{bmatrix} m_{11} & m_{12}\cos(\varphi_1 - \varphi_2) \\ m_{21}\cos(\varphi_1 - \varphi_2) & m_{22} \end{bmatrix}$$

$$\mathrm{g}(\varphi) = \begin{bmatrix} k_{11}\sin(\varphi_1) \\ k_{12}\sin(\varphi_2) \end{bmatrix}$$

$$m_{11} = m_1 lc_1^2 + m_2 l_1^2 + I_1, m_{12} = m_2 l_1 lc_2,$$

$$m_{21} = m_2 l_1 lc_2, m_{22} = m_2 lc_2^2 + I_2$$

$$k_{11} = -[m_1 lc_1 + m_2 l_1]g, k_{12} = -m_2 g lc_2$$

The nonlinear term in $\Xi(\phi)$ is clearly a bounded function:

$$\rho_1 = \cos(\varphi_1 - \varphi_2), -1 \le \rho_1 \le 1$$

To facilitate a state-space formulation, the vector field $\mathrm{g}(\varphi)$ with $\varphi \in R^2$ can bearranged in the form of $G(\varphi)\varphi$ and function $\phi_2(\varphi)$ can now be defined which is bounded,

$$\sin(\varphi_1) = \left(\frac{\sin(\varphi_1)}{\varphi_1}\right)\varphi_1 = \rho_2(\varphi).\varphi_1$$

$$-0.2 \le \rho_2 \le 1.$$

Similarly,

$$\sin(\varphi_2) = \left(\frac{\sin(\varphi_2)}{\varphi_2}\right)\varphi_2 = \rho_3(\varphi)\,.\,\varphi_2$$

$$-0.2 \leq \rho_3 \leq 1$$

To define the two-link system state space representation, let:

$$x = \begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{bmatrix} = \begin{bmatrix} \varphi_1 \\ \varphi_2 \\ \dot{\varphi}_1 \\ \dot{\varphi}_2 \end{bmatrix} \text{ and } W_b = \begin{bmatrix} 0 & 0 \\ 0 & 0 \\ 1 & 0 \\ 0 & 1 \end{bmatrix}$$

The LTV state space equation is as follows:

$$\dot{x} = A(\varphi)x + B(\varphi)u + Ed + R_1 f$$

where

$$A(\varphi) = \Pi^{-1}\begin{bmatrix} 0 & I \\ -\mathrm{G}(\varphi) & 0 \end{bmatrix}, B(\varphi) = \Pi^{-1}W_b,$$

$$\Pi = \begin{bmatrix} I & 0 \\ 0 & \Xi(\varphi) \end{bmatrix}, \Xi(\varphi) = \begin{bmatrix} m_{11} & m_{12}\rho_1 \\ m_{21}\rho_1 & m_{22} \end{bmatrix}$$

$$\mathrm{G}(\varphi) = \begin{bmatrix} k_{11}\rho_2 & 0 \\ 0 & k_{12}\rho_3 \end{bmatrix}$$

$$-1 \leq \rho_1 \leq 1, -0.2 \leq \rho_2 \leq 1, -0.2 \leq \rho_3 \leq 1$$

Assume that only $\varphi_1(t)$ and $\varphi_2(t)$ are measurable, so that:

$$C(\varphi) = C = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \end{bmatrix}$$

Assume further that the system is disturbed by a zero-mean Gaussian random disturbance $d(t)$ with variance magnitude and with disturbance distribution vector:

$$E = [1 \quad 0 \quad 0 \quad 0]^T$$

The considered fault is an actuator fault acting on the second actuator, so that the fault distribution vector is

$$B_f = [0 \quad 0 \quad 0 \quad 1]^T$$

The proof that $\Pi$ is non-singular follows from $\Xi(\varphi)$. As $\Pi$ is block diagonal, its determinant is given by $\Xi(\varphi)$. It is thus only required to show that $m_{11}m_{22} \neq m_{12}m_{21}$ . $m_{12} = m_{21}$ (by symmetry) and $m_{11} > m_{22}$since $I_1 > I_2$ and $m_1 > m_2$, hence $\Pi$ is non-singular.

*B. Observer based residual Generator Design*

Following the proposed procedure, the residual generator design is shown in this subsection.

**Step 1**: The desired observer eigenvalues are set to be parametric to obtain more design freedom as:

$$\Lambda = \{\lambda_1 \quad \lambda_2 \quad \lambda_3 \quad \lambda_4\}.$$

**Step 2:** Using elementary transformation and the rational matrix factorization method, the following are obtained:

$$N(\theta, s) = \begin{bmatrix} s & 0 \\ 0 & s \\ 1 & 0 \\ 0 & 1 \end{bmatrix},$$

$$M(\theta, s) = \begin{bmatrix} s^2 + \dfrac{6.5346\rho_2}{0.0833 + \rho_1^2 - \rho_1} & \dfrac{-9.8(2\rho_1 - 1)\rho_2}{0.0833 + \rho_1^2 - \rho_1} \\ \dfrac{-2.45 * (2\rho_1 - 1)\rho_3}{0.0833 + \rho_1^2 - \rho_1} & s^2 + \dfrac{2.45\rho_3}{0.0833 + \rho_1^2 - \rho_1} \end{bmatrix}.$$

**Step 3:** Note that

$$CE = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix},$$

So $p = 1$, and a basis for $LKer(CE)$may be taken as

$$\xi^T = [0 \quad 1]$$

Hence $Q = [0 \quad \alpha]$

**Step 4:** Then noting that:

$$QC = [0 \quad \alpha \quad 0 \quad 0],$$

one desired left eigenvector is $[0 \quad \alpha \quad 0 \quad 0]^T$and other left eigenvectors can be chosen arbitrarily only to satisfy $det(L) \neq 0$ . So, other parameters are given in a parametric way from:

$$f_i^T = [x_{i1} \quad x_{i2}], i = 2,3,4$$

Using the parametric eigenstructure assignment approach, the first desired eigenvector is projected into the allowable subspace by setting:

$$f_1^T = [N^T(\lambda_1)N(\lambda_1)]^{-1}N^T(\lambda_1)C^T\alpha\xi = \begin{bmatrix} 0 \\ \alpha\dfrac{\lambda_1}{\lambda_1^2 + 1} \end{bmatrix}$$

**Step 5:** The achieved eigenvector matrix can be obtained by (6) as given in **Theorem 1**.

**Step 6:** To simplify the calculation, some parameters are chosen at this step. If the parameters are chosen as:

$$x_{21} = 1, x_{22} = 0, x_{31} = 0,$$

$$x_{32} = 1, x_{41} = 0, x_{42} = 1.$$

Using$K(\theta) = W(\theta)R(\theta)^{-1}$. The observer gain is obtained as in (8).

$$K = \begin{bmatrix} (\lambda_3 + \lambda_2) & \frac{(\lambda_1 - \lambda_3)(\lambda_3 - \lambda_4)}{\lambda_2 - \lambda_3} \\ 0 & (\lambda_1 + \lambda_4) \\ -\lambda_3\lambda_2 + \frac{6.53446\rho_2}{K_o} & \lambda_3\lambda_2 + \frac{-2.45(2\rho_1 - 1)\rho_3}{K_o} \\ \frac{-9.8(2\rho_1 - 1)\rho_2}{K_o} & \lambda_1\lambda_4 + \frac{8.06642\rho_3}{K_o} \end{bmatrix} \quad (8)$$

$$K_o = (-0.764 + 2.5\rho_1^2 - 2.5\rho_1)$$

**Step 7:** The achieved closed-loop eigenvalues are:

$$\Lambda = \{\lambda_1 \quad \lambda_2 \quad \lambda_3 \quad \lambda_4\}.$$

To stabilize the observer system, let $real(\lambda_i) < 0, i = 1,2,3,4$. The required transient response performance can be achieved by suitably choosing the parametric eigenvalues.

The achieved transfer function matrix between the residual and disturbance is:

$$G_{rd}(s) = [0]$$

It is apparent that the disturbance is completely de-coupled because the transfer function matrix between the residual and disturbance is zero.

The transfer function between the residuals and faults is:

$$G_{rf}(s) = \frac{\alpha}{s^2 - (\lambda_1 + \lambda_4)s + \lambda_1\lambda_4}$$

So, the steady-state gain matrix $G_{rf}(0)$

$$G_{rf}(0) = \frac{\alpha}{\lambda_1\lambda_4}$$

From the above it is easy to choose suitable values of $\lambda_1$ *and* $\lambda_4$ to achieve a desired transient response and set $\alpha = \lambda_1\lambda_4$ to obtain good steady-state fault estimation.

The above analysis shows that the disturbances are decoupled completely and the residual is sensitive to the fault. This implies that the proposed design approach has achieved the desired goals. In the next subsection, some Simulink results are given.

### *C. Simulation result*

The open-loop two-link manipulator is unstable. Therefore, a constant controller is designed first using an observer state feedback structure while the estimated state is provided by the designed residual generator. The LPV system is simulated with a step and sinusoidal signals as shown in Figs. 2 & 3. Noting that the initial estimation is not good because both the two-link manipulator and observer systems are not in steady state and the state estimation error is large during the transient phase. The fault estimation is close to the real fault signal after 2 seconds as shown both in Figs. 2 & 3. The LPV fault estimator can provide good estimation performance when the real system is in a steady state.

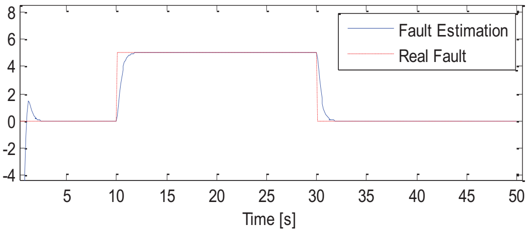

Figure 2. Fault estimation result for step fault signal

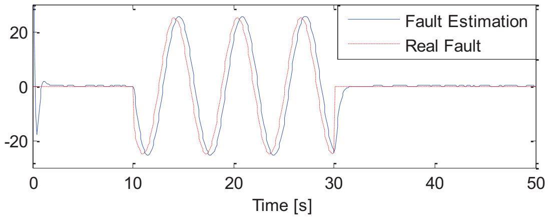

Figure 3. Fault estimation result for sinusoidal signal

## IV. Conclusion

This paper proposes an LPV fault detection approach using eigenstructure assignment which is robust in the sense of disturbance decoupling. The disturbances which can be considered to represent modeling uncertainty can be completely decoupled if the disturbance distribution and output matrix satisfy a rank condition. If this is not the case the disturbance can be decoupled as much as possible by suitable choice of design freedom. A two-link manipulator case is studied to show the usefulness of the proposed design procedure. The Simulink results show that for one fault case, the designed residual generator works well. Future studies will be concerned with multi-fault cases and how to use the detected fault information to accommodate faults and improve the system reliability.

***Abstract*—In this paper feasibility of modelling approach based on a bilinear system approximation is demonstrated on one of the most frequently met processes in chemical engineering, namely a continuous stirred tank reactor. Selected examples of such systems from the literature are considered and modelled with a use of dynamic bilinear systems. Advantages of this approach are presented and discussed.**

## I. Introduction

Chemical reactor is often described as 'the most important unit operation in a chemical process', see [1]. The task of its modelling and control is commonly encountered in the literature representing a practical nonlinear industrial problem, see [2], [3], [4]. A popular model of a chemical reactor is the so-called continuous stirred tank reactor (CSTR). CSTR consists of a closed tank to which an input stream is fed in and the output stream fed out in a continuous manner, whilst a content is constantly stirred. Modelling of CSTRs is challenging mainly due to i) possibility of occurrences of rapid reactions (the so-called ignition-extinction phenomena), hence fast changing process gain and dynamics, and also due to ii) nonlinear steady-state behaviour, see [1] and [5].

This paper demonstrates that the CSTRs can be modelled by employing an approach based on bilinear system (BS) description. In order to increase modelling flexibility of BSs, an extension consisting of a static nonlinearity that transforms the input signal is proposed. Such a structure, referred to as a Hammerstein-bilinear system (HBS), see [6], [7], is considered and compared to BS and Hammerstein system (HS) models.

The use of BS based approach is motivated twofold. First, BSs retain a close structural relationship with linear models, hence standard well understood notions from classical linear system theory such as system time constants, damping/natural frequency and steady-state gain are to large extent retained. This follows from the property that BS structure can be interpreted as a linear time-varying system, which also greatly facilitates the control design. Second, BSs preserve linearity w.r.t. the parametrisation, which aids in their identification by allowing for standard parameter estimation methods to be used.

In this paper three different CSTR models are considered. Two of the models are isothermal, whilst the third model is an example of a diabatic CSTR, see [1].

## II. Model structures

HBS structure belongs to a sub-class of so-called output affine models, i.e. models that retain affinity w.r.t. the output signals, see [8]. It comprises of a cascade connection of a static (memoryless) nonlinearity followed by a dynamic time-invariant affine BS and is given by

$$y_k = \sum_{j=1}^{n_a} a_j y_{k-j} + \sum_{i=1}^{n_b} b_i v_{k-i} + \sum_{j=1}^{n_a}\sum_{i=1}^{n_b} \eta_{ij} v_{k-i} y_{k-j} + c \quad (1)$$

$$v_k = f(u_k) \quad (2)$$

where $a_j$, $b_i$, $\eta_{ij}$ and $c$ are model parameters. The bilinearity is defined as a product between system output $y_k$ and the intermediate input variable $v_k$, and $f(\cdot)$ denotes a general scalar static nonlinear function. Note that not all bilinear coefficients must necessarily be present in (1), hence a particular structure can be obtained by setting selected $\eta_{ij}$ to zero.

The HBS can be interpreted as a generalisation of both of its constituent subsystems, i.e. HS and BS models. In particular, a BS is obtained from (1)-(2) by setting $u_k = v_k$, i.e. by selecting $f(x) = x$, which gives

$$y_k = \sum_{j=1}^{n_a} a_j y_{k-j} + \sum_{i=1}^{n_b} b_i u_{k-i} + \sum_{j=1}^{n_a}\sum_{i=1}^{n_b} \eta_{ij} u_{k-i} y_{k-j} + c \quad (3)$$

Similarly, a HS is obtained by setting $\eta_{ij} = 0 \ \forall \ i, j$ in (1)-(2), which leads to

$$y_k = \sum_{j=1}^{n_a} a_j y_{k-j} + \sum_{i=1}^{n_b} b_i v_{k-i} + c \quad (4)$$

$$v_k = f(u_k) \quad (5)$$

Also, a linear (or more precisely an affine) structure is obtained by imposing both restrictions simultaneously, i.e. $\eta_{ij} = 0 \ \forall i, j$ and $u_k = v_k$.

In this paper, for simplicity, it is assumed that the input static nonlinearity is modelled as a polynomial of order $n_\alpha$, i.e.

$$f(x) = \sum_{l=1}^{n_\alpha} \alpha_l x^l \quad (6)$$

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

Consequently, a particular HBS structure is given by a quadruplet that defines the number of $a$, $b$, $\eta$ and $\alpha$ coefficients, i.e. HBS($n_a$,$n_b$,$n_\eta$,$n_\alpha$). Moreover, the sum of all coefficients plus unity (to account for an offset), corresponds to the total number of degrees of freedom (DoF) in a given structure. An analogous notation is used w.r.t. other structures that can be derived from the HBS model.

## III. Parameter estimation

The HBS structure is bilinear in terms of parametrisation, due to the products between $\alpha$ and $a$, and also between $\alpha$ and $\eta$ coefficients. A well known approach to solve such problems is to use the so-called bilinear parametrisation method (BPM), see [9]. The BPM solves the estimation problem in a two step manner, where in the first step $\alpha$ parameters are fixed and $a$, $b$, $\eta$ parameters are calculated, whilst in the second step $a$, $b$ and $\eta$ remain fixed and $\alpha$ parameters are computed [10]. Because the two subproblems separately are linear w.r.t. the unknowns, the ordinary least squares algorithm [9] can be applied, which renders the overall procedure numerically efficient, and this is the approach used here. An analogous technique can also be applied to HS models, see [11], whilst the parameters of affine and BS structures can be estimated by using a single ordinary least squares technique.

## IV. Simulation studies

### A. Performance criteria and experimental setup

In order to quantify the accuracy of models obtained, two performance criteria are used. Namely, the coefficient of determination and the (normalised) integral of absolute error, defined, respectively, as follows

$$\mathrm{R}_\mathrm{T}^2 = 100\left(1 - \frac{\|y-\hat{y}\|_2^2}{\|y-\bar{y}\|_2^2}\right) \tag{7}$$

$$\mathrm{IAE} = \frac{1}{N}\sum_{k=1}^{N}|y_k - \hat{y}_k| \tag{8}$$

where $y$ and $\hat{y}$ denote vectors composed of the measured (noisy) system outputs and outputs generated by the estimated model, respectively, and $\bar{y}$ is the mean value of $y$. The notation $\|\cdot\|_2$ denotes the Euclidean norm.

Because the main interest of experiments lies in the modelling capabilities of the model structures considered, relatively long input-output data consisting of $N = 20,000$ samples are used. Three data sets are considered, i.e. identification and two validation data sets. The sampling time is chosen as $0.1$s. In the case of the identification data set and the first validation data set, the input signal is generated as a series of uniformly distributed steps between the minimal and maximal range for a given system. The probability of transition to a different level is selected randomly with a uniform switching probability of $10\%$, providing a reasonable compromise between the content of transient and steady-state data. Additionally, to ensure that the input is sufficiently exciting, a normally distributed, white and zero-mean noise sequence of comparatively small variance is added. To render the identification experiment more realistic, the measured output is assumed to be contaminated with an additive, normally distributed, white and zero-mean disturbances such that the resulting signal-to-noise ratio is approximately 37dB. The second validation data set comprises of a monotonic staircase input, which allows the performance of the identified models to be evaluated with the emphasis placed on the steady-state behaviour. Also, to provide an indication of the complexity of the models, the corresponding DoF are considered.

### B. Isothermal CSTR with a first-order irreversible reaction

*1) System description:* The first isothermal CSTR model considered, referred to as the CSTR1, is given by the following equations, see [1] for details, i.e.

$$\frac{dC_A(t)}{dt} = \frac{F(t)}{V}C_{Af} - \left(\frac{F(t)}{V} + k\right)C_A(t) \tag{9}$$

$$\frac{dC_B(t)}{dt} = -\frac{F(t)}{V}C_B(t) + kC_A(t) \tag{10}$$

and describes a first-order irreversible reaction $A \xrightarrow{k} B$ where $k$ is the reaction rate per unit volume. The remaining variables are: $C_A(t)$, $C_B(t)$ - concentrations of substances $A$ and $B$ inside the tank of a constant volume $V$, respectively, $F(t)$ - inflow/outflow mass rate, $C_{Af}$ - inflow concentration of substance $A$. Only the substance $A$ is present in the inflow stream, and inflow and outflow mass rates are equal. The actual units are unimportant and hence are not included. It is assumed that the manipulated variable is $F(t)$ and that $C_B(t)$ is the output of interest. The task consists of identifying a model between $F(t)$ and $C_B(t)$.

The values of the parameters were chosen as $V = 1$, $k = 0.2$, $C_{Af} = 1$ and the initial states of the process as $C_{a0} = C_{b0} = 0.5$, where the subscript zero denotes the initial value. The input $F(t)$ is in range of $(0,\ 1]$.

It is observed that a product, i.e. bilinearity, between the input $F(t)$ and the state $C_A(t)$ occurs in (9) and that an analogous product between the input $F(t)$ and the state $C_B(t)$ is also present in (10). The steady-state characteristic of the CSTR1 model is plotted in Figure 1, where it is observed that the curve resembles the type of steady-state characteristics typical of BSs. Therefore, these observations substantiate the usage of a bilinear based modelling approach.

*2) Identification results:* Selected identification results are given in Table I. First, it is observed that the model is considerably nonlinear because the third order affine structure resulted in $\mathrm{R}_\mathrm{T}^2$ below 90% for all three data sets. Further increase of the order of the affine structure does not lead to any significant improvements in modelling performance. HS models show clear improvement, allowing for $\mathrm{R}_\mathrm{T}^2$ of approximately 98% in the case of the HS(1,1,4) to be achieved for all three data sets. Further increase of the order of the input polynomial does not lead to significant improvements in model fitting. This is due to the fact that the nonlinear steady-state characteristic is not a complex function, and it is rather the changing system dynamics that is not captured by the HS type structures. When considering the results obtained from BS models, an evident

TABLE I
CSTR1 - QUANTIFIED IDENTIFICATION AND VALIDATION RESULTS FOR MODEL STRUCTURES CONSIDERED.

improvement in the approximation performance is noted, i.e. the $R_T^2$ of almost 100% is obtained with the IAE criterion decreasing by approximately 7 times, when compared to the best HS model. This means that both, the nonlinear steady-state characteristic and the changing system dynamics are approximated well by the BS structures with only 4 or 5 DoF. Because the only source of nonlinearity in the underlying process equations arises from product terms, cf. (9)-(10), this result could have been anticipated.

Representative graphical results of the identification are given in Figures 2 and 3, showing the performances of the selected estimated models on arbitrarily chosen intervals of the validation data sets 1 and 2, respectively. It is observed that in the case of both figures the actual system output is virtually undistinguishable from that generated by the identified BS(2,1,1) structure. Consequently, it is concluded that a BS structures are appropriate for modelling the CSTR1 process.

### C. *Isothermal CSTR with the Van de Vusse reaction*

*1) System description:* The second isothermal CSTR model considered, see [1], referred to as the CSTR2, is given by

$$\frac{dC_A(t)}{dt} = \frac{F(t)}{V}\big(C_{Af} - C_A(t)\big) - k_1 C_A(t) - k_3 C_A^2(t) \quad (11)$$

$$\frac{dC_B(t)}{dt} = -\frac{F(t)}{V} C_B(t) + k_1 C_A(t) + k_2 C_B(t) \quad (12)$$

$$\frac{dC_C(t)}{dt} = -\frac{F(t)}{V} C_C(t) + k_2 C_B(t) \quad (13)$$

$$\frac{dC_D(t)}{dt} = -\frac{F(t)}{V} C_D(t) + \frac{1}{2} k_3 C_A^2(t) \quad (14)$$

with the behaviour governed by the so-called Van de Vusse reaction kinetics. The reactions

$$A \xrightarrow{k_1} B \xrightarrow{k_2} C \quad (15)$$

$$2A \xrightarrow{k_3} D \quad (16)$$

TABLE II
CSTR2 - QUANTIFIED IDENTIFICATION AND VALIDATION RESULTS FOR MODEL STRUCTURES CONSIDERED.

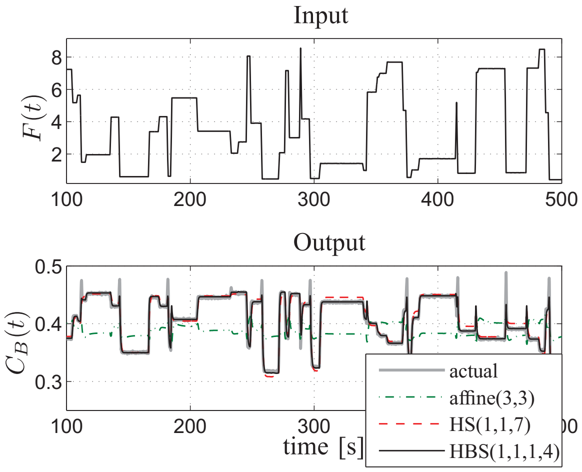

Fig. 5. CSTR2 - Selected representative results of identification on validation data set 1 in the interval [100, 500]s.

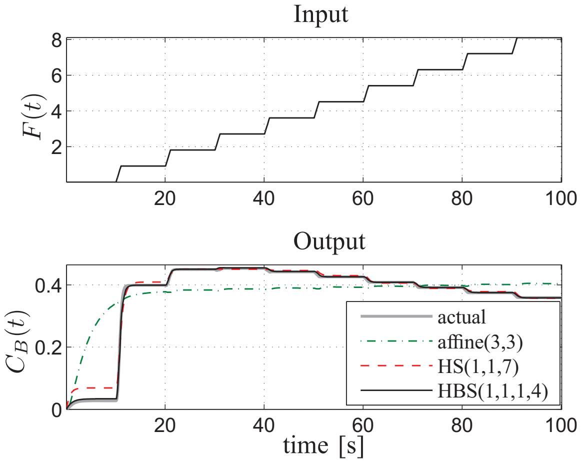

Fig. 6. CSTR2 - Selected results of identification on validation data set 2.

are irreversible and described by the reaction rate constants $k_1$, $k_2$ and $k_3$. The remaining variables are: $C_A(t)$, $C_B(t)$, $C_C(t)$, $C_D(t)$ - concentrations of substances $A$, $B$, $C$ and $D$ inside the tank of constant volume $V$, respectively, $F(t)$ - inflow/outflow mass rate, $C_{Af}$ - inflow concentration of substance $A$. Only the substance $A$ is present in the inflow stream, and inflow and outflow mass rates are equal. It is assumed that the manipulated variable is $F(t)$, whilst $C_B(t)$ is the output of interest. Therefore, the modelling task consists of identifying a model between $F(t)$ and $C_B(t)$.

The values of the parameters were chosen as: $V = 1$, $k_1 = 5/6$, $k_2 = 3$, $k_3 = 10/6$, $C_{Af} = 10$ and the initial states of the process are $C_{a0} = C_{b0} = 0$. The input $F(t)$ is postulated to vary between $(0, 9]$.

It is observed that a bilinearity between the input $F(t)$ and the state $C_A(t)$ is present in (11) and an analogous bilinearity between the input $F(t)$ and the state $C_B(t)$ appears in (12). However, in contrast to (9) corresponding to the CSTR1 model, here the product term is not the only source of nonlinearity in the evolution of $C_A(t)$. This is due to the presence of the expression $C_A^2(t)$ in (11), whose influence is controlled by the rate constant $k_3$.

Consequently, it is concluded that although the underlying system equations indicate that a bilinear type behaviour is present, it may be infeasible to model the process by a BS only over the entire range of its operation. This hypothesis is confirmed by considering the steady-state characteristic of the CSTR2 process given in Figure 4, where it is observed that the system exhibits the input multiplicity (IM) property [3]. Such static behaviour cannot be captured by a BS, due to its inherent structural limitations. This stands in contrast to HS and HBS that are structurally capable of IM, hence are anticipated to be more appropriate for modelling of the CSTR2 process.

*2) Identification results:* The identification results are given in Table II, where a low value of $\mathrm{R}_{\mathrm{T}}^2$ for all three data sets in the case of the affine model indicates that the overall process is considerably nonlinear. Further increase of the order of the affine structure does not result in noticeable improvements in fitting. The performance criteria of BS structures are not included in the table because it was not possible to fit such models, i.e. the corresponding $\mathrm{R}_{\mathrm{T}}^2$ values were negative. This result confirms the inappropriateness of using BS structures for approximating processes exhibiting IM. A considerable improvement is achieved in the case of HS structures, when compared to the affine model, with $\mathrm{R}_\mathrm{T}^2$ of about 97% on average for all three data sets obtained by HS(1,1,7) with 10 DoF. The results obtained by the HBS(1,1,4) and HBS(1,1,5), with 8 and 9 DoF, respectively, show further fitting improvements with both models achieving $\mathrm{R}_\mathrm{T}^2$ of approximately 98% for the identification data set and the validation data set 1, and almost 100% for the validation data set 2. Compared to the HS(1,1,7) the IAE was reduced by approximately threefold in the case of the first two data sets, and fourfold in the case of the third data set.

Representative graphical results obtained from the identification procedure are presented in Figures 5 and 6, showing the performances of the selected estimated models on arbitrarily chosen intervals of the validation data set 1 and 2, respectively. Whilst in the case of Figure 5 slight discrepancies between the actual output and that generated by the estimated HBS(1,1,1,4) model are observed, the two corresponding curves are virtually indistinguishable in the case of Figure 6. Also, it is noted that the system exhibits a non-minimum phase behaviour when $F(t)$ is high and changes to a lower value. This behaviour, which is observed to be manifested by spikes in the $C_B(t)$ signal, increases the difficulty of obtaining an acceptable approximation. Consequently, despite such a challenging task, the modelling results obtained by the HBS(1,1,1,4) structure can be treated as very satisfactory in overall.

### D. *Diabatic CSTR*

*1) System description:* The considered diabatic CSTR model, see [1] and [5], referred to as the CSTR3, is given by

$$\frac{dC_A(t)}{dt} = \frac{F(t)}{V}\big(C_{Af} - C_A(t)\big) - k_0 r(t) C_A(t) \tag{17}$$

$$\frac{dT(t)}{dt} = \frac{F(t)}{V}\big(T_f - T(t)\big) + \frac{-\Delta H}{\rho c_p} k_0 r(t) - \frac{US}{V\rho c_p}\big(T(t) - T_j(t)\big) \tag{18}$$

where the first order reaction rate per unit volume is given by the so-called Arrhenious expression, i.e.

$$r(t) = \exp\left(\frac{\Delta E}{RT(t)}\right) \tag{19}$$

The other variables are: $C_A(t)$ - concentration of substance $A$ inside a tank of the constant volume $V$, $F(t)$ - inflow/outflow mass rate, $C_{Af}$ - inflow concentration of substance $A$, $k_0$ - pre-exponential factor, $R$ - ideal gas constant, $\Delta E$ - activation energy, $T(t)$ - reactor temperature, $T_f$ - inflow (feed) temperature, $T_j(t)$ - jacket temperature, $U$ - overall heat transfer coefficient, $-\Delta H$ - heat of reaction, $\rho$ - density, $S$ - area for heat exchange, $c_p$ - heat capacity. Only the substance $A$ is present in the inflow stream, and inflow and outflow mass rates are equal. It is assumed that the manipulated variable is $T_j(t)$, whilst $C_A(t)$ is the output of interest. Therefore, the modelling task consists of identifying a model between $T_j(t)$ and $C_A(t)$.

TABLE III
CSTR3 - QUANTIFIED IDENTIFICATION AND VALIDATION RESULTS FOR MODEL STRUCTURES CONSIDERED.

Considering equations (17) and (18), it is noted that in each case bilinearities are present, i.e. products between $F(t)$ and the state $C_A(t)$ in the first equation and between $F(t)$ and the state $T(t)$ in the second equation. These, however, are clearly not the only contributions that render nonlinearity of the overall behaviour. This is due to the presence of nonlinear relationships involving an exponent of $T(t)$ that appear in both equations.

A steady-state characteristic of the CSTR3 model, given in Figure 7, shows the presence of the output multiplicity (OM) property [3]. Because non of the model structures investigated in this paper is structurally capable of OM, see [8], only a restricted range of the process operation is considered, i.e. the range of $T_j \in [273,\ 306)$ within which OM is absent. Consequently, because the operating range is limited, it might be possible that a bilinear type behaviour will, in fact, be prevailing.

The values of the parameters were chosen as: $F(t) = 1$,

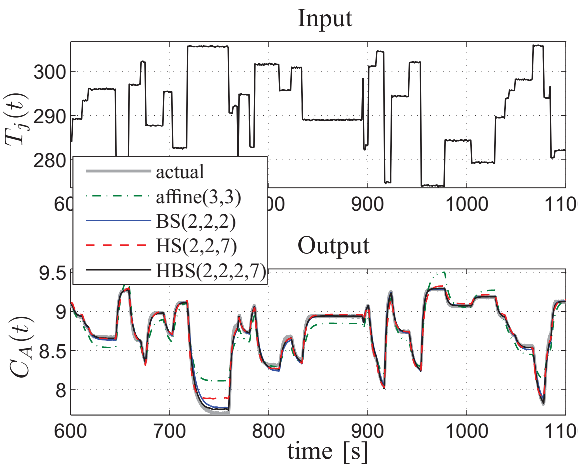

Fig. 8. CSTR3 - Selected representative results of identification on validation data set 1 in the interval $[600,\ 1100]$s.

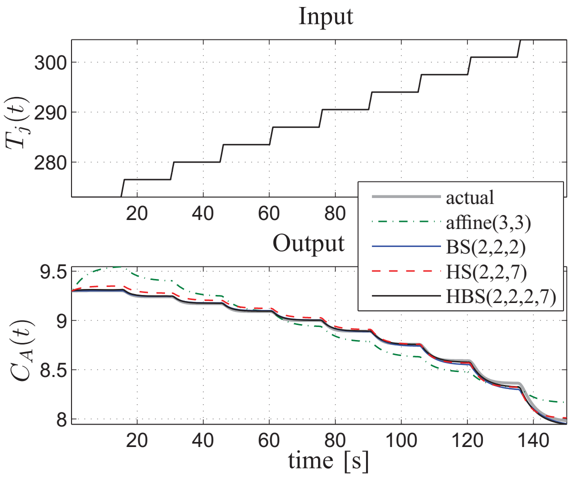

Fig. 9. CSTR3 - Selected results of identification on validation data set 2.

$V = 1$, $k_0 = 9703 \times 3600$, $-\Delta H = 5960$, $\rho c_p = 500$, $US = 150$, $\Delta E = 11843$, $R = 1.987$ and the initial states of the process are $C_{A0} = 8.5$ and $T_0 = 305$.

*2) Identification results:* The identification results obtained are collected in Table III, from where it is observed that the affine model achieved reasonable results close to 90% in terms of $\mathrm{R}_\mathrm{T}^2$ in the case of all three data sets. Further increase of the order of the affine structure does not provide any considerable improvements. First order HS structures yielded results that are better by approximately 8% on average in terms of the $\mathrm{R}_\mathrm{T}^2$ criterion and approximately twice on average in terms of the IAE criterion. This indicates a clear improvement and justifies the need for a nonlinear model structure. The best fitting among HS structures is obtained for a second order HS structure, i.e. HS(2,2,7) with a seventh order polynomial and 12 DoF in total. It is interesting to notice that these values are close to those produced by a relatively simple BS structure, i.e. BS(1,1,1), with only 4 DoF. A boundary of 99% in terms of the $\mathrm{R}_\mathrm{T}^2$ criterion is exceed by a second order BS model with 7 DoF. The fitting is improved, if at all, only slightly by first order HBS structures, and it is the second order HBS model, i.e. HBS(2,2,2,7), in the case of which the results improve more significantly. However, this comes at the cost of 14 DoF, when compared to only 7 DoF in the case of BS(2,2,2).

Representative graphical results generated from the estimated models are depicted in Figures 8 and 9, and demonstrate the performances of the selected models on arbitrarily chosen intervals of the validation data set 1 and 2, respectively. It is observed that the outputs of the estimated models BS(2,2,2) and HBS(2,2,2,7) are both virtually undistinguishable from the actual system output in both figures. Consequently, by taking into account the corresponding DoF and a pragmatic point of view, it is the second order BS that appears to be a preferable choice in this case.

## V. Conclusions

The paper has demonstrated feasibility of BS based modelling approach for approximating CSTRs. It has been shown that BS models are capable of capturing both, i.e. the dynamic and static behaviour of the exemplary CSTR systems considered. In the case of the CSTR process exhibiting the IM property, a BS structure with an additional nonlinear memoryless element transforming the input, i.e. a HBS structure, has shown to be an appropriate choice.

*Abstract*—**Vibration isolation systems with nonlinear stiffness under sinusoidal excitation exhibit unwanted jump phenomena and superharmonics when they are lightly damped. These characteristics can be suppressed by linear viscous damping but the force transmissibility over the high frequency range increases as a result. In this study, nonlinear viscous damping will be chosen to solve this problem with the aid of a single-degree-of-freedom model with cubic stiffness. Simulation results show that nonlinear viscous damping can reduce the resonant peak as well as suppressing the adverse properties of nonlinear stiffness, jumps and harmonics, without compromising the transmissibility over the high frequency range. Nonlinear damping preserves the benefits of linear damping while removing the undesirable effects over the non-resonant regions and therefore improves the overall performance.**

**Keywords: nonlinear damping, nonlinear spring, jump phenomena, duffing, OFRF**

## I. Introduction

Passive vibration isolation systems are employed in many engineering applications where objects require protection from undesired vibration force or displacement. They are usually installed between the source of the disturbance and equipment requiring protection in order to reduce the level of vibration transmitted to the object. A single-degree-of-freedom (sdof) vibration isolator, modelled by a linear mass-spring-damper system, has been well-studied by many authors [1]–[9]. The need for nonlinear vibration isolation and the recent developments are summarised by Ibrahim [10].

The nonlinearity usually takes the form of either a nonlinear spring force or a nonlinear damping force. There are a number of works focusing on Duffing-type isolators where the restoring spring force is a cubic function of the displacement [11]–[14]. Compared to the linear case, the nonlinear stiffness term could lower the force transmissibility around the resonant frequency range. In some cases, the resonant frequency can be reduced, resulting in a larger frequency range of vibration isolation. One major drawback of nonlinear stiffness, however, is the jump phenomena, where the transmissibility suddenly jumps up or down when there is a small change in the frequency of the excitation signal. The inherent instability and the resulting high level of higher harmonics may cause some concerns. The effects of the nonlinear spring force on an sdof system was compared with that of the nonlinear damping force by Zhang et al. [15]. Their results showed that nonlinear damping is preferable as a significant reduction of the peak transmitted force can be achieved without bifurcations in the system. The study by Lang et al [16] showed that the nonlinear viscous damping force could complement the drawbacks of linear viscous damping by modifying the force transmissibility in the resonant region without causing any detrimental effects over the non-resonant regions.

The application of nonlinear stiffness to vibration isolation has a longer history than the use of nonlinear viscous damping. Because of the different pros and cons of these two nonlinear forces, this paper aims to examine the benefits brought by nonlinear viscous damping when it is incorporated into an isolator with nonlinear stiffness. The nonlinear stiffness may be an internal property of the isolator or it may be an inherit property of the system that requires protection from vibration. The isolation system with cubic stiffness is represented by an sdof mass-spring-damper model. The transmissibility performance over a range of frequencies for different levels of linear and nonlinear damping obtained by simulation will be displayed. The comparison of the transmissibility curves will reveal the benefits of nonlinear viscous damping over linear viscous damping. The jump phenomena and the harmonics caused by the spring nonlinearity can be suppressed by either linear or nonlinear damping but only nonlinear damping can maintain the performance over high frequency regions simultaneously.

An sdof mass-spring-damper model with nonlinear spring and damping forces under sinusoidal excitation is described in Section II. The influence of nonlinear damping on this model are given in Section III. Simulation results and discussions are provided in Section IV and finally a conclusion is given in Section V.

## II. SDOF VIBRATION ISOLATORS WITH SPRING AND DAMPING NONLINEARITY

Consider a single-degree-of-freedom (sdof) vibration isolation system under a sinusodial excitation force $f_{in}(t)$ as shown in Figure 1, where

$$f_{in}(t) = A\sin(\bar{\omega}t) \tag{1}$$

with magnitude $A$ and frequency $\bar{\omega}$. The force transmitted to the immobile base, $f_{out}(t)$, is related to $f_{in}(t)$ by the equations of motion of the nonlinear vibration isolation system given by

$$\begin{cases} M\ddot{x}(t) + C_1\dot{x}(t) + C_2[\dot{x}(t)]^3 \\ +K_1x(t) + K_2[x(t)]^3 = f_{in}(t) = A\sin(\bar{\omega}t) \\ \\ f_{out}(t) = C_1\dot{x}(t) + C_2[\dot{x}(t)]^3 + K_1x(t) + K_2[x(t)]^3 \end{cases} \tag{2}$$

where $x(t)$ is the displacement of the moving mass, $M$ is the mass, $C_1$ the viscous damping constant, $C_2$ the cubic viscous damping constant, $K_1$ the linear spring constant, $K_2$ the cubic spring constant. When $K_2, C_2 = 0$, System (2) is identical to a well-studied linear system. When $K_2 \neq 0$ and $C_2 = 0$, it becomes a Duffing-type vibration isolator which exhibits jump-up and jump-down phenomena as discussed in many publications [13], [17], [18].

For the purpose of general analysis, System (2) is reduced to a non-dimensional form which is non-specific to chosen values of $M$ and $K_1$. By denoting the resonant frequency $\omega_0 = \sqrt{K_1/M}$, the first equation in System (2) becomes

$$\ddot{y}(\tau) + \xi_1\dot{y}(\tau) + \xi_2[\dot{y}(\tau)]^3 + y(\tau) + \gamma[y(\tau)]^3 = \sin(\Omega\tau) \tag{3}$$

where

$$\begin{aligned} \tau &= \omega_0 t, && (4)\\ \Omega &= \frac{\bar{\omega}}{\omega_0}, && (5)\\ y(\tau) &= \frac{K_1}{A}x(t), && (6)\\ \gamma &= \frac{A^2K_2}{K_1^3}, && (7)\\ \xi_1 &= \frac{C_1}{\sqrt{K_1M}}, && (8)\\ & && (9) \end{aligned}$$

and

$$\xi_2 = \frac{C_2A^2}{\sqrt{(K_1M)^3}}. \tag{10}$$

System (2) can be viewed as a single-input two-output system by substituting in

$$y_1(\tau) = y(\tau) \tag{11}$$

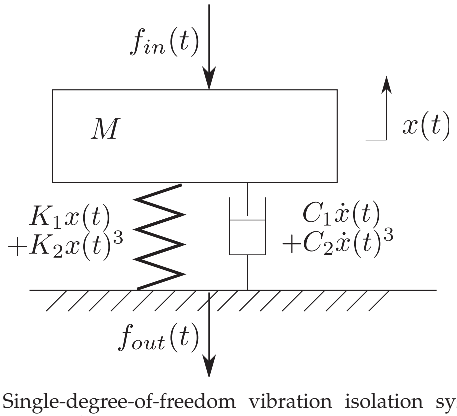

Fig. 1. Single-degree-of-freedom vibration isolation system with nonlinear cubic stiffness and nonlinear cubic viscous damping

and

$$y_2(\tau) = y_1(\tau) + \gamma[y_1(\tau)]^3 + \xi_1\dot{y}_1(\tau) + \xi_2[\dot{y}_1(\tau)]^3 \tag{12}$$

hence the model becomes

$$\begin{cases} \ddot{y}_1(\tau) + y_2(\tau) = u(\tau) = \sin(\Omega\tau) \\ y_2(\tau) = y_1(\tau) + \gamma[y_1(\tau)]^3 + \xi_1\dot{y}_1(\tau) + \xi_2[\dot{y}(\tau)]^3. \end{cases} \tag{13}$$

The force transmissibility $T_1(\Omega)$, the ratio of the magnitude of the transmitted force at the excitation frequency to that of the excitation force, can be deduced from equations (2), (4) - (10) and (13). In the time domain, this gives

$$\begin{aligned} \frac{f_{out}(t)}{A} &= \frac{C_1\dot{x}(t) + C_2[\dot{x}(t)]^3 + K_1x(t) + K_2[x(t)]^3}{A} && (14)\\ &= y_1(\tau) + \gamma[y_1(\tau)]^3 + \xi_1\dot{y}_1(\tau) + \xi_2[\dot{y}_1(\tau)]^3 && (15)\\ &= y_2(\tau). && (16) \end{aligned}$$

By applying Fourier transform to $y_2(\tau)$ and evaluating at $\omega = \Omega$ gives

$$T_1(\Omega) = \Big|Y_2(j\omega)|_{\omega=\Omega}\Big| = \Big|Y_2(j\Omega)\Big|. \tag{17}$$

Equation (17) implies that the force transmissibility of the system can be evaluated by examining the spectrum of the second output of System (13).

Because of the system's nonlinearity, the second output $y_2(\tau)$ contains the fundamental frequency of the input signal as well as harmonics. As System (13) has cubic stiffness and cubic damping, the third harmonics of the output may be significant. This harmonic effect can be described by $T_3(\Omega)$ defined as

$$T_3(\Omega) = \Big|Y_2(j\omega)|_{\omega=3\Omega}\Big|. \tag{18}$$

The numerical simulation results of System (13) will be presented in Section III. The effects of nonlinear viscous damping on the performance of vibration isolation will be shown by $T_1(\Omega)$ and $T_3(\Omega)$.

## III. The effects of nonlinear viscous damping on a Duffing-type vibration isolator

From analysis and observation, the following conclusions can be made.

**Proposition 1**

*(i)*

When $\Omega \approx 1$, there exists a $\bar{\xi_2} > 0$ such that

$$\left.\frac{d[T_1(\Omega)]^2}{d\xi_2}\right|_{\Omega\approx 1} < 0 \tag{19}$$

if $0 < \xi_2 < \bar{\xi_2}$ for $0 \le \gamma < \bar{\gamma}$ where $\bar{\gamma}$ is the maximum value of $\gamma$ beyond which jump phenomena will be observed in System (13).

*(ii)*

When $\Omega \ll 1$ or $\Omega \gg 1$, there exists a $\bar{\xi_2} > 0$ such that

$$T_1(\Omega)|_{\xi_2>0} \approx T_1(\Omega)|_{\xi_2=0} \tag{20}$$

if $0 < \xi_2 < \bar{\xi_2}$ for $0 \le \gamma < \bar{\gamma}$ where $\bar{\gamma}$ is the maximum value of $\gamma$ beyond which jump phenomena will be observed in System (13).

*(iii)*

For fixed values of $\gamma, \xi_1 > 0$, if System (13) exhibits jump phenomena, there exists a $\bar{\xi_2}$ such that the jumps are eliminated.

The complete proof is still under study but a brief description of the idea is provided here. System (13) is a polynomial form nonlinear differential equation model, the input and the two outputs of which can be represented by a Volterra series around the zero equilibrium point in the time domain [19]. The force transmissibility (i.e. the spectrum of the second output) can be related to the input spectrum using the output frequency response function (OFRF) concept [20]. The OFRF defines the relationship between the output spectrum (the force transmissibility) and the parameters which characterise the nonlinearity of a Volterra system ($\gamma$ and $\xi_2$) for a given input and fixed values of the linear terms. This concept is applied to a vibration isolation system with linear stiffness and nonlinear damping in a theoretical study by Lang et al. [16]. The same approach can be applied to System (13) which has an extra nonlinear stiffness term. Its force transmissibility $T_1(\Omega)$ can then be expressed as a polynomial function of $\gamma$ and $\xi_2$. The derivative of $[T_1(\Omega)]^2$ with respect to $\xi_2$ can be obtained for $\Omega \approx 1$ to prove conclusion (i) and the values of $T_1(\Omega)$ for $\xi_2 > 0$ and $\xi_2 = 0$ are compared to reach conclusion (ii).

Conclusion (iii) states that the jump phenomena can be eliminated by nonlinear damping. As the Volterra model cannot capture the jump phenomena, the OFRF concept cannot be applied here. An alternative approach, the harmonic balance method, can be used for this analysis [11], [12], [21]–[27]. The solution of the second output of System (13) is assumed to be of the form of a truncated Fourier series. Substituting this into System (13) and equating coefficients related to each harmonic components yields an expression for $T_1(\Omega)$. This well-known method has been the main tool for the analysis of Duffing systems and can now be extended to the study of a Duffing system with an additional nonlinear damping term.

The three conclusions of Proposition 1 are based on some previous analyses and observations from numerical examples given in Section IV. It is worth pointing out that for System (13), the following remark about the harmonics in the system output can also be made.

**Remark 1**

When $\Omega \approx 1$, there exists a $\bar{\xi_2} > 0$ such that

$$\left.\frac{d[T_3(\Omega)]^2}{d\xi_2}\right|_{\Omega\approx 1} < 0 \tag{21}$$

if $0 < \xi_2 < \bar{\xi_2}$ for $0 \le \gamma < \bar{\gamma}$ where $\bar{\gamma}$ is the maximum value of $\gamma$ beyond which jump phenomena will be observed in System (13).

The present study extends the findings of Lang et al. [16] to a vibration isolation system with nonlinear stiffness. The effects of nonlinear damping are concluded by Proposition 1 and Remark 1. Equation (19), the first conclusion of Proposition 1, suggests that an increase in the value of cubic damping leads to a reduction in the force transmissibility around the resonant frequency range and the second conclusion, summarised by Equation (20), indicates that the the transmissibility over the frequency range far away from the resonant frequency remains unaffected by nonlinear damping. These findings conclude that the ideal properties of nonlinear damping found by Lang et al. [16] also hold true for systems with nonlinear stiffness for certain values of $\gamma$. The jump phenomena is addressed by the third conclusion which shows that the cubic damping, when it reaches a high enough level, can remove the jump phenomena caused by the nonlinear spring thus greatly improving the system stability. Remark 1 focuses on the superharmonics produced by the nonlinear spring. The highest level of superharmonics is produced when the excitation frequency is near the resonant frequency. The derivative of $[T_3(\Omega)]^2$ with respect to $\xi_2$ is negative so Equation (21) indicates that the third harmonic can be reduced by nonlinear damping. These are the main advantages of including nonlinear viscous damping on a Duffing-type system.

## IV. Simulation results and discussion

Numerical simulation studies were conducted using the standard MATLAB solver for ordinary differential equations (`ode45`) to demonstrate the effects of nonlinear viscous damping on a Duffing-type vibration isolation system. The results are presented in Figures 2 to 6.

The advantage of nonlinear viscous damping over conventional linear damping on an sdof vibration isolation system with linear stiffness, as described in the study by Lang et al. [16], are summarised by Figures 2 and 3. In Figure 2, the system has linear stiffness and linear damping with $\xi_1$ = 0.1, 0.2 and 0.4. As the linear damping parameter $\xi_1$ increases, $T_1(\Omega)$ around the resonant region decreases but there is an undesirable increase in $T_1(\Omega)$ in the high frequency region. In Figure 3, the value of $\xi_1$ is kept constant at 0.1 while the cubic damping parameter $\xi_2$ takes the values 0, 0.2 and 0.4. In this case, the resonance at $\Omega \approx 1$ is suppressed by the increase of $\xi_2$ while $T_1(\Omega)$ over the frequency ranges of $\Omega \ll 1$ and $\Omega \gg 1$ is unaffected.

The simulation is repeated for System (13) where the nonlinear stiffness is taken into account (i.e. $\gamma > 0$). Figure 4 shows the effects of linear damping with the presence of nonlinear stiffness. The contrast of the effects of linear and nonlinear viscous damping can be observed by comparing Figure 4 with Figures 5 and 6, where the cubic viscous damping constant $\xi_2$ takes the values 0.2, 0.4 and 0.6 for $\gamma = 0.1$ and $\gamma = 0.2$ respectively. Similar to the case with pure linear stiffness, the cubic viscous damping again modifies the resonant region without causing detrimental effects in the non-resonant regions. It is clear that the increase of $\xi_1$ leads to an increase of $T_1(\Omega)$ over the high frequency range whereas the increase of $\xi_2$ does not. Thus, nonlinear viscous damping has a significant advantage over linear viscous damping on vibration isolation even with the presence of nonlinear stiffness. These observations are summarised by the first two conclusions of Proposition 1.

Nonlinear viscous damping may also address the well-known jump-up and jump-down phenomena of systems with nonlinear stiffness. To ensure stability, jump avoidance should be an important feature of a vibration isolator. The study by Ravindra and Mallik [18] found that the jump phenomena could be eliminated by linear viscous damping. With pure linear viscous damping, the simulation results in Figure 4 shows a jump occurring at $\Omega \approx 1.4$ when $\xi_1 = 0.1$ for $\gamma = 0.2$ and $\xi_2 = 0$ but the jump no long exists when the level of linear damping increases to $\xi_1 = 0.2$. The trade-off of applying linear damping to remove the jump phenomena is the adverse effects on the transmissibility over the high frequency range. This problem can be overcome by employing nonlinear viscous damping as discussed above. In Figures 5 and 6, the jumps disappear when $\xi_2$ increases from 0 to 0.2 while the shape of the force transmissibility curve remains unchanged for $\Omega \ll 1$ and $\Omega \gg 1$. This is the conclusion (iii) of Proposition 1.

Under the excitation of a sinusoidal input force, the output of an sdof system with nonlinear stiffness exhibits some harmonics. To achieve a good level of isolation, these harmonics, which are transmitted to the base, should be minimised. The spectrum of the second output of System (13) contains a strong component at the excitation frequency $\Omega$ plus the higher harmonics at $n\Omega$, where $n = 3, 5, 7, \cdots$. The effects of the fifth and higher harmonics are neglected as their magnitudes are small. The simulation results of $T_3(\Omega)$, the third harmonics, are illustrated in Figures 7 and 8. Consider the case when $\gamma = 0.2$ and $\xi_1 = 0.1$, two peaks, one at $\Omega \approx 0.4$ and another at $\Omega \approx 1.1$, are observed in Figure 7. The magnitudes of both peaks decrease as the value of nonlinear viscous damping increases. This is the conclusion of Remark 1. While $T_1(\Omega)$ measures the force transmissibility at the fundamental frequency, $T_3(\Omega)$ indicates the level of output force at 3Ω. The sum of $T_1(\Omega)$ and $T_3(\Omega)$ (and the higher harmonics terms) measures the overall energy transmissibility. Nonlinear damping can reduce the peaks occurring in both $T_1(\Omega)$ and $T_3(\Omega)$ so it can also remove energy at frequencies $\Omega \approx 1$ from an sdof system with nonlinear stiffness effectively.

The effects of linear damping on the third harmonics $T_3(\Omega)$ are included in Figure 8 for completeness. The results suggest that linear damping reduces $T_3(\Omega)$ over the whole frequency range, as opposed to just the $\Omega \approx 1$ region in Figure 7. This means that linear damping is better at suppressing the higher harmonics than nonlinear damping. However, when the total energy transmitted is considered, an increase in $\xi_2$ leads to a far greater rise in $T_1(\Omega)$ than the fall in $T_3(\Omega)$ for $\Omega \gg 1$. In the nonlinear damping case, $T_3(\Omega)$ rises from 0.003 (-52 dB) to 0.008 (-42 dB) when $\xi_2$ increases from 0.2 to 0.6 at $\Omega = 3$. This increase is very small in absolute terms. Nonlinear damping therefore remains the preferred choice over linear damping on a vibration isolation system with nonlinear stiffness.

## V. Conclusions

A vibration isolation system with nonlinear stiffness and linear viscous damping has been studied by many researchers. The force transmitted contains harmonics of the excitation frequency. The jump-up and jump-down phenomena occurs when the level of linear damping is small. This current study shows that the overall performance of vibration isolation is enhanced by the introduction of nonlinear viscous damping based on an sdof model described in Section II . The simulation results reveal important features of nonlinear viscous damping on a Duffing-type system outlined in Section III. The nonlinear damping parameter can eliminate the jump phenomena and reduce the third harmonics of the transmitted force when the excitation frequency is close to the resonant frequency. These may also be achieved by linear viscous damping but the nonlinear

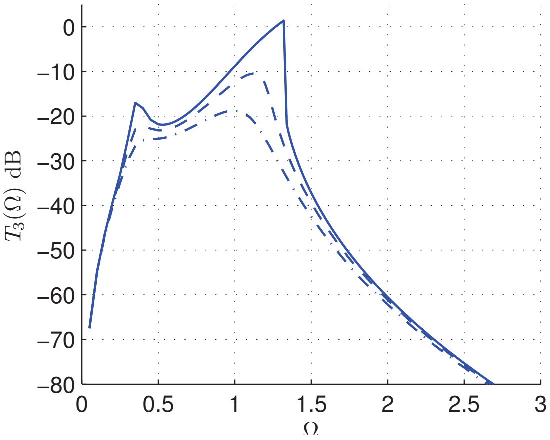

Fig. 8. The third harmonic of the force transmissibility of System (2) with nonlinear stiffness and linear viscous damping, where $\gamma = 0.1$ and $\xi_2 = 0$. Solid: $\xi_1 = 0.2$; Dashed: $\xi_1 = 0.4$; Dot-dashed: $\xi_1 = 0.6$.

damping parameter has a major additional advantage - it lowers the force transmissibility over the frequencies range around the resonant region while keeping the high frequency range unaffected. These features bring significant benefits to passive vibration isolation when nonlinear stiffness is present.

Theoretical analyses including a rigorous proof for Proposition 1 using the OFRF approach and the harmonic balance method will be provided in a later publication. Further studies will focus on the practical applications of this concept on different engineering designs. There are some recent research results on achieving nonlinear viscous damping by controlling the output of Magnetorheological dampers [28]–[30]. The authors will continue to explore this idea and apply the concept of nonlinear viscous damping to areas such as car suspension control and shock absortion for structures.

# Stabilisation of Multi-Input Nonlinear Systems Using Associated Angular Approach

Zahra Sangelaji
Department of Engineering Systems
University of Greenwich
UK
Email: z.sangelaji@greenwich.ac.uk

***Abstract*—In this paper the stabilisation of multi-input nonlinear systems is studied using the associated angular approach. In this method, a nonlinear system is converted into two associated subsystems, the so-called radial and spherical subsystems. For a single input nonlinear system, the control is designed using the one dimensional radial system to stabilise the radial and consequently the original nonlinear system. For multi-input systems, the control is also designed based on the radial subsystem, however, the method is not straightforward in comparison with single input systems. The control law includes a weighting function which is determined based on the system performance and control action. Some examples are presented to illustrate the effect of various scenarios of using the proposed method.**

## I. Introduction

In recent years, various methods have been developed to design a control for many classes of nonlinear systems including linearisation [1], optimal control [2], [3], $H_\infty$ control [4], [5], sliding mode control (SMC) [6] using quantised feedback [7] and adaptive control [8]-[9]. Output feedback control design is also a method for stabilisation of a broad class of nonlinear systems which has been studied in the last two decades. This method is mainly used when the system output is measurable and some states are not available or they are very difficult to measure [1]. Full state-feedback control design methods are utilized to stabilise a nonlinear system globally, particularly, when the states are measurable. These methods include sliding mode control [10], backstepping [11], zero dynamics based on high gain [12] and neural network [13]. However many established methods only guarantee the local stability [1] or ultimate boundedness of the states [14]. Sangelaji and Banks [15]-[16] have proposed associated angular approach for the global stabilisation of a general class of single-input nonlinear systems by using the angular form. In this method, the system is converted into two nonlinear subsystems. The trajectories of a subsystem which move on a sphere is termed the spherical subsystem and the other, a scalar nonlinear system is called the radial subsystem. The method straightforwardly yields a controller when there is no singularity except the origin in the input map function. For single-input systems, the control law is generally simple for many cases and the method is applicable to a large class of nonlinear systems. Whenever the input map of the radial subsystem is zero, the radial control is not definable. In this case, some mild conditions are proposed to guarantee the system stability [17] or the radial control or control design method should be modified such that the designed control is definable everywhere within the operating region and also stabilises the system. The radial control can be continuous or discontinuous depending on the structure of the input map. The method was originally established for single input nonlinear systems [15], [16]. In this paper the method is extended to multi-input nonlinear systems which are not straightforward, because the control can not be driven using the associated angular subsystems as proposed for single input systems. The proposed control stablises the multi-input nonlinear system. The presented method can be applied to any nonlinear system while most of the existing methods are applicable to particular classes of nonlinear systems. The drawback of the angular method is the singularity points in which the control is not definable. Similar methods as established for single input nonlinear systems are required to remove the singularities.

This paper is organised as follows: In Section II the associated angular method is studied. In Section III the multi-input system is presented. In Section IV, the special cases of the design weighting matrix, are considered. Examples illustrating the control design process are presented in Section V. Finally conclusions are presented in Section VI.

## II. Associated angular method for single input nonlinear systems

Consider the nonlinear system:

$$\dot{x} = A(x) + B(x)u \tag{1}$$

where $x \in \mathbb{R}^n$ is the state, $u$ is the scalar control, $A(x) \in \mathbb{R}^n$ and $B(x) \in \mathbb{R}^n$.

Let $\mathbb{S}^n \subseteq \mathbb{R}^n$ be the unit $n$-ball, i.e. $S^n = \{z \in \mathbb{R}^n : \|z\| = 1\}$ and $\mathbb{R}^+$ be the set of positive real numbers. The map

$$\varphi : \mathbb{R}^n - \{0\} \to \mathbb{R}^+ \times \mathbb{S}^n$$
$$x \to \big(\|x\|, \frac{x}{\|x\|}\big)$$

is a diffeomorphism from $\mathbb{R}^n - \{0\}$ onto $\mathbb{R}^+ \times \mathbb{S}^n$. Note that even as $x$ tends to zero, $\dfrac{x}{\|x\|}$ $(= z)$ is on the unit ball. The origin is removed from the domain of the function $\varphi$; otherwise the origin corresponds to infinity pair $(0, z)$ where $z$ is any point in $\mathbb{S}^n$. This obstacle can be removed if a unique pair say $(0, z_0)$ with $z_0 = (1, \ldots, 0)$ corresponds to the origin. Using diffeomorphism $\varphi$ the system (1) is converted into the associated radial and spherical subsystems as presented in the following Lemma.

**Lemma 1.** *The system (1) can be written in the form*

$$\dot{r} = \lambda_A + \lambda_B u \tag{2}$$

$$\dot{z} = \frac{1}{r}\big(\bar{A}(r,z) + \bar{B}(r,z)u\big) \tag{3}$$

*from which the following control is obtained*

$$u = -\frac{\lambda_A + \alpha r}{\lambda_B} \tag{4}$$

*where*

$$\bar{A}(r,z) = A(r,z) - z^T A(r,z) z$$

$$\bar{B}(r,z) = B(r,z) - z^T B(r,z) z$$

*Also* $\lambda_A = z^T A(r,z)$, $\lambda_B = z^T B(r,z)$, $r = \|x\|$, $z = \dfrac{x}{\|x\|}$ *and* $\alpha > 0$ *is a constant real number. Moreover, the control (4) stabilises the system (1).*

*Proof:* Since $r = \|x\|$ and $r^2 = x^T x$,

$$2r\dot{r} = 2x^T \dot{x} \tag{5}$$

Therefore

$$r\dot{r} = x^T\big(A(x) + B(x)u\big) \tag{6}$$

and

$$\dot{r} = \frac{x^T(A(x) + B(x)u)}{r} \tag{7}$$

Substituting $x = rz$ into (7) yields

$$\begin{aligned} \dot{r} &= z^T(A(r,z) + B(r,z)u) \\ &= \lambda_A + \lambda_B u \end{aligned} \tag{8}$$

On the other hand, using $z = \dfrac{x}{r}$ and (6) one can obtain

$$\begin{aligned} \dot{z} &= \frac{1}{r}\dot{x} - \frac{\dot{r}}{r^2}x \\ &= \frac{1}{r}\Big(A(r,z) + B(r,z)u\big) - \frac{1}{r^3}\big(x^T A(r,z) + x^T B(r,z)u\Big)x \\ &= \frac{1}{r}\big(\bar{A}(r,z) + \bar{B}(r,z)u\big) \end{aligned} \tag{9}$$

with

$$\bar{A}(r,z) = A(r,z) - z^T A(r,z) z$$

$$\bar{B}(r,z) = B(r,z) - z^T B(r,z) z$$

Select the control

$$u = -\frac{\lambda_A + \alpha r}{\lambda_B} \tag{10}$$

where $\alpha > 0$ is a real number. Then from (6)

$$r\dot{r} = -\alpha r^2 \tag{11}$$

So $\dot{r} = -\alpha r$ which guarantees the stability of the subsystem (2) and therefore, the system (1).

Note that the $z$-subsystem operates on the unit ball and $r$-subsystem is scalar. The real positive number $\alpha$ is a design parameter and only affects the degree of the stability of the system. In other words, for large values of $\alpha$ the state settling time is shorter in comparison with small values of $\alpha$. One way to ensure the accessibility of the control (10) is to consider some specific constrains on $\alpha$.

## III. Multi-input systems

The control design and stabilisation problem using the angular approach, which has been studied in section II is only applicable to single-input nonlinear systems and its extension to a general class of nonlinear system is not straightforward. The degree of nonlinearity in the system is not an important issue for using this method, while the most existing methods are applicable for specific nonlinear classes of nonlinear system in which the structure and the nature of nonlinearities affect the process of the control design. In this section, the angular method is extended to design an appropriate control for multi-input nonlinear systems and the stabilisation criteria are also presented.

Consider the multi-input nonlinear affine system

$$\dot{x} = A(x) + B(x)u \tag{12}$$

where $A(x) \in \mathbb{R}^{n\times n}$, $B(x) \in \mathbb{R}^{n\times m}$, $u \in \mathbb{R}^m$ and $x \in \mathbb{R}^n$. Let $r = \|x\|$ and $z = \frac{x}{\|x\|}$ then

$$\begin{aligned} r\dot{r} &= x^T \dot{x} \\ &= x^T A(x) + x^T B(x) u \end{aligned}$$

Therefore

$$\dot{r} = \frac{1}{r}(\lambda_A(x) + (\lambda_B(x)u) \tag{13}$$

$$\dot{z} = \frac{1}{r}\Big[\big(A - z^T A z\big) + \big(B - z^T B z\big)u\Big] \tag{14}$$

where $\lambda_A = x^T A(x)$, $\lambda_B = x^T B(x) \in \mathbb{R}^{1\times m}$ and $u \in \mathbb{R}^{m\times 1}$. Suppose that there is an $\alpha > 0$ such that $\dot{r} = -\alpha r$. The condition $\dot{r} = -\alpha r$ is a sufficient condition for stability of the system. Therefore the equation (13) implies

$$\lambda_B u = -\lambda_A(x) - \alpha r^2 \tag{15}$$

Since the $r$-subsystem is a one-dimensional system, the vector control input $u$ should be selected such that (15) is satisfied. Select the control

$$u = -\frac{(x^T A(x) + \alpha r^2) R B^T(x) x}{x^T B(x) R B^T(x) x} \tag{16}$$

where the weighting matrix $R$ is nonsingular. Substituting control (16) in (13) yields

$$\begin{aligned}\dot{r} &= \frac{1}{r}(x^TA(x) + x^TB(x)u)\\ &= \frac{1}{r}\left[x^TA(x) + x^TB(x)\frac{(-x^TA(x) - \alpha r^2)RB^T(x)x}{x^TB(x)RB^T(x)x}\right]\\ &= \frac{1}{r}(x^TA(x) + \frac{(-x^TA(x) - \alpha r^2)x^TB(x)RB^T(x)x}{x^TB(x)RB^T(x)x})\\ &= \frac{1}{r}(x^TA(x) - x^TA(x) - \alpha r^2)\\ &= -\alpha r\end{aligned}$$

Therefore, if $x^TBRB^Tx \neq 0$ the control (16) stabilises the system (12). When $x^TBRB^Tx = 0$ the control (16) should be modified. The methods in [16] for removing the singularities, i.e. for points belong to the set

$$\Pi = \{x \in \mathbb{R}^n : x^TBRB^Tx = 0\}$$

may straightforwardly be extended to the nonlinear system (12).

**Remark 1.** *When $m = 1$, the system (12) is a single input system. In this case, $B^T(x)x \in \mathbb{R}$ and $R \in \mathbb{R}$. If $B^T(x)x \neq 0$ the control (16) coincides with the control 10*

$$u = -\frac{x^TA(x) + \alpha r^2}{x^TB(x)}$$

## IV. Selection of the weighting matrix $R$

The control (16) depends on the weighting matrix $R$ and can be selected based on desired system performance and control action. Various selection of the weighting matrix $R$ in (16) yields various alternative controls. However, for any selection of $R$, the control (16) stabilises the system. Consider the following cases:

(*i*) Let $R = \beta I_m \in \mathbb{R}^{m\times m}$ where $\beta > 0$. Then

$$u = -\frac{(\lambda_A(x) + \alpha r^2)B^T(x)x}{x^TB(x)B^T(x)x} \tag{17}$$

or

$$u = -\frac{x^T(A(x) + \alpha x)B^T(x)x}{x^TB(x)B^T(x)x}$$

Therefore, for any $\beta > 0$ the selection of $R = \beta I$ does not yield different control law. In fact, any $\beta$ result in the same control as is given by (17).

(*ii*) Assume that $B$ is full rank. Select $R = (B^TB)^{-1}$. The control (16) is now in the following form

$$u = -\frac{(\lambda_A(x) + \alpha r^2)(B^TB)^{-1}B^Tx}{x^TB(B^TB)^{-1}B^Tx} \tag{18}$$

or

$$u = -\frac{x^T(A + \alpha x)(B^TB)^{-1}B^Tx}{x^TB(B^TB)^{-1}B^Tx}$$

Note that usually $R$ is considered a symmetric positive-definite matrix. However, the weighting matrix $R$ may be considered only as a nonsingular matrix. Control (18) when $R$ is nonsingular matrix guarantees the stability of the multi-input system (12).

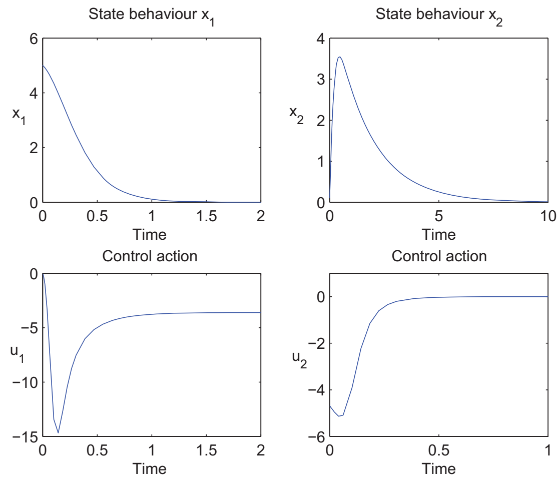

Fig. 1. Responses of the multi-input system using the radial control (16)

## V. Examples

In this section two examples are presented to show the various scenarios of design of an angular controller. In the first example, the control is straightforwardly obtained as there is no singularities (except the origin), if the parameters are appropriately selected. The second example indicates the case when there are singularities. In this case a suitable condition is required.

### A. *Example 1*

Consider the system

$$\begin{aligned}\dot{x}_1 &= (-1 + x_1)x_1 + x_1u_2\\ \dot{x}_2 &= 4x_1 + 3x_2 + x_2u_1\end{aligned}$$

The state space representation of the nonlinear system is

$$\dot{x} = \begin{pmatrix} -1 + x_1 & 0 \\ 4 & 3 \end{pmatrix}\begin{pmatrix} x_1 \\ x_2 \end{pmatrix} + \begin{pmatrix} 0 & x_1 \\ x_2 & 0 \end{pmatrix}\begin{pmatrix} u_1 \\ u_2 \end{pmatrix} \tag{19}$$

For this system, $x^TAx$ and $B^Tx$ are given by

$$\begin{aligned}x^TAx &= x_1^2(-1 + x_1) + 4x_1x_2 + 3x_2^2\\ B^Tx &= \begin{pmatrix} x_2^2 \\ x_1^2 \end{pmatrix}\end{aligned}$$

The control (17) with $R = I_2$ is

$$\begin{aligned}u &= \begin{bmatrix} u_1 \\ u_2 \end{bmatrix}\\ &= -\frac{x_1^2(-1 + x_1) + 4x_1x_2 + 3x_2^2 + \alpha(x_1^2 + x_2^2)}{x_2^4 + x_1^4}\begin{bmatrix} x_2^2 \\ x_1^2 \end{bmatrix}\end{aligned}$$

The simulation results are shown in Figure 2 for $\alpha = 0.3$.

Now consider

$$R = \begin{pmatrix} \gamma & 0 \\ 0 & \beta \end{pmatrix}$$

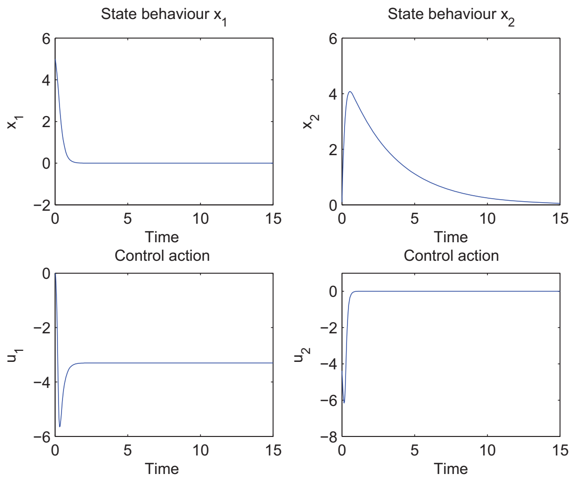

Fig. 2. Responses of the multi-input system using the radial control (17).

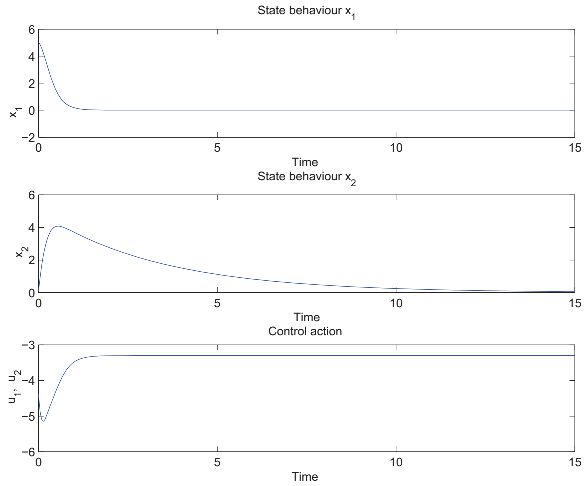

Fig. 3. Responses of the multi-input system using the radial control (18).

where $\gamma \neq \beta$ are positive numbers. Then

$$RB^T x = \begin{pmatrix} \gamma x_2^2 \\ \beta x_1^2 \end{pmatrix}$$

The control (16) is now in the following form

$$\begin{aligned} u &= \begin{pmatrix} u_1 \\ u_2 \end{pmatrix} \\ &= -\frac{x_1^2(-1+x_1)+4x_1x_2+3x_2^2+\alpha(x_1^2+x_2^2)}{\gamma x_2^4+\beta x_1^4}\begin{pmatrix} \gamma x_2^2 \\ \beta x_1^2 \end{pmatrix} \end{aligned}$$

If the weighting matrix $R$ is selected such that $\alpha\beta < 0$. Then the control (20) is not defined for all $x$ satisfying $\gamma x_2^4 + \beta x_1^4 = 0$ and therefore the number of singular points are infinite, whilst if $\alpha\beta > 0$ the control (20) is definable for all $x \in \mathbb{R}^n - \{0\}$. Thus, the selection of $R$ is significantly important for designing multi-input nonlinear systems. This example shows that a suitable selection of R is a way for removing the singularities. The simulation results are depicted in Figure 1. The values for $\alpha = 0.3$, $\gamma = 6$, $\beta = 0.3$ and initial conditions $x_0 = [5, 0.1]$ are considered for simulation.

In this example, $B$ is full rank for all $x_1 \neq 0$ and $x_2 \neq 0$. Therefore, $R$ can be selected as $R = (B^TB)^{-1}$. Therefore,

$$B^TB = \begin{pmatrix} x_2^2 & 0 \\ 0 & x_1^2 \end{pmatrix}, \quad (B^TB)^{-1} = \begin{pmatrix} \frac{1}{x_2^2} & 0 \\ 0 & \frac{1}{x_1^2} \end{pmatrix}$$

and

$$x^TAx = x_1^2(-1+x_1)+4x_1x_2+3x_2^2$$
$$x^TB(B^TB)^{-1}B^Tx = x_2^2 + x_1^2$$

Since for $(x_1, x_2) \neq (0,0)$, $x^TB(B^TB)^{-1}B^Tx \neq 0$, the control is defined for all $(x_1, x_2) \neq 0$ and in this case both control laws $u_1$ and $u_2$ are the same

$$u_1 = u_2 = -\frac{x_1^2(-1+x_1)+4x_1x_2+3x_2^2+\alpha(x_1^2+x_2^2)}{x_1^2+x_2^2}$$

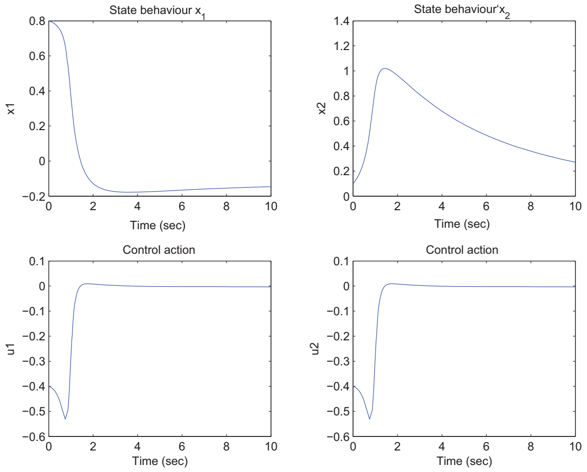

Fig. 4. Responses of the multi-input system using the radial control (20) and $\alpha = 0.4$.

Figure 3 shows the simulation results for $\alpha = 0.3$. This example illustrates that different selections of $R$ yield various controls. When $R = (B^TB)^{-1}$ the two control inputs $u_1$ and $u_2$ are the same, whilst other choice of $R$ presents a control vector with different components. Therefore, based upon the desired system performance and response, the weighting function may be selected.

### B. Example 2

Consider the system

$$\dot{x}_1 = x_2 + x_1u_1 - x_2u_2$$
$$\dot{x}_2 = x_1x_2 - x_2u_1 + x_1u_2$$

The system can be written as

$$\dot{x} = \begin{pmatrix} 0 & 1 \\ x_2 & 0 \end{pmatrix}\begin{pmatrix} x_1 \\ x_2 \end{pmatrix} + \begin{pmatrix} x_1 & -x_2 \\ -x_2 & x_1 \end{pmatrix}\begin{pmatrix} u_1 \\ u_2 \end{pmatrix}$$

For this example

$$B^T x = \begin{pmatrix} x_1^2 - x_2^2 \\ 0 \end{pmatrix}$$

$$B^T B = \begin{pmatrix} x_1^2 + x_2^2 & -2x_1x_2 \\ -2x_1x_2 & x_1^2 + x_2^2 \end{pmatrix}$$

and

$$(B^T B)^{-1} = \frac{1}{(x_1^2 - x_2^2)^2} \begin{pmatrix} x_1^2 + x_2^2 & 2x_1x_2 \\ 2x_1x_2 & x_1^2 + x_2^2 \end{pmatrix}$$

Therefore,

$$x^T A x = x_1 x_2^2 + x_1 x_2$$

$$(B^T B)^{-1} B^T x = \frac{1}{x_1^2 - x_2^2} \begin{pmatrix} x_1^2 + x_2^2 \\ 2x_1x_2 \end{pmatrix}$$

$$x^T B (B^T B)^{-1} B^T x = x_1^2 + x_2^2$$

Assume that for all nonzero $x_1$ and $x_2$, $x_1 \neq x_2$. Then the control is

$$u = -\frac{x_1x_2^2 + x_1x_2 + \alpha(x_1^2 + x_2^2)}{x_1^2 - x_2^2} \begin{pmatrix} 1 \\ \dfrac{2x_1x_2}{x_1^2 + x_2^2} \end{pmatrix} \tag{20}$$

The simulation results are shown in Figure 4.

Note that all angular methods proposed for single input systems can straightforwardly be extended to multi-input systems.

## VI. Conclusions

In this paper the control design using the angular approach for multi-input nonlinear systems have been addressed. The radial control law includes a nonsingular weighting matrix which yield various control laws whenever it is not selected as a multiplication of an identity matrix. The weighting matrix does not necessarily have to be a positive-definite, however it only needs to be a nonsingular matrix. A suitable selection of weighting matrix can prevent any singularities in the radial control law. The control (16) has been designed such that when the system is single-input, this control coincides with the control (10). In single-input case, the weighing matrix is not required. In fact, in this case the weighting matrix is only a number.

All methods for single input systems for removing the singularities which have been presented in [15] and [16] are required to be extended to the multi-input nonlinear systems. In particular, similar methods as that presented in [16] should be established for removing the singularities including modifying the control, imposing a sufficient condition on design parameters, using the weighting norm and dynamical radial method.

# Optimal Output Regulation of Minimum Phase Nonlinear Systems

Attaullah Y. Memon[†]

*Abstract*— **This paper studies the design of an optimal stabilizing controller for output regulation of minimum phase nonlinear systems in the Lyapunov redesign framework of our earlier work [6], and investigates the asymptotic robustness properties of the overall feedback design, given that the optimal stabilizing controller itself possesses strong robustness properties by construction. The motivation comes from the flexibility of incorporating any stabilizing controller within the proposed framework, and we seek for control design methods that yield stabilizing controllers with some additional desirable properties like optimality, disturbance rejection and robustness in the presence of matched uncertainties e.g. static nonlinearities, uncertain parameters and the unmodeled fast dynamics. We exploit the optimal control design methods developed by Kokotovic and his co-researchers [3], [4], [7] for nonlinear systems, where it is shown that in addition to achieving the asymptotic stability of the system and minimizing a cost functional, the optimal feedback control guarantees stability margins which characterize the robustness properties.**

## I. INTRODUCTION

In this paper, the problem of optimal output regulation of minimum-phase nonlinear systems is considered. The output regulation problem deals with the design of a controller to make the output of a plant asymptotically track reference signals and reject disturbance signals, both produced by an autonomous external system called the *exosystem*. In our earlier work [6], we used the Lyapunov redesign and saturated high-gain feedback approach to design the stabilizing compensator, and included a conditional servocompensator by modifying the original controller that yields asymptotic error regulation without degrading the transient performance. One special feature of the Lyapunov redesign framework of [6] is that it allows us to start with *any* stabilizing controller and then include a conditional servocompensator by modifying the original controller to achieve the desired control objectives. This flexibility of incorporating any stabilizing controller within our framework motivates us to seek for control design methods that yield stabilizing controllers with some additional desirable properties like optimality, disturbance rejection and robustness in the presence of matched uncertainties e.g. static nonlinearities, uncertain parameters and the unmodeled fast dynamics. Herein, we take into consideration the optimal control design methods developed by Kokotovic and his co-researchers [3], [4], [7] for the stabilization of nonlinear systems, where it is shown that in addition to achieving the asymptotic stability of the system and minimizing a cost functional, the optimal feedback control guarantees stability margins which characterize the robustness properties. A major handicap in designing such controller is that it requires the solution of the complicated Hamilton-Jacobi-Bellman (HJB) partial differential equations. Kokotovic and co-researchers introduced an inverse approach [7] to the optimal control design for nonlinear systems, which abrogates the requirement of solving the HJB equations in order to design optimal feedback controllers. We incorporate an optimal stabilizing controller in the Lyapunov redesign framework of [6], to investigate the problem of output regulation of nonlinear systems using conditional servocompensators. We concentrate on the asymptotic robustness properties of the overall Lyapunov-redesign + conditional servocompensator framework, given that the optimal stabilizing controller itself possesses strong robustness properties (e.g. robustness to matched uncertainties and unknown disturbances) by design.

The rest of the paper is organized as follows. We present a brief review of Lyapunov redesign framework of [6] in the next section. Section III introduces the definitions of stability margins for nonlinear systems which are due to [7], and can be considered as the starting point of control design in this paper. Section IV states the problem formulation and assumptions, and is followed by the closed-loop analysis in Section V. A simple example is worked out in Section VI. Finally, Section VII draws the conclusions.

## II. OUTPUT REGULATION USING CONDITIONAL SERVOCOMPENSATORS

In this section we briefly review the Lyapunov redesign approach to output regulation problem using conditional servocompensators [6]. Consider the SISO nonlinear system

$$\begin{aligned} \dot{\xi} &= \tilde{f}(\xi, w) + \tilde{g}(\xi, w)u \\ e &= \tilde{h}(\xi, w) \end{aligned} \tag{1}$$

where $\xi \in R^n$ is the state, $u$ is the control input, $e$ is the regulation error and the functions $\tilde{f}$, $\tilde{g}$ and $\tilde{h}$ are sufficiently smooth. The plant is subjected to a vector of *exogenous* input variables, which are generated by the known exosystem

$$\dot{w} = S_0 w \tag{2}$$

where $S_0$ has distinct eigenvalues on the imaginary axis and $w(t)$ belongs to a compact set $\mathcal{W}$. Suppose that for all $w \in \mathcal{W}$, there exist a continuously differentiable mapping $\xi = \pi(w)$, with $\pi(0) = 0$, and a continuous mapping $\chi(w)$, generated by the internal model

$$\frac{\partial \tau(w)}{\partial w} S_0 w = S\tau(w), \qquad \chi(w) = \Gamma\tau(w)$$

[†] The author is with the Faculty of Electronics & Power Engineering, PN Engineering College, National University of Sciences & Technology, Karachi, Pakistan. (E-mail: attaullah@pnec.edu.pk)

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

where $S$ has distinct eigenvalues on the imaginary axis, such that

$$\begin{aligned} \frac{\partial \pi(w)}{\partial w} S_0 w &= \tilde{f}(\pi, w) + \tilde{g}(\pi, w)\chi(w) \\ 0 &= h(\pi, w) \end{aligned} \tag{3}$$

With the change of variables $x = \xi - \pi$, the system (1) can be represented by

$$\dot{x} = f(x, w) + g(x, w)[u - \chi(w)] \tag{4}$$

The system (4) is in the form where the state feedback regulation problem can be formulated as a state feedback stabilization problem by treating $\chi(w)$ as a matched uncertainty. Suppose there is a locally Lipschitz function $\psi(x, w)$, with $\psi(0, w) = 0$, and a continuously differentiable Lyapunov function $V(x, w)$, possibly unknown, such that

$$\alpha_1(\|x\|) \leq V(x, w) \leq \alpha_2(\|x\|) \tag{5}$$

$$\frac{\partial V}{\partial w} S_0 w + \frac{\partial V}{\partial x}[f(x, w) + g(x, w)\psi(x, w)] \leq -W(x) \tag{6}$$

$\forall x \in \mathcal{X} \subset R^n$, $w \in \mathcal{W}$, where $W(x)$ is a continuous positive definite function and $\alpha_1$ and $\alpha_2$ are class $\mathcal{K}$ functions. The system (4) can be re-written as

$$\begin{aligned} \dot{x} &= f(x, w) + g(x, w)\psi(x, w) \\ &\quad + g(x, w)u - g(x, w)[\chi(w) + \psi(x, w)] \end{aligned} \tag{7}$$

Let $\Omega = \{V(w, x) \leq c_1\} \subset \mathcal{X}$ be a compact set for some $c_1 > 0$ and $\delta(x)$ be a function such that

$$\|\chi(w) + \psi(x, w)\| \leq \delta(x) \qquad \forall x \in \Omega, \quad \forall w \in \mathcal{W} \tag{8}$$

Suppose $(\partial V / \partial x) g(x, w)$ can be expressed as

$$(\partial V / \partial x) g(x, w) = \upsilon(x) H(x, w) \tag{9}$$

where $\upsilon(x)$ is a known, locally Lipschitz function, with $\upsilon(0) = 0$, and $H(x, w)$ is a, possibly unknown, function such that $0 < \theta \leq |H(x, w)| \leq k$, $\forall x \in \Omega$, $\forall w \in \mathcal{W}$.

A *conditional servocompensator* [6] is introduced via the saturated high-gain feedback controller

$$u = -\alpha(x) sat\,(s/\mu) \tag{10}$$

where $s = \upsilon(x) + K_1\sigma$, the saturation function is defined as

$$sat\,(s/\mu) = \begin{cases} \frac{s}{|s|} & \text{if} \quad |s| \geq \mu \\ \frac{s}{\mu} & \text{if} \quad |s| \leq \mu \end{cases} \tag{11}$$

and $\sigma$ is the output of the conditional servocompensator

$$\dot{\sigma} = (S - JK_1)\sigma + \mu J sat\left(\frac{s}{\mu}\right) \tag{12}$$

with $\mu > 0$ being the width of the boundary layer. The pair $(S, J)$ is controllable and $K_1$ is chosen such that $S - JK_1$ is Hurwitz. The function $\alpha(x)$ is chosen to satisfy

$$\alpha(x) \geq \frac{k}{\theta}\delta(x) + \alpha_0, \quad \alpha_0 > 0 \tag{13}$$

It is shown in [6] that if $\sigma(0)$ is $O(\mu)$, the state $\sigma(t)$ of the conditional servocompensator (12) will always be $O(\mu)$.

The analysis in [6] shows that, for sufficiently small $\mu$, every trajectory of the closed-loop system (2), (4), (10) and (12) asymptotically approaches a disturbance-dependant manifold of the form $\{x = 0, \sigma = \bar{\sigma}\}$, on which the regulation error is zero. The state feedback design is extended to output feedback for a class of minimum-phase, input-output linearizable systems. For this class of systems, the state feedback control can be designed as a partial state feedback law that does not use the states of the internal dynamics. A reduced-order high-gain observer is used to estimate the states of the linearizable part of the system, which are derivatives of the output. The output feedback controller, obtained by replacing the states by their estimates, recovers the transient and asymptotic properties of the state feedback controller. The performance recovery is shown using the separation principle of [1] and [2].

## III. Inverse optimal control design [7]

It is well known that the optimal control as a design tool guarantees robustness and stability margins. This design approach deals with the problem of finding a feedback control $u(x)$ for the nonlinear system

$$\dot{x} = f(x) + g(x)u \tag{14}$$

with the objective that the $u(x)$ achieves asymptotic stability of the equilibrium $x = 0$ and minimizes the cost functional

$$J = \int_0^\infty (l(x) + u^T R(x) u) dt \tag{15}$$

where $l(x) \geq 0$ and $R(x) > 0$ for all $x$. A direct determination of the optimal feedback law $u(x)$ for nonlinear optimal control problems requires us to solve the Hamilton-Jacobi-Bellman (HJB) partial differential equations. On the other hand, the robustness properties achieved as a result of the optimality do not depend on a particular choice of functions $l(x) \geq 0$ and $R(x) > 0$. This motivated Freeman and Kokotovic' [3], [4] to pursue the development of the design methods that solve the inverse problem of optimal stabilization. In the inverse approach, a stabilizing feedback is designed first and then shown to be optimal for the cost functional (15). The problem is *inverse* since the functions $l(x) \geq 0$ and $R(x) > 0$ are determined through the stabilizing feedback design process rather than being chosen by the designer.

### *A. Design of the Stabilizing Inverse Optimal Control*

A stabilizing control law $u(x)$ solves an inverse optimal control problem for the system (14) if it can be expressed as

$$u = -k(x) = -\frac{1}{2} R^{-1}(x)(L_g V(x))^T, \; R(x) > 0, \tag{16}$$

where $V(x)$ is a positive semidefinite function (to be called a Control Lyapunov Function (CLF), hereafter) and satisfies the following condition, with $u = -\frac{1}{2}k(x)$,

$$\dot{V} = L_f V(x) - \frac{1}{2} L_g V(x) k(x) \leq 0 \tag{17}$$

With the choice of $l(x) \triangleq -L_f V(x) + \frac{1}{2} L_g V(x) k(x) \geq 0$, $V(x)$ is a solution of the HJB equation

$$l(x) + L_f V(x) - \frac{1}{4}(L_g V(x)) R^{-1}(x)(L_g V(x))^T = 0 \quad (18)$$

Therefore, the control law $u(x)$ is an inverse optimal stabilizing control law for the system (14) if it achieves the asymptotic stability of $x = 0$ for the system (14) and is of the form (16) with $V(x)$ that satisfies the condition (17).

The importance of the existence of a CLF in the framework of inverse optimal control design is that, when a CLF is known, an inverse optimal stabilizing control law can be given by Sontag's formula [8]

$$u_s(x) = \begin{cases} -\Big(c_0 + \frac{a_x + \sqrt{{a_x}^2 + ({b_x}^T b_x)^2}}{{b_x}^T b_x}\Big) b_x & , \ b_x \neq 0 \\ 0 & , \ b_x = 0 \end{cases} \quad (19)$$

where $a_x = L_f V(x)$, $b_x = (L_g V(x))^T$, and $c_0$ is a positive constant. It is shown in [7] that the control law (19) is Lipschitz continuous at $x = 0$, if $V(x)$ is a CLF that satisfies the *small control property*[1] for the nonlinear system (14), and is optimal stabilizing for the cost functional

$$J = \int_0^\infty (\frac{1}{2} p(x) b^T(x) b(x) + \frac{1}{2p(x)} u^T R(x) u) dt \quad (20)$$

where

$$p(x) = \begin{cases} c_0 + \frac{a_x + \sqrt{{a_x}^2 + ({b_x}^T b_x)^2}}{{b_x}^T b_x} & , \ b_x \neq 0 \\ c_0 & , \ b_x = 0 \end{cases} \quad (21)$$

An important consequence of the optimality of the control law (19) is that it has a sector stability margin $(\frac{1}{2}, \infty)$, and, under certain assumptions, it achieves a disk stability margin $D(\frac{1}{2})$. These stability margins, which are defined below, provide guaranteed robustness in the presence of matched uncertainties e.g. static nonlinearities, uncertain parameters and the unmodeled fast dynamics.

### B. Stability Margins for Nonlinear Systems

The basic robustness properties of nonlinear feedback systems can be characterized in terms of stability margins, e.g. *gain*, *sector* and *disk stability margins*. Consider the nonlinear feedback system shown in Figure.1 where $u$ and $y$ are of the same dimension and $\Delta$ represents modeling uncertainty at the input side. Under the nominal conditions, the feedback loop consists of the (nominal) nonlinear plant $H$ with the nominal control $u = -k(x) = -y$, and $\Delta$ is identity. The nominal system is denoted by $(H, k)$ and the perturbed system by $(H, k, \Delta)$. The input uncertainties can be static or dynamic. The two most common static uncertainties are *unknown static nonlinearity* and *unknown parameters*. The dynamic uncertainty arises due to unmodeled fast dynamics of the system. The following definitions are due to [7].

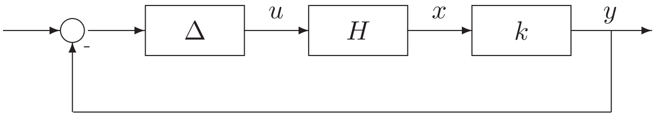

Fig. 1. Nonlinear Feedback Loop with the Control Law $u = k(x)$ and an Input Uncertainty $\Delta$

**Definition 1.** *(Gain Margin) The nonlinear system $(H, k)$ is said to have a gain margin $(\alpha, \beta)$ if the perturbed closed-loop system $(H, k, \Delta)$ is globally asymptotically stable for any $\Delta$ which is of the form $diag\{\kappa_1, \cdots, \kappa_m\}$ with constants $\kappa_i \in (\alpha, \beta), i = 1, \cdots, m$.*

**Definition 2.** *(Sector Margin) The nonlinear system $(H, k)$ is said to have a sector margin $(\alpha, \beta)$ if the perturbed closed-loop system $(H, k, \Delta)$ is globally asymptotically stable for any $\Delta$ which is of the form $diag\{\varphi_1(\cdot), \cdots, \varphi_m(\cdot)\}$ where $\varphi_i(\cdot)$'s are locally Lipschitz static nonlinearities which belong to the sector $(\alpha, \beta)$.*

**Definition 3.** *(Disc Margin) The nonlinear system $(H, k)$ is said to have a disc margin $D(\alpha)$ if the perturbed closed-loop system $(H, k, \Delta)$ is globally asymptotically stable for any $\Delta$ which is globally asymptotically stable and input feedforward passive [7], with a radially unbounded storage function.*

It follows from the definition of disc margin that a nonlinear system having a disc margin $D(\alpha)$ also has gain and sector margins $(\alpha, \infty)$. A disk margin guards against two types of input uncertainties: static nonlinearities and dynamic uncertainties arising from unmodeled fast dynamics of the system.

## IV. PROBLEM FORMULATION AND CONTROL DESIGN

Consider the single-input single-output minimum-phase nonlinear system

$$\begin{aligned} \dot{\zeta} &= \tilde{f}(\zeta, w) + \tilde{g}(\zeta, w)\varphi(u) \\ e &= \tilde{h}(\zeta, w) \end{aligned} \quad (22)$$

where $\zeta \in R^n$ is the state, $u$ is the control input, and $e$ denotes the regulation error. The nonlinear function $\varphi(u)$ belongs to a sector $[\theta_1, \theta_2]$ and satisfies the inequality

$$\theta_1 u^2 \leq u\varphi(u) \leq \theta_2 u^2, \quad 0 \leq \theta_1 \leq \theta_2 \quad (23)$$

The plant is subjected to a set of *exogenous* input variables $w$ that belong to a compact set $\mathcal{W} \in R^w$, which include unknown disturbances to be rejected and references to be tracked. The functions $\tilde{f}$, $\tilde{g}$ and $\tilde{h}$ are sufficiently smooth in $\zeta$ on a domain $\Xi \subset R^n$ and are continuous in $w$ for $w \in \mathcal{W}$. Our goal is to design a controller to asymptotically regulate $e$ to zero.

[1] A nonlinear system $\dot{x} = f(x, u)$, with a known Lyapunov function $V(x)$, is said to satisfy the *small control property* if for every $\epsilon > 0$ there exists a $\delta > 0$ such that for all $\|x\| < \delta$ there exists $u$ with $\|u\| < \epsilon$ so that $\dot{V}(x)$ is negative definite.

We now cast the given output regulation problem in the Lyapunov redesign framework of Section II. As described there, $\zeta = \pi(w)$ is a zero-error invariant manifold and $\chi(w)$ is the steady-state control that maintains the motion on this manifold, in the presence of any exogenous input $w$, which is generated by the exosystem (2). With the change of variables $x = \zeta - \pi(w)$, the system (22) can be represented by

$$\dot{x} = f(x,w) + g(x,w)[\varphi(u) - \chi(w)] \tag{24}$$

where $f(x,w) = \tilde{f}(x+\pi,w) - \tilde{f}(\pi,w) + [\tilde{g}(x+\pi,w) - \tilde{g}(\pi,w)]\chi(w)$ and $g(x,w) = \tilde{g}(x+\pi,w)$.

In what follows, we assume that an optimal stabilizing state feedback controller $\psi(x)$ is available for the nominal system

$$\dot{x} = f(x,w) + g(x,w)u \tag{25}$$

such that the origin of the nominal closed-loop system

$$\dot{x} = f(x,w) + g(x,w)\psi(x) \tag{26}$$

is uniformly asymptotically stable. It is shown in [7] that if $\psi(x)$ is an optimal stabilizing state feedback controller for the system (25) for a cost functional

$$J = \int_0^\infty (l(x) + u^T R(x)u)dt \tag{27}$$

with $l(x) \geq 0$ and $R(x) > 0$ for all $x$, then it achieves a sector margin $(\frac{1}{2},\infty)$. The optimal stabilizing feedback control $\psi(x)$ takes the form

$$\psi(x) = -\frac{1}{2}R^{-1}(x)(L_gV(x))^T,\ R(x) > 0, \tag{28}$$

where the *optimal value function* $V(x)$ is radially unbounded, and is such that the time-derivative of $V$ along the solutions of the closed-loop system (26) is

$$\dot{V} = L_fV(x) - \frac{1}{4}L_gV(x)R^{-1}(x)(L_gV(x))^T \leq 0 \tag{29}$$

As reviewed in Section III, we use the inverse design approach [7], in which a stabilizing feedback controller is designed first and then shown to be optimal for the cost functional (27). When $V(x)$ (called *Control Lyapunov Function*, hereafter) is known, an inverse optimal stabilizing feedback control $\psi(x)$ for the nominal system (25) can be given by Sontag's formula (19), that yields in a sector stability margin $(\frac{1}{2},\infty)$, and, if $R(x) = I$, it achieves a disk stability margin $D(\frac{1}{2})$.

**Assumption 1.** *There exists a smooth positive-definite, and radially unbounded function $V(x,w)$ for the system (25) that satisfies*

$$L_gV(x,w) = 0 \quad \Rightarrow L_fV(x,w) < 0, \quad \forall x \neq 0 \tag{30}$$

**Remark 1.** *Any Lyapunov function whose time-derivative can be rendered negative definite is a CLF. The importance of CLF concept in the framework of inverse optimality is that, when a CLF is known, an inverse optimal stabilizing control such as (19) can be designed, and the CLF becomes an optimal value function.*

It follows that, with a known $V$, the optimal feedback control $\psi(x)$ can robustly stabilize the system (25) in the presence of any sector-bounded nonlinearity $\varphi$ that belongs to a sector $[\theta_1,\theta_2]$. Our goal is to show that with the optimal feedback control $\psi(x)$ we can solve the problem of robust output regulation in the presence of sector nonlinearity $\varphi$. The results of [6] can not be directly applied since the nature of problem differs in that, the Equation (4) depends linearly on control, whereas in the current problem the control depends on a sector-bounded nonlinear function $\varphi$. Furthermore, with Assumption 1, Equations (5)-(6) can be written as

$$\alpha_1(\|x\|) \leq V(x,w) \leq \alpha_2(\|x\|) \tag{31}$$

$$\frac{\partial V}{\partial w}S_0w + \frac{\partial V}{\partial x}[f(x,w) + g(x,w)\varphi(\psi(x))] \leq -W(x) \tag{32}$$

$\forall x \in X \subset R^n$ and $\forall w \in \mathcal{W}$, where $\alpha_1$ and $\alpha_2$ are some class $\mathcal{K}$ functions, $W(x)$ is a continuous positive definite function, and $X$ is a given domain that contains the origin.

The system (24) can also be written as

$$\begin{aligned}\dot{x} \quad &= \quad f(x,w) + g(x,w)\varphi(\psi(x)) + g(x,w)\varphi(u)\\ &\quad\ - g(x,w)[\chi(w) + \varphi(\psi(x))]\end{aligned} \tag{33}$$

We use Lyapunov redesign to construct the saturated high-gain feedback controller to deal with the uncertain term $[\chi(w) + \varphi(\psi(x))]$. Let $\Omega = \{sup_{w\in\mathcal{W}}V(x,w) \leq c_1\} \subset X$, for some $c_1 > 0$, and $\delta(x)$ be a continuous function, independent of the sector-bounded nonlinearity $\varphi(\cdot)$, such that

$$\|\chi(w) + \varphi(\psi(x))\| \leq \delta(x), \quad \forall x \in \Omega,\ \forall w \in \mathcal{W} \tag{34}$$

For simplicity, with $H = 1$, $(\partial V/\partial x)g(x,w)$ as given in (9) can be expressed as

$$(\partial V/\partial x)g(x,w) = \upsilon(x), \quad \forall x \in \Omega,\ \forall w \in \mathcal{W} \tag{35}$$

where $\upsilon(x)$ is a known, locally Lipschitz function, with $\upsilon(0) = 0$. We introduce the conditional servocompensator via the saturated high-gain feedback controller

$$u = -\alpha(x)sat\,(s/\mu) \tag{36}$$

where $s = \upsilon(x) + K_1\sigma$, the continuous function $\alpha(x)$ is chosen such that

$$\alpha(x) \geq \delta(x) + \alpha_0, \quad \alpha_0 > 0 \tag{37}$$

the saturation function is defined as in (11) and $\sigma$ is output of the conditional servocompensator (12).

## V. CLOSED-LOOP ANALYSIS

We will now show that, for sufficiently small $\mu$, the set $\Phi = \Omega \times \left\{V_0(\sigma) \leq \mu^2c_2\right\}$ is a subset of the region of attraction, and for all initial conditions in $\Phi$, every trajectory of the closed-loop system

$$\begin{aligned}\dot{w} \quad &= \quad S_0w\\ \dot{x} \quad &= \quad f(x,w) + g(x,w)\varphi(\psi(x))\\ &\quad\ + g(x,w)\varphi\left(-\alpha(x)sat\,(s/\mu)\right)\\ &\quad\ - g(x,w)[\chi(w) + \varphi(\psi(x))]\\ \dot{\sigma} \quad &= \quad (S - JK_1)\sigma + \mu J sat\,(s/\mu)\end{aligned} \tag{38}$$

asymptotically approaches an invariant manifold on which the error is zero. The forthcoming analysis follows the outline of the analysis in [6], with various technical differences due to the nature of the problem under consideration. We start by showing that the set $\Phi$ is positively invariant and there is a class $\mathcal{K}$ function $\rho$ such that every trajectory in $\Phi$ enters the set $\Phi_\mu = \{\|x\| \leq \rho(\mu)\} \times \left\{V_0(\sigma) \leq \mu^2 c_2\right\}$ in finite time and stays thereafter. The derivative of $V(x, w)$ along the trajectories of the closed-loop system (38) satisfies

$$\begin{aligned}
\dot{V} &= \frac{\partial V}{\partial w} S_0 w + \frac{\partial V}{\partial x}[f(x,w) + g(x,w)\varphi(\psi(x))] \\
&\quad + \frac{\partial V}{\partial x} g(x,w)\varphi\left(-\alpha(x) sat\left(s/\mu\right)\right) \\
&\quad - \frac{\partial V}{\partial x} g(x,w)[\chi(w) + \varphi(\psi(x))] \\
&= \frac{\partial V}{\partial w} S_0 w + \frac{\partial V}{\partial x}[f(x,w) + g(x,w)\varphi(\psi(x))] \\
&\quad + \upsilon(x)\varphi\left(-\alpha(x) sat\left(s/\mu\right)\right) \\
&\quad - \upsilon(x)[\chi(w) + \varphi(\psi(x))] \\
&\leq -W(x) + [s - K_1\sigma]\varphi\left(-\alpha(x) sat\left(s/\mu\right)\right) \\
&\quad - [s - K_1\sigma][\chi(w) + \varphi(\psi(x))] \\
&= -W(x) + s\varphi\left(-\alpha(x) sat\left(s/\mu\right)\right) \\
&\quad - (K_1\sigma)\varphi\left(-\alpha(x) sat\left(s/\mu\right)\right) \\
&\quad - s[\chi(w) + \varphi(\psi(x))] + (K_1\sigma)[\chi(w) + \varphi(\psi(x))]
\end{aligned}$$

Inside $\Phi$, $\|\sigma\| \leq \mu\sqrt{c_2/\lambda_{min}(P_0)}$. Using this along with (23), (37) and (11), it can be shown that when $|s| \geq \mu$, we have [2]

$$\begin{aligned}
\dot{V} &\leq -W(x) - \theta_1\alpha(x)\left|s\right| + \theta_1\alpha(x)\left\|K_1\right\|\left\|\sigma\right\| \\
&\quad + \delta(x)\left|s\right| + \delta(x)\left\|K_1\right\|\left\|\sigma\right\|
\end{aligned}$$

$$\begin{aligned}
\dot{V} &\leq -W(x) - [\theta_1\alpha(x) - \delta(x)]\left|s\right| + [\theta_1\alpha(x) \\
&\quad + \delta(x)]\left\|K_1\right\|\left\|\sigma\right\| \\
&\leq -W(x) + \mu\gamma_1 \qquad (39)
\end{aligned}$$

where $\gamma_1 = \max_{x\in\Omega} k_0[\theta_1\alpha(x) + \delta(x)]$, in which the constant $k_0 = \|K_1\|\sqrt{c_2/\lambda_{min}(P_0)}$.

Similarly, when $|s| \leq \mu$, we have

$$\begin{aligned}
\dot{V} &\leq -W(x) - \theta_1\alpha(x)\frac{s^2}{\mu} + \theta_1\alpha(x)\left\|K_1\right\|\left\|\sigma\right\|\frac{s}{\mu} \\
&\quad + \delta(x)\left|s\right| + \delta(x)\left\|K_1\right\|\left\|\sigma\right\| \\
&\leq -W(x) + \mu\gamma_2 \qquad (40)
\end{aligned}$$

where $\gamma_2 = \max_{x\in\Omega}\ k_0\left[\theta_1\alpha(x) + \delta(x)(1 + 1/k_0)\right] \ \geq \gamma_1$. From (39) and (40),

$$\dot{V} \leq -W(x) + \mu\gamma_2, \quad \forall (x,\sigma) \in \Phi$$

Hence, from [5, Theorem 4.18], for sufficiently small $\mu$, $\Phi$ is positively invariant and all trajectories starting in $\Phi$ enter the positively invariant $\Phi_\mu$ in finite time and stay thereafter.

In the next step, we use $V_s = \frac{1}{2}s^2$, and Assumption 2, below, to show that the trajectories reach the boundary layer $\{|s| \leq \mu\}$ in finite time.

**Assumption 2.** $(\partial\upsilon/\partial x)g(x,w)$ *can be expressed as*

$$(\partial\upsilon/\partial x)g(x,w) = \beta(x), \quad k_p \leq |\beta(x)| \leq k_q, \quad k_q > k_p > 0$$

*for all* $x \in \{\|x\| \leq \rho(\mu)\}$ *and for all* $w \in \mathcal{W}$*. Furthermore,* $\alpha(0) \geq \left(\frac{k_q}{\theta_1 k_p}\right)\delta(0) + \alpha_0,\ \alpha_0 > 0$.

For $(x,\sigma) \in \Phi_\mu$

$$\begin{aligned}
s\dot{s} &= s\frac{\partial\upsilon}{\partial x}[f(x,w) + g(x,w)\varphi(\psi(x))] \\
&\quad + s\beta(x)\varphi\left(-\alpha(x) sat\left(s/\mu\right)\right) \\
&\quad - s\beta(x)[\chi(w) + \varphi(\psi(x))] + sK_1(S - JK_1)\sigma \\
&\quad + \mu s K_1 J sat\left(s/\mu\right)
\end{aligned}$$

When $|s| \geq \mu$, we have

$$\begin{aligned}
s\dot{s} &\leq -k_p\theta_1\alpha(x)\left|s\right| + k_q\left\|[\chi(w) + \varphi(\psi(x))]\right\|\left|s\right| \\
&\quad + \left\|\frac{\partial\upsilon}{\partial x}[f(x,w) + g(x,w)\varphi(\psi(x))]\right\|\left|s\right| \\
&\quad + \left\|\sigma\right\|\left\|K_1\right\|\left\|(S - JK_1)\right\| \\
&\quad + \mu\left\|K_1\right\|\left\|J\right\|\left|s\right|
\end{aligned}$$

Inside $\Phi_\mu$, $\|\sigma\| \leq \mu\sqrt{c_2/\lambda_{min}(P_0)}$. Also, the function $\frac{\partial\upsilon}{\partial x}[f(x,w) + g(x,w)\varphi(\psi(x))]$ is continuous such that $\frac{\partial\upsilon}{\partial x}[f(0,w) + g(0,w)\varphi(\psi(x)(0,w))] = 0$. Therefore, the norm $\left\|\frac{\partial\upsilon}{\partial x}[f(x,w) + g(x,w)\varphi(\psi(x))]\right\|$ together with the norms $\|\sigma\|\,\|K_1\|\,\|(S_J K_1)\|$, $\mu\|K_1\|\,\|J\|$, $\|\alpha(x) - \alpha(0)\|$, and $\|\delta(x) - \delta(0)\|$ can be bounded by a class $\mathcal{K}$ function $\rho_1(\mu)$. Hence,

$$\begin{aligned}
s\dot{s} &\leq -\theta_1 k_p\alpha(0)\left|s\right| + k_q\delta(0)\left|s\right| + \rho_1(\mu)\left|s\right| \\
\Rightarrow \quad \dot{V}_s &\leq -k_p\left[\theta_1\alpha_0 - \frac{\rho_1(\mu)}{k_p}\right]\left|s\right| \qquad (41)
\end{aligned}$$

Thus, for sufficiently small $\mu$, all trajectories inside $\Phi_\mu$ would reach the boundary layer $\{|s| \leq \mu\}$ in finite time. Inside the boundary layer, the closed-loop system (38) is given by

$$\begin{aligned}
\dot{w} &= S_0 w \\
\dot{x} &= f(x,w) + g(x,w)\varphi(\psi(x)) \\
&\quad + g(x,w)\varphi\left(-\alpha(x)s/\mu\right) \\
&\quad - g(x,w)[\chi(w) + \varphi(\psi(x))] \qquad (42) \\
\dot{\sigma} &= S\sigma + J\upsilon(x)
\end{aligned}$$

By following the analysis in [6], it can be shown that inside the boundary layer, the trajectories of the closed-loop system (42) will asymptotically approach an invariant manifold on

[2] When $|s| \geq \mu$, from (23) and (11), we have:

$$\begin{aligned}
\theta_1 u^2 &\leq u\varphi(u) \\
\theta_1\left(-\alpha(x)\frac{s}{|s|}\right)^2 &\leq -\alpha(x) sat\left(s/\mu\right)\varphi\left(-\alpha(x) sat\left(s/\mu\right)\right) \\
-\alpha(x)\theta_1\frac{s^2}{|s|} &\geq s\varphi\left(-\alpha(x) sat\left(s/\mu\right)\right) \\
\Rightarrow -\alpha(x)\theta_1\left|s\right| &\geq s\varphi\left(-\alpha(x) sat\left(s/\mu\right)\right)
\end{aligned}$$

Similarly, when $|s| \leq \mu$, we have:

$$-\alpha(x)\theta_1(s^2/\mu) \geq s\varphi\left(-\alpha(x) sat\left(s/\mu\right)\right)$$

which the regulation error is zero. These conclusions are formally summarized in the following theorem.

**Theorem 1.** *Under stated assumptions, consider the closed-loop system (38). Suppose $w(0) \in \mathcal{W}$. Then, there exists $\mu^* > 0$ such that $\forall \mu \in (0, \mu^*]$, the set $\Psi = \Omega \times \left\{V_0(\sigma) \leq \mu^2 c_2\right\}$ is a subset of the region of attraction, and for all initial conditions in $\Psi$, the state variables are bounded and* $\lim_{t\to\infty} \ e(t) = 0$.

## VI. ILLUSTRATIVE EXAMPLE

Consider the nonlinear system

$$\begin{aligned} \dot{\zeta}_1 &= \zeta_2 \\ \dot{\zeta}_2 &= 2\zeta_1\zeta_2 + u + d(t) \\ y &= \zeta_1 \end{aligned} \tag{43}$$

It is desired to achieve optimal regulation of the system's output $y$ to a constant reference signal $r_0$ in the presence of a disturbance signal, $d(t) = d_0 sin(\omega t)$. Both these signals are generated by the exosystem

$$\dot{w} = \begin{bmatrix} 0 & \omega & 0 \\ -\omega & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} w, w(0) = \begin{bmatrix} d_0 \\ 0 \\ r_0 \end{bmatrix}, \begin{bmatrix} d(t) \\ r_0 \end{bmatrix} = \begin{bmatrix} w_1 \\ w_3 \end{bmatrix}$$

With change of variables $x_1 = \zeta_1 - w_3, x_2 = \zeta_2$, we have

$$\begin{aligned} \dot{x}_1 &= x_2 \\ \dot{x}_2 &= 2(x_1 + w_3)x_2 + u + w_1 \\ e &= x_1 \end{aligned} \tag{44}$$

To achieve a sector margin for the nominal system, we use a CLF to design an optimal stabilizing control [7]. With

$$A = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, B = \begin{pmatrix} 0 \\ 1 \end{pmatrix}, P = \begin{pmatrix} 1 & c \\ c & 1 \end{pmatrix},$$

the Ricatti inequality $A^T P + PA - PBB^T P < 0$ is satisfied for any $c \in (0, 1)$. Then, $V = x^T P x$ is a CLF for the nominal nonlinear system. Assumption 1 is satisfied with this CLF which is also an optimal value function. Furthermore, using Sontag's Formula (19), we get the optimal stabilizing control law for the nominal system as

$$\begin{aligned} \psi(x) &= -2x_1x_2 \\ &\quad - \frac{\alpha_1 x_1 + \sqrt{(2x_1x_2\alpha_2 + x_2\alpha_1)^2 + \alpha_2{}^4}}{\alpha_2} \end{aligned} \tag{45}$$

in which $\alpha_1 = x_1 + cx_2$, and $\alpha_2 = cx_1 + x_2$. This optimal stabilizing control law has two desirable properties, namely, it has a sector margin $(\frac{1}{2}, \infty)$, and it can achieve a disk margin $(\frac{1}{2})$ for the nominal system. The system (44) can also be written as

$$\begin{aligned} \dot{x} &= Ax + B[f(x, w) + g(x, w)(u - \chi(w))] \\ e &= Cx \end{aligned} \tag{46}$$

where

$$A = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \quad B = \begin{pmatrix} 0 \\ 1 \end{pmatrix}, \quad C = \begin{pmatrix} 1 & 0 \end{pmatrix},$$

$$f(x, w) = 2(x_1 + w_3)x_2 + w_1 + g(x, w)\chi(w)$$

and $\chi(w) = -\left(\frac{w_1 + 2w_3}{g(w)}\right)$. With this formulation, the problem fits into the Lyapunov redesign framework as given by (33) with an optimal stabilizing controller (45), and by using the control $u$ of the form (36), it can be shown that the system yields zero steady-state regulation error in the presence of disturbance signal generated by the exosystem.

## VII. CONCLUSIONS

This paper incorporates an optimal stabilizing controller in the Lyapunov redesign framework of [6], and investigates the asymptotic robustness properties of the overall feedback design, given that the optimal stabilizing controller itself possesses strong robustness properties by design. The motivation comes from the flexibility of incorporating any stabilizing controller within the framework as proposed in [6], and we seek for control design methods that yield stabilizing controllers with some additional desirable properties like optimality, disturbance rejection and robustness in the presence of matched uncertainties e.g. static nonlinearities, uncertain parameters and the unmodeled fast dynamics. The synthesis of such controller requires the solution of the complicated Hamilton-Jacobi-Bellman (HJB) partial differential equations. Here, we exploit the inverse optimal control design methods presented in [7] for nonlinear systems, where it is shown that in addition to achieving the asymptotic stability of the system and minimizing a cost functional, the optimal feedback control law which is designed based on the existence of a Control Lyapunov Function (CLF), guarantees stability margins which characterize the system's robustness properties. A simple illustrative example is also presented to delineate the overall design process.

*Abstract*—**In this paper we research on the run time characteristics of non-magnetic hydraulic navigation simulator and approach a corresponding control strategy. Since the simulator is designed to be non-magnetic, it consists of long hydraulic pipes separating electric part and mechanical part to avoid the magnetic interference from electric part. Meanwhile the mechanical part is made of non-magnetic materials. Hydraulic motor, instead of electric motor, is used to drive the simulator and it stands varied load at run time. Because of the non-magnetic design, normal control strategy doesn't satisfy the system. We analyze the characteristics of the simulator system both in frequency-domain and time-domain with the help of transfer function and AMESim, which is a modeling environment for simulation of engineering, to make the characteristics clear and finally propose a PID based control strategy (denoted as $D_{ff}$ - $PIDD^2$ in this paper) combining feedforward differential controller ($D_{ff}$) and 2nd order differential controller ($D^2$) for the system. At last we verify the control strategy with position tracking simulation and obtain a satisfied result.**

***Keywords-non-magnetic; long-hydraulic pipe; navigation simulator; $D_{ff}$ - $PIDD^2$; AMESim simulation***

## I. Introduction

Non-magnetic navigation simulator is a platform which is used to test and to calibrate magnetic navigation devices [1]. Magnetic navigation devices are widely used to obtain accurate direction data in various fields, such as military, aviation, aerospace, resource exploration, and etc. When being tested and calibrated, magnetic navigation device is installed in the middle of inner ring of the simulator (Fig. 1) and the direction data from magnetic navigation device will be compared with the precisely controlled rotation data of the simulator. The simulator we work on is designed for a magnetic navigation device which navigates depending on the geomagnetic field. The geomagnetic field is very small (6e-5T averagely) compared to common magnetic fields in our daily life and is easy to be deformed in space by some paramagnetic or diamagnetic media. Because of the special characteristics of the geomagnetic field, the simulator has to be designed without influencing the magnitude and direction of the geomagnetic field nearby.

To achieve the non-magnetic requirement, generally there are three driven schemes for navigation simulator: motor driven, pneumatic driven and hydraulic driven. Motor driven simulator requires separating the motor and the tested device to avoid the magnetic interference from electric motor. The non-magnetic motion simulator used by U.S. Coastal System Station is based on motor driven scheme [2]. Pneumatic driven avoids the magnetic interference in principle. The motion platform designed by University of Newcastle, UK, which is used to test high-precision magnetic device, is based on pneumatic driven scheme [3]. Hydraulic driven also in principle avoids the magnetic interference and the compressibility of hydraulic oil is much less than gas so that it is more likely to achieve high-precision positioning and fast motion tracking. Besides driven scheme, non-magnetic materials are necessity to construct the simulator. Some commonly used non-magnetic materials are austenitic stainless steel, copper alloy, polymers, ceramic material, and etc. [4].

The non-magnetic navigation simulator we designed is based on the hydraulic driven scheme and many other design features, which will be included in the next section, to achieve non-magnetic requirement. Because of the non-magnetic requirement, the run time characteristics of the system are quite different from normal navigation simulator and normal PID control strategy doesn't satisfy the system. In this paper we focus on the derivation of control strategy for the non-magnetic navigation simulator. And we focus more on the theoretical control scheme rather than real application details so that only the most important and crucial features of the system will be counted and some necessary supplementary control strategies for real application, e.g. using low-pass filter to eliminate high frequency noise signal from sensor, may be neglected in this paper. The performance of the derived control strategy will be verified by a simulated simulator system tracking a sine wave position singal with AMESim software.

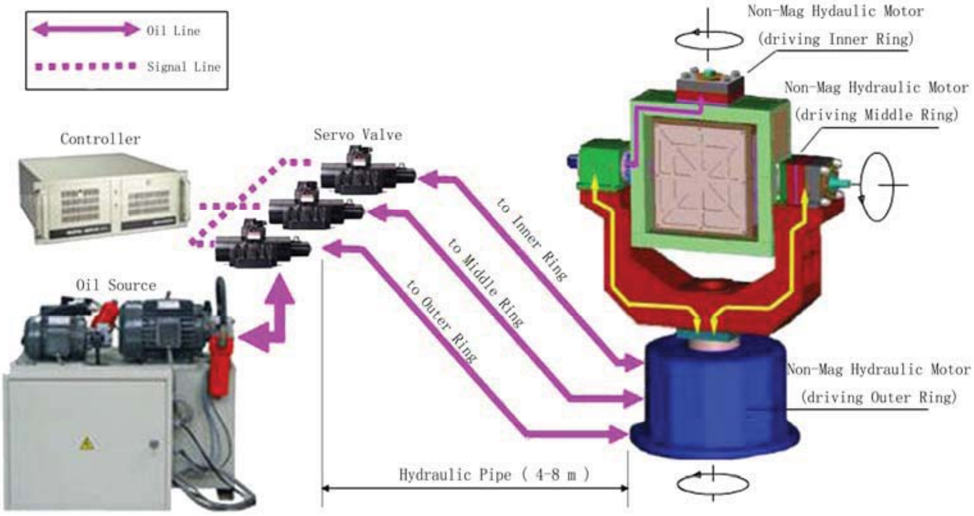

Figure 1. System composition of non-magnetic hydraulic navigation simulator

## I. Principle of the Navigation Simulator

The basic structure of the non-magnetic hydraulic navigation simulator system is shown in Fig. 1.

Generally we divide the system into the electronic control part and the mechanical part. They are connected by signal lines mainly including current signals from controller to servo valves and feedback angular displacement signals from angle sensors to controller. Angle sensor is mounted at the end of each non-magnetic hydraulic motor. The angle sensor on the simulator is a kind of optical encoder, which is a passive device and has an acceptable influence on geomagnetic field [5].

The fundamental principle of the whole system is close to a classic valve controlled hydraulic motor system. But there are several different features in this navigation simulator, which are mainly designed to achieve the non-magnetic requirement. These features are:

- We use beryllium bronze (Cu-Be-Co) [6] and other non-magnetic materials for hydraulic pipe and mechanical components of the navigation simulator;
- We use hydraulic motor made of non-magnetic materials instead of electric motor and optical angle sensor instead of electromagnetic sensor;
- In order to eliminate the electromagnetic interference from the servo valve and oil source side, we separate the mechanical part and the electric part by connecting them with long hydraulic pipes.

When the simulator runs, three servo valves independently control the rotation of three rings, which are known as pitch (outer ring), course (middle ring), and roller (inner ring). The controller outputs the current signals, which are computed based on the feedback angular displacement and our control strategy, to control the spool position of servo valve so that each ring can rotate at a set speed or to a set position.

## II. Modeling with AMESim

In order to know the run time characteristics of navigation simulator especially the influence of non-magnetic designs on the system and approach a suitable control strategy, we model and simulate the system with AMESim (Fig. 2). We set up two models for different reasons. The model with no controller is used to simulate the open-loop characteristic of the system and to check the characteristic of each component. The model with $D_{ff}$ - PIDD$^2$ controller is to test the effectiveness of our control strategy and to simulate the open-loop characteristic of the controller-controlled system as well. During modeling we focus on the most important parts of the system to make the model neat and effective. Here are some instructions for the AMESim model of non-magnetic navigation simulator system:

- We set the oil source pressure to follow the equation of $p_s$=95+5sin(200πt) (bar) to simulate the pressure ripple caused by periodic rotation of pump at oil source side;
- To smooth the ripple and to keep a steady oil pressure inside the pipe we set up an accumulator right after oil source and the filter;
- We select a three-position-four-port servo valve, the spool dynamics of which is modeled as a 2nd order system with a specified natural frequency and damping ratio;
- The hydraulic pipe is modeled as distributive hydraulic line with lumped elements [7];
- Without losing the effectiveness of the model, we simply model the hydraulic motor as an ideal fixed displacement hydraulic motor and we only simulate one ring of the simulator because the three rings have similar characteristics and work independently;
- The rotary load is set with specified moment of inertia, coefficient of viscous friction, Coulomb friction torque, and stiction torque [8].

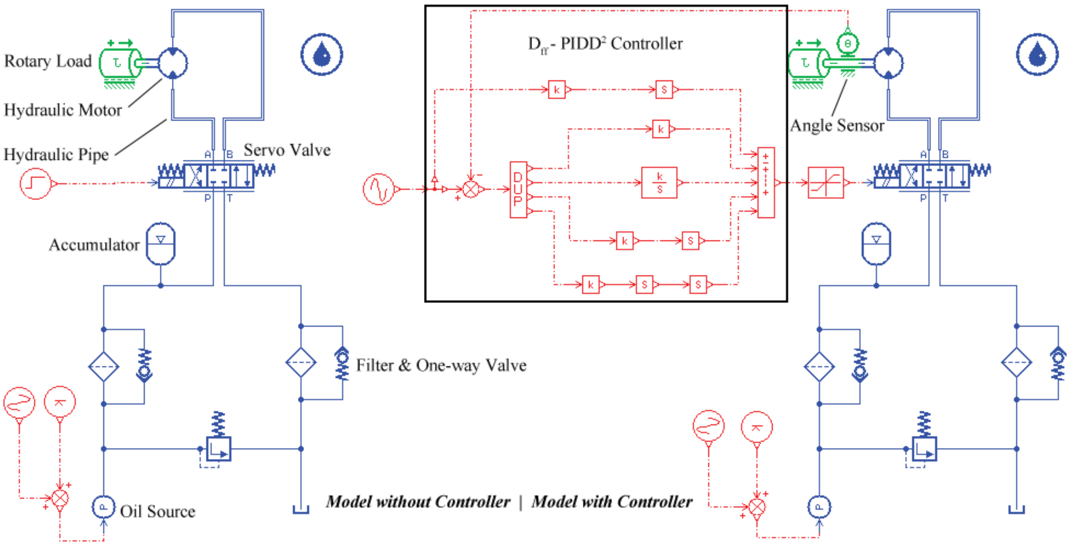

Figure 2. Model with no controller (left) and model with $D_{ff}$ - PIDD$^2$ controller (right)

The distributive hydraulic line model describes the hydraulic pipe as line with several nodes (Fig. 3). The compressibility of the fluid and expansion of the pipe/hose wall with pressure are considered in the model by using an effective bulk modulus. Pipe friction is taken into account using a friction factor based on the Reynolds number and relative roughness. And inertia of the fluid is also taken into account. The parameters of the whole model are set in Table I.

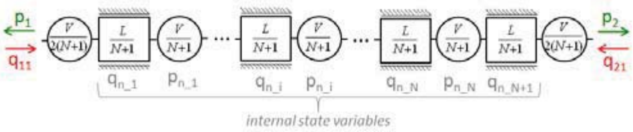

Figure 3. The principle of distributive hydraulic line model (Source: AMEHelp HL042)

TABLE I. PARAMETERS OF NON-MAGNETIC HYDRAULIC NAVIGATION SIMULATOR AMESIM MODEL

| No. | Parameters | Value or Expression |
|---|---|---|
| 1 | Oil source pressure (bar) | 95+5sin(200πt) |
| 2 | Accumulator volume (L) | 6.3 |
| 3 | Accumulator pre-charge pressure (bar) | 80 |
| 4 | Valve rated current (mA) | 40 |
| 5 | Valve nature frequency (Hz) | 80 |
| 6 | Valve damping ratio (null) | 0.8 |
| 7 | Valve flow rate at maximum opening (L/min) | 10 |
| 8 | Valve pressure drop at maximum opening (bar) | 35 |
| 9 | Pipe inner diameter (mm) | 8 |
| 10 | Pipe wall thickness (mm) | 2 |
| 11 | Pipe length (m) | 5 |
| 12 | Pipe relative roughness (null) | 1.5e-4 |
| 13 | Pipe Young's modulus (bar) | 1.3e+6 |
| 14 | Pipe internal node number (null) | 5 |
| 15 | Motor displacement (cm$^3$/rev) | 80 |
| 16 | Load moment of inertia (kgm$^2$) | 5 |
| 17 | Load viscous friction coefficient (Nm/[rev/min]) | 0.1 |
| 18 | Load stiction torque (Nm) | 4 |
| 19 | Load coulomb friction torque (Nm) | 2 |
| 20 | Position tracking signal (degree) | 40sin(πt) |

## III. Simulation and Analysis

### A. *Fundamental analysis of the system*

As we mentioned in the principle section, the fundamental part of the system is a valve controlled hydraulic motor system. So firstly we study on the characteristics of this fundamental part in frequency-domain. The linearized flow rate incremental equation of hydraulic valve is defined as:

$$\Delta q_{Lv} = K_q \Delta x_v - K_c \Delta p_{Lv} \tag{1}$$

where $q_{Lv}$ is flow rate, $x_v$ is spool position, $p_{Lv}$ is load pressure, $K_q$ is flow rate gain, $K_c$ is flow-pressure coefficient. Then we give out the expression of angular displacement of hydraulic motor directly [9]:

$$\theta_m(s) = \frac{\frac{K_q}{D_m}\frac{K_{sv}}{\frac{s^2}{\omega_{sv}^2}+\frac{2\zeta_{sv}}{\omega_{sv}}s+1} i_c(s) - \frac{K_{ce}}{D_m^2}(1+\frac{V_t}{4\beta_e K_{ce}}s)T_{ml}(s)}{s(\frac{s^2}{\omega_h^2}+\frac{2\zeta_h}{\omega_h}s+1)} \tag{2}$$

where $i_c$ is current signal output by controller, $T_{ml}$ is torque load reflected on hydraulic motor shaft, $D_m$ is displacement of motor, $K_{ce}$ is total flow-pressure coefficient, $\beta_e$ is effective bulk modulus of motor system, $\omega_{sv}$ is servo valve natural frequency, $\zeta_{sv}$ is servo valve damping ratio, $K_{sv}$ is servo valve gain, $\omega_h$ is hydraulic natural frequency, $\zeta_h$ is hydraulic damping ratio.

In order to reduce the complexity of the model, we temporarily make the assumption $T_{ml}(s) = 0$, which means motor load is zero for the moment. Then (2) reduces to

$$\frac{\theta_m(s)}{i_c(s)} = \frac{K_q K_{sv}/D_m}{s(\frac{s^2}{\omega_h^2}+\frac{2\zeta_h}{\omega_h}s+1)(\frac{s^2}{\omega_{sv}^2}+\frac{2\zeta_{sv}}{\omega_{sv}}s+1)} \tag{3}$$

It can be seen from (3), if we neglect the long hydraulic pipe and assume zero motor load, the model with no controller is a first order astatic system with two oscillation elements, which can be theoretically regulated by a PID controller [10].

### B. *Analysis of hydraulic motor load*

The second step we take the hydraulic motor load into account. The motor load is defined as:

$$T_{ml} = C_1\dot{\omega}_m + C_2\omega_m + C_3(1-|\mathrm{sgn}(\omega_m)|) + C_4 \tag{4}$$

where $\omega_m$ is the angular velocity of motor, $C_1$, $C_2$, $C_3$, and $C_4$ are constants defined in Table I (No. 16-19). The transfer function of the system will become very complicated when combining (2) and (4), and it will be difficult to draw a proper control strategy. So we analyze the system in time-domain based on AMESim simulation result.

The motor load influences the system by changing the load pressure, i.e. the pressure difference between the inlet and outlet of motor. Recalling (1), we see if the opening amount of valve spool keeps unchanged while the load pressure increases/decreases, the flow through the motor will reversely decrease/increase. In order to eliminate the varied motor load influence on the flow rate, we introduce compensation current to simultaneously act on the opening amount of spool. According to (4) we need to involve angular velocity and acceleration of the motor and a constant into control signals. Because the velocity signal is already able to be reflected in the PID controller and the constant is relatively small compared to other terms in (4), we only introduce an extra 2nd order differential controller ($D^2$) to get the acceleration of the motor. Through the simulation of model with $D_{ff}$ - PIDD$^2$ controller tracking a sine wave position signal in AMESim (detailed simulation parameters will be included in later section), it can be seen from Fig. 4 that the simulated output of $D^2$ controller is always in the same pace with the motor load and reflects the acceleration of motor.

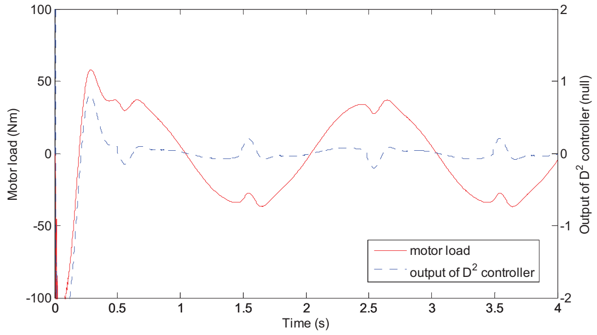

Figure 4. Comparison of motor load and $D^2$ controller output in model with $D_{ff}$ - PIDD$^2$ controller

### C. *Analysis of long hydraulic pipe*

At last we research on control strategy with long hydraulic pipe taken into consideration. The distributive hydraulic line model describes the pipe as a line with several nodes and calculates the pressure and flow rate in each node with the following equations (Source: AMEHelp HL042):

$$\begin{cases} \frac{\partial p_p}{\partial t} = -\frac{\beta_{ep}}{A_p}\cdot\frac{\partial q_p}{\partial x} \\ \frac{\partial q_p}{\partial t} = \frac{A_p}{\rho}\cdot\frac{\partial p_p}{\partial x} - gA_p\sin(\theta_p) - v\frac{\partial q_p}{\partial x} - \frac{f_f q_p^2 \mathrm{sgn}(q_p)}{2D_pA_p} \end{cases} \tag{5}$$

where $p_p$ is pressure in node, $q_p$ is flow rate in node, $A_p$ is the cross-sectional area of pipe, $\beta_{ep}$ is the effective bulk modulus of pipe/fluid combination, $\rho$ is the oil density, $D_p$ is the diameter of the section of pipe, $\theta_p$ is the inclination of pipe, $v$ is the mean velocity of flow in node, $f_f$ is the friction factor of node.

It can be seen that, the derivative of the flow rate is determined by applying conservation of momentum principles to a control volume cell. Forces due to pressure, gravity and pipe friction are taken into account as well as convection of momentum. And we again analyze the pipe effect in time-domain. As shown in Fig. 5, through the simulation of model with no controller tracking a step position signal, the simulated flow rate in hydraulic motor delays about 0.2 second compared to flow rate at port A of the servo valve.

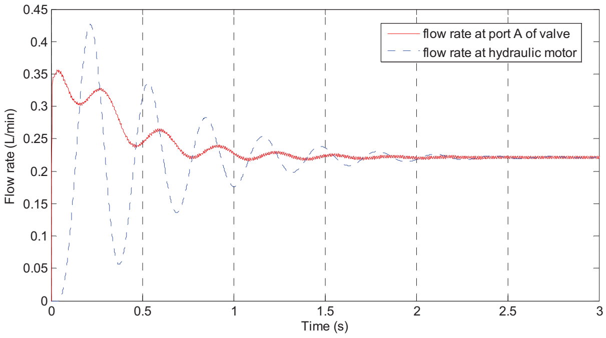

Figure 5. Flow rate in model with no controller

Because pipe is the only component connecting motor and servo valve, it is obviously that the long hydraulic pipe causes the time delay. It means if we could give out the tracking signal a certain time period in advance, we are able to cancel the flow rate delay in pipe. We now assume the tracking signal can be described as a continuous differentiable function f(t), then for $t_B > t_A$ and $t_B - t_A << 1$ we have

$$\begin{aligned} f(t_B) &= f(t_A + t_B - t_A) \\ &= f(t_A) + f'(t_A)(t_B - t_A) + f''(t_A)(t_B - t_A)^2 + \cdots \end{aligned} \quad (6)$$

Since $t_B - t_A << 1$, we neglect the terms with order equal to or higher than 2. Equation (6) reduces to

$$f(t_B) - f(t_A) \approx f'(t_A)(t_B - t_A) \quad (7)$$

Equation (7) shows that we can approach the incremental of signal at $t_B$ to signal at $t_A$ with the derivative of signal at $t_A$. Inspired by this equation we introduce the feedforward differential controller ($D_{ff}$) into control strategy:

$$D_{ff} = Ks \quad (8)$$

Compared to (7), we roughly have gain $K = t_B - t_A$.

### *D. Overall control strategy and simulation result*

Combining all above analysis, we draw the overall control strategy for the system. We use a PID controller as fundamental control strategy together with a $D^2$ controller regulating the hydraulic motor load fluctuation and a $D_{ff}$ controller eliminating time delay effect caused by long hydraulic pipe. In order to check the effectiveness of the controllers, we simulate a position tracking test in AMESim. The tracking signal is set to be a sine wave position signal described in Table I (No. 20), which meets the non-magnetic simulator specification. The result of the simulation test is shown in Fig. 7 with controller parameters in Table II.

Through the comparison between $D_{ff}$ - PID control and PID control, we see the $D_{ff}$ controller effectively eliminates the time delay of the system. Through the comparison of $PIDD^2$ control and PID control, we see the $D^2$ controller reduces the tracking error fluctuation of the system at start stage, during which the motor load changes rapidly and greatly (Fig. 4). Because our system stands varied motor load and the feedback signal is angular displacement of motor, the $D^2$ controller precisely catches the load fluctuation and compensates it to the control current signal. $D^2$ controller is rarely seen in traditional control strategy because it usually introduces instability to system. In real applications a low-pass filter might be used to eliminate high frequency noise signal from sensor.

Besides the time-domain analysis with AMESim, we also do a frequency-domain test (Bode diagram) of the two models in open-loop state. We analyze the stability of the two models based on Bode diagram stability criterion for open-loop system (Fig. 6) [11]. This criterion defines the magnitude crossover frequency ($\omega_{mc}$) as the frequency where the magnitude is equal to 0 and the phase crossover frequency ($\omega_{pc}$) as the frequency where phase shift is equal to -180 degree. If at the phase crossover frequency, the corresponding magnitude is less than 0 dB, then the feedback system is stable. According to Bode diagram criterion (using the vertical lines in Fig. 8 as reference), the model with no controller is not stable while the model with controller is stabilized. The diagram also shows that model with $D_{ff}$ - $PIDD^2$ controller has faster response in low frequency region and broader frequency band without phase delay. Although the attenuation of model with controller in high frequency region becomes slower, it is within an acceptable amount.

TABLE II. CONTROLLER PARAMETERS FOR SINE POSITION TRACKING SIMULATION

| **Controller** | **PID** | **PIDD$^2$** | **D$_{ff}$ - PID** | **D$_{ff}$ - PID** |

## IV. Conclusion

Through modeling, simulation and analysis of non-magnetic hydraulic navigation simulator, we conclude that the simulator is a time-delay valve controlled hydraulic motor system with varied motor load. We firstly focus on the most fundamental parts of the system, i.e. valve controlled hydraulic motor, which is a common hydraulic system and on which mature control strategy can be applied. Secondly we analyze the special parts of the system in time-domain with simulation results. During this process we isolate each component and come up with different control strategies. Finally we propose the $D_{ff}$ - PIDD$^2$ controller for the system, which is proven more effective than the traditional PID controller theoretically and with simulation as well. The $D_{ff}$ - PIDD$^2$ controller may also be applied to real applications of similar system with time delay or varied force/torque load.

# Trajectory tracking control of a car-like mobile robot in presence of sliding

Faiza Hamerlain
Division Robotique et Productique, CDTA,
Cité du 20 Août 1956, BP N°17, Baba Hassen, Alger, Algérie.
hamerlainf@yahoo.fr

Abstract- This paper investigates the trajectory tracking control problem of a nonholonomic car-like mobile robot in the presence of sliding effects. Sliding (slipping and skidding) effects are treated as disturbances and introduced into the kinematic model of the car-like using the singular perturbation approach. In order to compensate for the effects of tire slipping and skidding, a robust second order sliding mode controller is developed based on the super twisting algorithm. It is theoretically proven that for car-like vehicle subjected to sliding, the lateral-longitudinal deviations and the orientation errors can be stabilized near the origin. Simulations results show the effectiveness and the robustness of the proposed controller with respect to the sliding effects.

Index Terms- Car-like Mobile Robot, Second order sliding mode, Tracking control, Sliding effects.

## I. Introduction

The control problem of nonholonomic systems with parameter uncertainties has been extensively studied in past decades. Regarding the trajectory tracking problem of the Wheeled Mobile Robots WMR, many works address violation of the nonholonomic constraints. A robust control law against decoupled skidding and slipping effects has been proposed for solving a velocity tracking problem for a unicycle-type robot [1]. For a dynamic model of the unicycle-type robot including sliding effects, simulation results were reported in [2], showing the robustness of a second order sliding tracking control with respect to the non ideal constraints and to the nonlinearities. In [3], a path tracking control of an autonomous robot was considered under slipping and unknown dynamics. A robust adaptive neural network controller was proposed for WMR with the aid of backsteeping techniques and the learning ability. Based on the backsteeping methods, a robust adaptive tracking controller was designed for farm agriculture vehicles in presence of sliding [4]. The sliding effects are introduced as time-varying parameters to the ideal kinematic model. Both simulation and experimental results confirm the high longitudinal-lateral tracking controller accuracy. In [5], it was derived kinematic models of WMR that explicitly relate the perturbations to the vehicle skidding and slipping that are geometrically well defined. This description allows the analyse of these perturbations from a control perspective. The reference [6] copes with the control of WMR not satisfying the ideal kinematic constraints by using slow manifolds methods, but the parameters characterizing the sliding effects are assumed to be exactly known. In [7], a time varying stabilizing control law based on the linear quadratic theory was proposed and the necessity for the trajectory to satisfy the dynamics of the skidding effects is pointed out. This feedback control law ensures the local asymptotic convergence of the error dynamics of the unicycle but only under some conditions on the reference trajectory (accelerations should be sufficiently small). In [8], a singular perturbation formulation was derived which leads to robust linearizing feedback laws ensuring trajectory tracking in presence of sufficiently small sliding effects. In [9], a discrete-time sliding mode control was proposed for trajectory tracking of the kinematic model of a unicycle type mobile robot in the presence of skidding effects. The sliding effect is modeled taking into account its most important component which is skidding for no straight trajectories. In [10], a robust adaptive controller based on the tunable dynamic oscillator was developed for a skid steer mobile robot in the presence of disturbances violating nonholonomic nonslipping constraint. Simulation results were performed to solve both the tracking and regulation problems.

In this paper, the robust trajectory tracking problem for a kinematic model of a car-like WMR in the presence of sliding effects is solved by means of a higher order sliding mode control. Using the singular perturbation approach [8], the kinematic tracking model of the car-like WMR is derived. Then, a second order sliding mode controller of the super twisting algorithm is used. The proposed control law is based on two nonlinear sliding manifolds ensuring the asymptotic tracking of the output variables in spite of the transgression of the nonholonomic constraints during the motion.

This paper is organized as follows, in Section 2 a kinematic tracking model considering sliding effects is derived and the problem statement is presented. The second order sliding mode control law is presented in Section 3, while Section 4 shows simulation results.

## II. Model of the car-like and problem statement

The Robucar in a single drive mode is an example of car-like WMR. For model simplicity, we assume that each axle of the physical wheels (front and rear) is represented by a virtual wheel located in the middle axle. Then, the schematic representation of the car-like WMR can be given by Figure 1. It is fully described by a four-dimensional vector of generalized coordinates $q = (x_P, y_P, \theta, \phi)^t$ where $x_P, y_P$ are the coordinates of point $P$, $\theta$ is the orientation angle of the vehicle w.r.t to a fixed frame and $\phi$ represents the front steering angle relative to the car body. $L$ denotes the WMR's wheelbase.

Note that mobile robot of type $(\delta_m, \delta_s)$ with a degree of mobility $\delta_m = 1$ and a degree of steerability $\delta_s = 1$ present four independent constraints (the non skidding constraint being the same for both driving wheels) of the form:

$$A^t(q)\dot{q} = 0 \tag{1}$$

with

$$\begin{aligned} A &= \begin{pmatrix} s(\theta) & s(\theta+\phi) & c(\theta) & c(\theta+\phi) \\ -c(\theta) & -c(\theta+\phi) & s(\theta) & s(\theta+\phi) \\ 0 & -s(\theta) & 0 & s(\theta) \\ 0 & 0 & 0 & 0 \end{pmatrix}, \\ c(\theta) &= \cos(\theta), s(\theta) = \sin(\theta). \end{aligned}$$

which correspond to the ideal hypothesis of a " pure rolling and non slipping " condition.

Defining a full matix $S(q)$ such that $A^t(q)S(q) = 0$, a vector $v = (v_1, v_2)^t$ exists satisfying

$$\dot{q} = S(q)v \tag{2}$$

with

$$S = \begin{pmatrix} c(\theta) & 0 \\ s(\theta) & 0 \\ \tan(\phi) & 0 \\ 0 & 1 \end{pmatrix},$$

where $v_1, v_2$ represent respectively the linear driven (steering) velocity of the car-like WMR

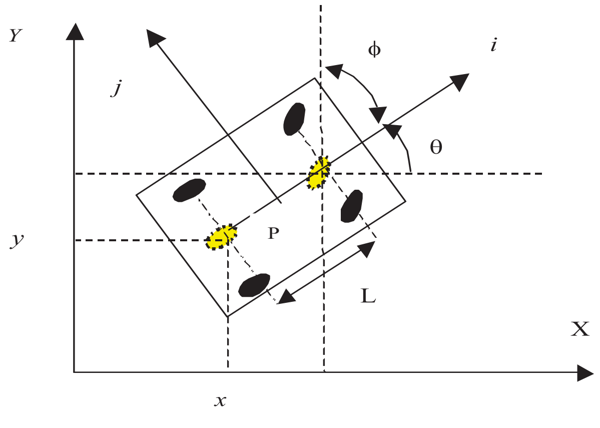

Figure 1. The car-like WMR.

In practise, it is well known that the nonholonomic constraints are never strictly satisfied during the motion of robot, due to various factors such as sliding, deformability or flexibility of the wheels. Hence, the kinematic model given by (2) is no longer valid. So, the interaction forces and slipping effects have to be modelled. Based on the singular perturbation formalism [8], the kinematic model of the car-like WMR with sliding can be expressed as:

$$\dot{q} = S(q)v + A_1\epsilon\mu_1 + A_2\epsilon\mu_2 + A_3\epsilon\mu_3 + A_4\epsilon\mu_4,$$

where $A_1, A_2, A_3, A_4$ are the colomns of the matrix $A, \mu$ is a four dimension vector reflecting the violation of the constraints and $\epsilon$ is a positive scalar, which is the inverse of the largest stiffness. $\epsilon\mu_1$ and $\epsilon\mu_2$ corresponds to skidding effects while $\epsilon\mu_3$ et $\epsilon\mu_4$ represents slipping effects.

Let $v_x$ and $v_y$ be the longitudinal and the lateral velocities of point $P$ (see Figure 1), respectively, and $v_\theta$ the vehicle angular velocity:

$$\begin{cases} v_x = v_1 + s(\phi)\varepsilon\mu_2 + \varepsilon\mu_3 + c(\phi)\varepsilon\mu_4, \\ v_y = \varepsilon\mu_1 + c(\phi)\varepsilon\mu_2 - s(\phi)\varepsilon\mu_4, \\ v_\theta = \tan(\phi)v_1 - c(\phi)\varepsilon\mu_2 + s(\phi)\varepsilon\mu_4, \end{cases} \tag{3}$$

Under the hypothesis of a quite small front steering angle, the kinematic model of the car-like WMR is given in the base frame by time evolution of point $P$ of coordinates:

$$\begin{pmatrix} \dot{x}_P \\ \dot{y}_P \\ L\dot{\theta} \end{pmatrix} = M(\theta) \begin{pmatrix} v_x \\ v_y \\ v_\theta \end{pmatrix}$$

with

$$M(\theta) = \begin{pmatrix} c(\theta) & s(\theta) & 0 \\ s(\theta) & -c(\theta) & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

The objective is to make the car-like robot follow a given reference trajectory that satisfies the kinematic equations of a virtual WMR:

$$\begin{pmatrix} \dot{x}_{Pr} \\ \dot{y}_{Pr} \\ L\dot{\theta}_r \end{pmatrix} = M(\theta_r) \begin{pmatrix} v_{xr} \\ v_{yr} \\ v_{\theta r} \end{pmatrix}, \tag{4}$$

where $(x_{Pr}, y_{Pr})$ is the position of a virtual reference vehicle at the point $(P_r)$ in the base frame, $\theta_r$ is the orientation. $v_{xr}$, $v_{yr}$ are the longitudinal lateral reference velocities at the point $(P_r)$ and $v_{\theta r}$ is the angular velocity. The reference velocities, as well as their first and second time derivatives, are assumed to be bounded for all $t$.

Denote by $e = \begin{pmatrix} \widetilde{x} & \widetilde{y} & L\widetilde{\theta} \end{pmatrix}^t$ the position tracking error vector expressed in the frame linked to the virtual vehicle, i.e.:

$$\begin{pmatrix} \widetilde{x}(t) \\ \widetilde{y}(t) \\ L\widetilde{\theta}(t) \end{pmatrix} = M^t(\theta_r) \begin{pmatrix} x_P(t) - x_{Pr}(t) \\ y_P(t) - y_{Pr}(t) \\ L\theta(t) - L\theta_r(t) \end{pmatrix} \tag{5}$$

By time derivation of (4), the full kinematic tracking model for the car-like can be easily developed (see these for detail):

$$\begin{cases} \dot{\widetilde{x}} = \frac{v_{\theta r}}{L}\widetilde{y} + c(\widetilde{\theta})\widetilde{v}_x + s(\widetilde{\theta})\widetilde{v}_y + p_{\widetilde{x}}(t,\widetilde{\theta})\widetilde{\theta}, \\ \dot{\widetilde{y}} = -\frac{v_{\theta r}}{L}\widetilde{x} + s(\widetilde{\theta})\widetilde{v}_x - c(\widetilde{\theta})\widetilde{v}_y + p_{\widetilde{y}}(t,\widetilde{\theta})\widetilde{\theta}, \\ L\dot{\widetilde{\theta}} = \widetilde{v}_\theta. \end{cases} \tag{6}$$

where

$$p_{\widetilde{x}}(t,\widetilde{\theta}) = \frac{(\cos(\widetilde{\theta})-1)}{\widetilde{\theta}}v_{xr} + \frac{\sin(\widetilde{\theta})}{\widetilde{\theta}}v_{yr},$$
$$p_{\widetilde{y}}(t,\widetilde{\theta}) = \frac{\sin(\widetilde{\theta})}{\widetilde{\theta}}v_{xr} + \frac{(1-\cos(\widetilde{\theta}))}{\widetilde{\theta}}v_{yr}.$$

Note that $p_{\widetilde{x}}(t,\widetilde{\theta})$ and $p_{\widetilde{y}}(t,\widetilde{\theta})$ are bounded functions. Sliding effects are treated as kinematic perturbations. As we can see, the model rely on the measurement of the parameter perturbations. Hence, its accurate measurement is difficult to obtain. To introduce the perturbations which can be present during the motion of the robot (Robucar), we have negligated the sliding of the rear wheels ($\mu_2 = \mu_4 = 0$) and take into account only the sliding of the front wheels ( $\epsilon\mu_1 \neq 0$, $\epsilon\mu_3 \neq 0$). Then, the system (3) becomes:

$$\begin{cases} v_x = v_1 + \varepsilon\mu_3 \\ v_y = \varepsilon\mu_1 \\ v_\theta = \tan(\phi)v_1 \end{cases} \tag{7}$$

In this situation, two solution are proposed here. The first one, by adding a term which represent the perturbations on the longitudinal velocity control $v_x$ (longitudinal sliding or slipping), and the second one, by modifying the reference trajectory that the vehicle must follow (lateral sliding or skidding). We introduce the longitudinal (lateral) perturbation in the expression of the velocity control (the reference trajectory) respectively, as follow:

$$\begin{cases} v_x = v_1 + \varepsilon\mu_3 \\ v_{yr} = -c(\widetilde{\theta}).\varepsilon\mu_1 \end{cases} \tag{8}$$

In the case when no sliding occurs, it is obvious that $v_x = v_1$ and $v_y = 0$.

The problem addressed in this paper is to find a state feedback controller which can guarantee the asymptotic stabilization of system (6) about the origin, i.e:

$$\lim_{t\to\infty}\widetilde{x}(t) = 0, \lim_{t\to\infty}\widetilde{y}(t) = 0, \lim_{t\to\infty}\widetilde{\theta}(t) = 0.$$

For this, a robust nonlinear control law based on second order sliding mode is derived in this paper. It will be assumed that only $x$, $y$, $\theta$ are available for measurement. it is shown that both the position and the angular tracking errors of the robot are asymptotically stabilized in an arbitrarily small neighborhood of the origin.

## III. Second order sliding mode controller

Sliding mode control approach exhibits relative simplicity of design and some robustness properties with respect to matching perturbations [11]. To overcome the well know chattering phenomenon while guaranteeing better convergence acuracy, second order sliding mode controllers have been proposed [12]. They are characterized by a discontinuous control acting on the second time derivatives of the sliding constraint s (instead of the first time derivative in classical sliding mode), whose vanishing defines the sliding manifold. The main principle of the second order sliding mode is to obtain a finite time convergence onto the second order sliding set $\{s = \dot{s} = 0\}$ (see, [14][13]).

Different kind of algorithms (twisting, drift , super twisting, sub-optimal...) able to ensure the finite time convergence have been proposed [13]. Here, the super twisting algorithm that only requires the knowlegde of the sliding surface will be adopted. In what follow, it is shown that both the position and the angular tracking errors of the robot are asymptotically stabilized in an arbitrarily small neighborhood of the origin.

### A. Design and attractivity of the sliding manifold

Let us define the sliding constraint $s = [s_1, s_2]^T$ as:

$$s_1 = \lambda_1\widetilde{x} + p_{\widetilde{x}}(t,\widetilde{\theta})\widetilde{\theta}, \tag{9}$$
$$s_2 = p_{\widetilde{y}}(t,\widetilde{\theta})\widetilde{\theta} + \lambda_2\widetilde{y}. \tag{10}$$

where $\lambda_1$, $\lambda_2$ are positive parameters. Note that the system has relative degree one with respect to both $s_1$ and $s_2$ and that the second time derivatives $s_1$and $s_2$ of are given by:

$$\ddot{s}_1 = \psi_1(\widetilde{x},\widetilde{y},\widetilde{\theta},t) + \dot{v}_1$$
$$\ddot{s}_2 = \psi_2(\widetilde{x},\widetilde{y},\widetilde{\theta},t) + \dot{v}_2$$

For sake of place, the expression of $\psi_1(\widetilde{x},\widetilde{y},\widetilde{\theta},t)$ and $\psi_2(\widetilde{x},\widetilde{y},\widetilde{\theta},t)$ are not reported here. The task is to generate a second order sliding mode on the second order sliding set given by the equalities: $s = \dot{s} = 0$. For this, assume that the reference velocities $(v_{1r}, v_{2r})$ and their first and second time derivatives are bounded and that the functions $\psi_i(\widetilde{x},\widetilde{y},\widetilde{\theta},t)$ are bounded such that $\left|\psi_i(\widetilde{x},\widetilde{y},\widetilde{\theta},t)\right| \leq K_i,\ i = 1,2$ where $K_i$ are positive constants. Then, it is known that one can apply the super twisting algorithm defined by the following control law [13]:

$$\begin{array}{l} v_i = -\lambda_{mi}\left|s_i\right|^{\frac{1}{2}} sign(s_i) + v_{1i}, \\ \dot{v}_{1i} = -W_i sign(s_i), \qquad i = 1,2 \end{array} \tag{11}$$

where $W_i$ and $\lambda_{mi}$ are positive constants that satisfy the following conditions:

$$\begin{cases} W_i > K_i \\ \lambda_{mi}^2 \geq 4K_i\frac{W_i+K_i}{W_i-K_i} \end{cases}$$

It can be shown that the control laws (11) generate a second order sliding mode on the second order sliding set $\{s = \dot{s} = 0\}$ (see [14], [13]). In particular this implies that:

$$\lambda_1\widetilde{x} = -p_{\widetilde{x}}(t,\widetilde{\theta})\widetilde{\theta} \tag{12}$$
$$\lambda_2\widetilde{y} = -p_{\widetilde{y}}(t,\widetilde{\theta})\widetilde{\theta} \tag{13}$$

### B. Asymptotic stability of the sliding motion

In order to show that, once in sliding mode, the posture errors of the robot are vanishing asymptotically, let us introduce the following candidate Lyapunov function:

$$V = \frac{1}{2}\left(\widetilde{x}^2 + \widetilde{y}^2\right).$$

The time derivative of $V$ along the trajectories of the system is given by:

$$\begin{aligned}\dot{V} &= \widetilde{x}\left(\frac{v_{\theta r}}{L}\widetilde{y} + c(\widetilde{\theta})\widetilde{v}_x + s(\widetilde{\theta})\widetilde{v}_y + p_{\widetilde{x}}(t,\widetilde{\theta})\widetilde{\theta}\right) \qquad (14)\\ &\quad +\widetilde{y}\left(-\frac{v_{\theta r}}{L}\widetilde{x} + s(\widetilde{\theta})\widetilde{v}_x - c(\widetilde{\theta})\widetilde{v}_y + p_{\widetilde{y}}(t,\widetilde{\theta})\widetilde{\theta}\right).\end{aligned}$$

Replacing the expressions (12) and (13) in (14), one gets:

$$\begin{aligned}\dot{V} &= -\lambda_1\widetilde{x}^2 - \lambda_2\widetilde{y}^2 + \widetilde{x}\left[c(\widetilde{\theta})\widetilde{v}_x + s(\widetilde{\theta})\widetilde{v}_y\right]\\ &\quad +\widetilde{y}\left[s(\widetilde{\theta})\widetilde{v}_x - c(\widetilde{\theta})\widetilde{v}_y\right]\end{aligned}$$

From the equations (12) and (13), we have:

$$\widetilde{y} = k(t,\widetilde{\theta})\widetilde{x}$$

with

$$k(t,\widetilde{\theta}) = \frac{\lambda_1 p_{\widetilde{y}}(t,\widetilde{\theta})}{\lambda_2 p_{\widetilde{x}}(t,\widetilde{\theta})}$$

Then one gets:

$$\begin{aligned}\dot{V} &= -\lambda_1\widetilde{x}^2 - \lambda_2\widetilde{y}^2 + \widetilde{x}\widetilde{v}_x\left[c(\widetilde{\theta}) + k(t,\widetilde{\theta})s(\widetilde{\theta})\right]\\ &\quad +\widetilde{x}\widetilde{v}_y\left[s(\widetilde{\theta}) - k(t,\widetilde{\theta})c(\widetilde{\theta})\right].\end{aligned}$$

As $p_{\widetilde{x}}(t,\widetilde{\theta})$ and $p_{\widetilde{y}}(t,\widetilde{\theta})$ are bounded for all $\widetilde{\theta}$, one can write:

$$\begin{aligned}\left|(c(\widetilde{\theta}) + k(t,\widetilde{\theta})s(\widetilde{\theta}))\right| &\leq \Gamma_1,\\ \left|(s(\widetilde{\theta}) - k(t,\widetilde{\theta})c(\widetilde{\theta}))\right| &\leq \Gamma_2.\end{aligned}$$

and suppose that

$$\begin{aligned}\|\widetilde{v}_x\| &\leq \Gamma_3 + \Gamma_4\|X\|,\\ \|\widetilde{v}_y\| &\leq \Gamma_5 + \Gamma_6\|X\|.\end{aligned}$$

where $\Gamma_1, \Gamma_2\ \Gamma_3, \Gamma_4, \Gamma_5, \Gamma_6$ are positive constants and $X = \begin{pmatrix}\widetilde{x} & \widetilde{y}\end{pmatrix}^t$.

Let us define $\lambda^\star = \min_{i=1,2}(\lambda_i)$, then one can write:

$$\dot{V} \leq -\lambda^\star\|X\|^2 + \|X\|^2\left(\frac{\Gamma_1\Gamma_3 + \Gamma_2\Gamma_5}{\|X\|} + \Gamma_1\Gamma_4 + \Gamma_2\Gamma_6\right)$$

Taking $\|X\| \geq \frac{\varepsilon}{2}$, this implies that

$$\dot{V} \leq -\lambda^* \|X\|^2 + \|X\|^2\left(\frac{2(\Gamma_1\Gamma_3 + \Gamma_2\Gamma_5)}{\varepsilon} + \Gamma_1\Gamma_4 + \Gamma_2\Gamma_6\right).$$

Define the ball $\mathcal{B}_{\varepsilon/2} = \left\{X : \|X\| \leq \frac{\varepsilon}{2}\right\}$. It results that outside the ball $\mathcal{B}_{\varepsilon/2}$, one has

$$\dot{V} \leq -\widetilde{\lambda}\|X\|^2 = -2\widetilde{\lambda}V$$

with

$$\widetilde{\lambda} = \lambda^\star - \left(\frac{2(\Gamma_1\Gamma_3 + \Gamma_2\Gamma_5)}{\varepsilon} + \Gamma_1\Gamma_4 + \Gamma_2\Gamma_6\right).$$

Thus $\dot{V}$ will be negative definite if the the parameter $\lambda^\star$ is chosen as:

$$\lambda^\star > \left(\frac{2(\Gamma_1\Gamma_3 + \Gamma_2\Gamma_5)}{\varepsilon} + \Gamma_1\Gamma_4 + \Gamma_2\Gamma_6\right)$$

Hence, with this choice of $\lambda^\star$ the solution of the system is given by

$$\|X(t)\| \leq \|X(0)\|\exp\left(-\widetilde{\lambda}t\right)$$

and there exists a finite time $t_1$ such that $\forall\, t > t_1 : X(t) \in \mathcal{B}_\varepsilon$. Thus, $\widetilde{x}$, $\widetilde{y}$ are stabilized in an arbitrarily small neighborhood of the origin. From the equations (12) and (13), it can be seen that the orientation angle error $\widetilde{\theta}$ is also stabilized in an arbitrarily small neighborhood of the origin.

## IV. Simulation results

In this section, simulation results on the kinematic model (6) using the proposed controller are presented. The sampling time is chosen to be $0.01s$ with the physical paramter $L = 1.2m$. The car-like WMR must follow a reference trajectory of a circular path in a time interval $T = 40s$. Simulation was performed testing the developed control both without and with sliding. The design of parameters of sliding surfaces and control gain are: $\lambda_1 = 1.5, \lambda_2 = 0.4, \lambda_{mi} = 1, W_i = 10^{-5}(i = 1, 2)$. Simulated tracking responses of the car-like WMR given in the base frame are reported relative to the two classes of simulations. Simulation results of the trajectory tracking of the car-like considering the ideal case (without sliding) are given in Figure 2 with initial condition: $\widetilde{x}(0) = 0.2m, \widetilde{y} = 0.1m, \widetilde{\theta}(0) = -0.1rd, v_{xr}(t) = 1m.s^{-1}, v_{\theta r}(t) = 0.03rd.s^{-1}$. The position tracking errors are given in the first line and the second line provides the orientation and steering angles errors, while the last line gives the input time error response (driven velocity) and the trajectories in the phase plane $(x, y)$. We remark that all the errors converge to the origin after a time equal to $10s$. Despite the initial errors of the car-like, this one joins the path made by the virtual vehicle and the control activity is accpetable and exhibits no chattering.

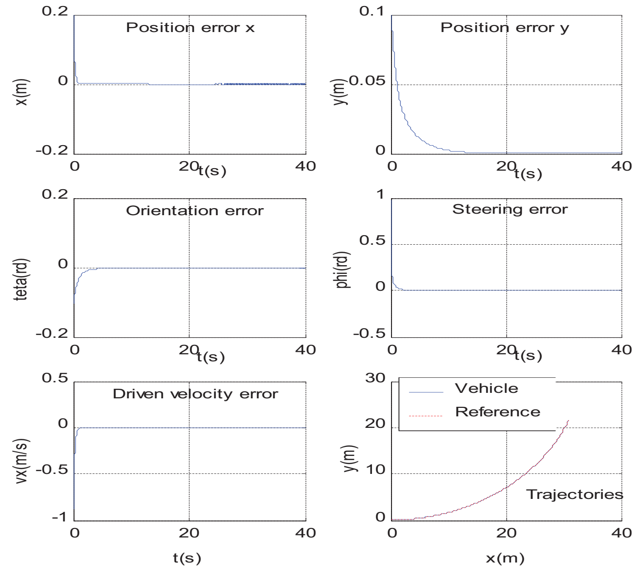

Figure 2. Tracking of the car-like without sliding.

As noted in the second section, two types of pertubations were introduced and applied to the car-like WMR at time $5s$. The first one is reported in Figure $3$, representing the vehicle slipping and the second one the vehicle skidding while curving, see Figure $4$. Simulation results for the trajectory tracking of the car-like considering only the slipping and both slipping and skidding are shown respectively in Figures $5, 6$ with null initial posture condition and $v_{xr}(t) = 0.6m.s^{-1}, v_{\theta r}(t) = 0.06rd.s^{-1}$. The Figures $5, 6$ shown that at the introduction of pertubations, the control inputs (driven velocity and steering angle) changes the values for converging to the desired reference one after the annulation of perturbations at time $t = 10s$. It can be seen that, the tracking of the car-like diverge quietly from the reference trajectory at time $t = 5s$ and its remains close to the reference trajectory after $t = 10s$. From these results, the robustness with respect to the sliding effects of the proposed sliding mode controller is confirmed.

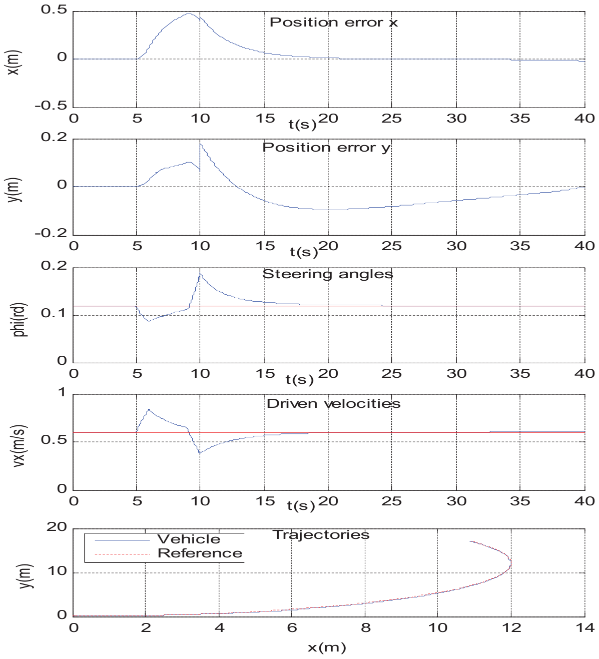

Figure 6. Tracking of the car-like with sliding.

## V. Conclusion

In this paper, we suggest higher order sliding mode control approach for solving the trajectory tracking problem for the car-like WMR considering sliding effects. Based on the tracking kinematic model of the car-like WMR, a second order sliding mode controller has been developed using the super twisting algorithm. The asymptotic convergence of the tracking errors has been proven by means of the Lyapunov function method. However, due to the nonlinearities, those errors are only stabilized in an arbitrarily small neighborhood of the origin. Simulation results are reported, showing the robustness of the proposed control law against nonlinearities and sliding effects. As a future work, it will be interesting to test the proposed tracking controller in experimentation and show how this approach works in real problems.

***Abstract*—In this work, a trajectory planning technique for an autonomous vehicle is proposed. A Predictive Control formulation is used both to plan a trajectory and control the vehicle in the presence of obstacles and dynamic constraints. However, some particularities of this sort of missions may make the time required for solution of the associated optimization problem prohibitive for a given sampling period. In this context, the possibility of using smaller prediction and control horizons is important to obtain a suitable control sequence within each sampling time. For this purpose, a trajectory planner which distributes waypoints along a previously established path is employed in the present paper. Each waypoint is determined so that it can be reached in a horizon which is smaller than the one necessary to reach the target set from the initial position, thus reducing the computational burden during the control phase. Moreover, during the planning phase the waypoints are chosen under the restriction that the target set should be reached within finite time so that the mission can be accomplished.**

***Index Terms*—Predictive control, trajectory planning, waypoint.**

## I. Introduction

Model-based Predictive Control (MPC) techniques involve the solution of an optimal control problem within a moving horizon, which is repeated (usually at every sampling time) on the basis of feedback from the sensors of the plant [1], [2]. One of the main advantages of MPC is the explicit treatment of constraints over the outputs and the controls of the plant. In aeronautical applications, it allows the various aircraft actuators to work closer to the limits of saturation, providing an increase in the flight envelope without compromising the safety of operation.

In typical problems of guidance of vehicles the state must reach a given set in finite time for the mission to be completed successfully [3]. Another issue is the existence of constraints that result in a non-convex optimization problem, such as the presence of obstacles which the vehicle must avoid.

In [3] the problem of reaching a terminal set in finite time is addressed by using a variable horizon MPC formulation and minimizing a weighted-time-fuel cost function. The resulting optimization problem is a *Mixed Integer Linear Programming* (MILP) one, because it involves both continuous and logical variables. A kinematic model of the vehicle is used to determine the trajectory, but vehicle guidance and control can be carried out by enhancing the model with rigid body and/or actuator dynamics. The obstacle avoidance constraints can also be encoded in the MILP formulation by using logical variables in conjunction with a "big-M" method, thus circumventing the difficulties brought about by the loss of convexity of the optimization problem.

However, the resulting MILP problem may not be feasible with small horizons, causing the need of larger ones in order to reach the terminal set from the initial state. In turn, larger horizons are associated with a higher number of optimization variables and may render the computational treatment of the optimization problem impracticable.

In this scenario, it may be convenient to split the mission into a series of intermediate goals that can be achieved within smaller horizons. Nevertheless, this division should be done judiciously, considering information about the limits of the actuators and constraints on the states of the plant, as well as the obstacles and the final goal of the mission. One way to accomplish the division is to introduce a sequence of waypoints, i. e., intermediate points through which the vehicle must pass to reach the terminal set. Such waypoints must be followed in a predetermined sequence obeying constraints and leading to the terminal set. Their determination must also take into account the capacity of achieving the waypoints from the current position of the vehicle within a horizon of acceptable size. Thus, the problem is divided into two steps: 1) off-line trajectory planning - involving the calculation of waypoints; 2) online execution of the planned trajectory. The first step is performed before the start of the maneuver.

In this work a technique for trajectory planning via waypoints in the presence of obstacles is proposed. The employment of such a technique along with an MPC-MILP formulation is evaluated regarding the computational burden involved in the control task.

The remainder of this paper is organized as follows. Section II reviews the MPC-MILP formulation adopted in the present work, which involves minimizing the weighted-time-fuel cost function to reach a given terminal set in the presence of obstacles [3]. Next, in Section III, trajectory planning for vehicles in the presence of obstacles is briefly discussed. The main contribution of this work is introduced in Section IV, in which the proposed approach for trajectory planning is presented. The scenarios adopted in the simulations are described in Section V. Section VI presents the simulation results of the proposed approach, which are compared to the direct application of the original MPC-MILP formulation. Finally, conclusions are drawn and suggestions for future work

- $r \in \mathbb{R}^2$: vehicle position;
- $b \in \{0,1\}$: binary variable associated to the horizon minimization;
- $b_{i,m}^{obs} \in \{0,1\}$: binary variables associated to the obstacle avoidance constraints;
- $k$: current time;
- $\hat{\Diamond}(k+i|k)$: predicted value of the variable $\Diamond$ at time $k+i$ based on the information available up to time $k$;
- $\Diamond^*$: optimal value of the variable $\Diamond$;
- $N(k) \in \mathbb{N}$: MPC control and prediction horizon;
- $C_r \in \mathbb{R}^{2\times n}$: matrix that extracts position information from the state vector;
- $\mathbb{U}(j) \subset \mathbb{R}^p$: set of admissible control values at time $j$;
- $\mathbb{X}(j) \subset \mathbb{R}^n$: set of admissible state values at time $j$;
- $\mathbb{Q}(N(k)+1) \subset \mathbb{R}^n$: set of terminal state values at the end of the horizon;
- $\mathcal{Z}_m \subset \mathbb{R}^2$: polygon defining the $m$-th obstacle;
- $V_i \in \mathbb{R}^2$: $i$-th vertex in the planned path;
- $\bar{N} \in \mathbb{N}$: maximal horizon in the one-step formulation;
- $\bar{N}_P \in \mathbb{N}$: maximal horizon between waypoints;
- $N_{WP} \in \mathbb{N}$: number of waypoints;
- $N_{obs} \in \mathbb{N}$: number of obstacles;
- $N_f \in \mathbb{N}$: number of sides in each obstacle;
- $N_V \in \mathbb{N}$: number of vertices in the planned path;
- $\alpha_i \in \mathbb{R}$: variable that determines the position of the $i$-th waypoint along the planned path;
- $M \in \mathbb{R}_+$: constant large enough to make terminal constraints inactive;
- $M_x \in \mathbb{R}_+$: constant large enough to make state constraints inactive;
- $M_u \in \mathbb{R}_+$: constant large enough to make control constraints inactive;
- $M_{obs} \in \mathbb{R}_+$: constant large enough to make obstacle avoidance constraints inactive;
- $M_{WP} \in \mathbb{R}_+$: constant large enough to make waypoint location constraints inactive;
- $r_x \in \mathbb{R}$: position along a coordinate axis in a horizontal plane regarding an arbitrary origin;
- $r_y \in \mathbb{R}$: position along a coordinate axis (perpendicular to the first) in a horizontal plane regarding an arbitrary origin;
- $v_x \in \mathbb{R}$: velocity regarding the $r_x$ position;
- $v_y \in \mathbb{R}$: velocity regarding the $r_y$ position;
- $a_x \in \mathbb{R}$: acceleration regarding the $v_x$ velocity;
- $a_y \in \mathbb{R}$: acceleration regarding the $v_y$ velocity;
- $\gamma \in \mathbb{R}$: weight of the term associated to the fuel consumption in the cost function;
- $\mathbf{1}_\Diamond \in \mathbb{R}^\Diamond$: column vector of $\Diamond$ elements equal to 1;
- $\|\Diamond\|_1$: 1-norm of the vector $\Diamond$.

## II. Predictive Control

As depicted in Fig. 1, the basic elements of a predictive controller operating in discrete time are:

- A model used to predict the state of the plant over a horizon of $N$ steps in the future, based on the current state $x(k)$ and the control sequence $\{\hat{u}(k+j|k)\},\ j = 0,\ldots,N-1$ to be applied.
- An algorithm to optimize the control sequence regarding the cost function specified for the problem and the existing constraints on inputs and states of the plant.

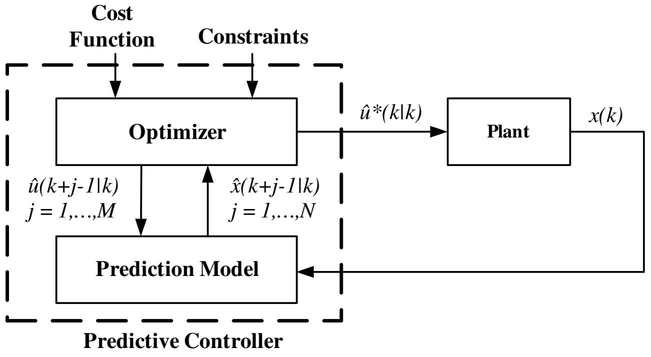

Fig. 1. Predictive control loop using state feedback.

In [3] the cost function is of the form:

$$J\left[\hat{x}(\cdot|k),\hat{u}(\cdot|k),N(k)\right] = \sum_{j=0}^{N(k)} \left(1+\gamma\left\|\hat{u}(k+j|k)\right\|_1\right),\ \ \gamma > 0 \tag{1}$$

subject to

$$\hat{x}(k+j|k) = \left\{ \begin{array}{l} x(k),\ j=0 \\ A\hat{x}(k+j-1|k) + B\hat{u}(k+j-1|k),\ j>0 \end{array} \right. \tag{2a}$$

$$\hat{x}(k+j|k) \in \mathbb{X}(j),\ \ j = 1,\ldots,N(k) \tag{2b}$$

$$\hat{u}(k+j|k) \in \mathbb{U}(j),\ \ j = 0,\ldots,N(k) \tag{2c}$$

$$\hat{x}(k+N(k)+1|k) \in \mathbb{Q}(N(k)+1) \tag{2d}$$

In the present work, robustness to unknown disturbances is not addressed in order to simplify the presentation of the main contribution, which will be stated in Section III. Therefore, the dependence of the sets $\mathbb{X}$, $\mathbb{U}$ and $\mathbb{Q}$ on $j$ and $N(k)$ is disregarded.

It can be seen from Eq. (1) that a compromise between the time to reach the terminal set and the fuel spent during the task is achieved by penalizing the time in the first term of the cost function and the fuel expense in the second. By manipulating the weight $\gamma$, the planner can be adjusted to put more emphasis in time minimization (small values of $\gamma$) or fuel expense minimization (large values of $\gamma$).

This cost is denoted simply by $J(k)$ to indicate that it is a function to be optimized at the sampling time $k$.

The optimal control sequence $\{\hat{u}^*(k+j|k), j = 0,\ldots,N(k)\}$ that minimizes the cost given by Eq. (1) subject to the constraints in Eqs. (2a), (2b), (2c) and (2d) usually cannot be analytically determined. Therefore, an optimization algorithm has to be used to obtain the control sequence subject to constraints. Customarily, an strategy known as "receding horizon" [2] is applied, i. e., only the first element of the control sequence is applied to the plant ($u(k) = \hat{u}^*(k|k)$) and the optimization is repeated at the next sampling time, making $u(k+1) = \hat{u}^*(k+1|k+1)$.

### *A. Horizon minimization*

If the terminal set is given in terms of linear constraints:

$$\begin{gathered} \mathbb{Q} = \{x : p_i^T x \le q_i,\ i = 1, \ldots, N_Q\}, \\ p_i \in \mathbb{R}^n,\ q_i \in \mathbb{R},\ i = 1, \ldots, N_Q \end{gathered} \tag{3}$$

then the terminal constraints can be rewritten as:

$$p_i^T \hat{x}(k+j+1|k) \le q_i + M[1 - b(j)],\ i = 1, \ldots, N_Q \tag{4}$$

with $b(j)$ defined as

$$b(j) = \begin{cases} 1, \text{ if } j = N(k), \\ 0, \text{ if } j \ne N(k) \end{cases} \tag{5}$$

The scalar $M$ must be taken so that $M > p_i^T x - q_i$, $\forall i$ for all admissible $x$ [4].

Thus, the cost can be recast in terms of a maximum preset value $\bar{N}$ for the horizon, that is

$$J(k) = \sum_{j=0}^{\bar{N}} \left(jb(j) + \gamma \left\|\hat{u}(k+j|k)\right\|_1\right) \tag{6}$$

subject to (4) with the following additional constraints:

$$\sum_{j=0}^{\bar{N}} b(j) = 1 \tag{7}$$

The cost expressed in Eq. (6) coincides with the one in Eq. (1) if the optimal value $N^*(k)$ for the horizon is less than or equal to $\bar{N}$ and the optimal control is null after $N^*(k)$, i. e., $\hat{u}^*(k+j|k) = 0,\ j > N^*(k)$. This last condition is guaranteed as the constraints in Eqs. (2b) and (2c) are imposed only up to the horizon $N^*(k)$. After this horizon, there is no constraint to be satisfied and thus the minimization of $\left\|\hat{u}(k+j|k)\right\|_1$ for $j > N^*(k)$ results in a zero control.

The state and control constraints up to the horizon $\bar{N}$ are rewritten in [3] using scalars large enough so that they become inactive after $N(k)$. Indeed, let the sets of admissible states and controls be

$$\begin{gathered} \mathbb{X} = \{x : r_{i,x}^T x \le q_i^x,\ i = 1, \ldots, N_x\}, \\ \mathbb{U} = \{u : r_{l,u}^T u \le q_l^u,\ l = 1, \ldots, N_u\}, \\ r_{i,x} \in \mathbb{R}^n,\ r_{l,u} \in \mathbb{R}^p,\ q_i^x,\ q_l^u \in \mathbb{R}, \\ i = 1, \ldots, N_x,\ l = 1, \ldots, N_u \end{gathered} \tag{8}$$

The constraints on the states and controls can then be rewritten as

$$\begin{aligned} & r_{i,x}^T \hat{x}(k+j|k) \le q_i^x + M_x \sum_{m=1}^{j-1} b(m),\ i = 1, \ldots, N_x \\ & r_{l,u}^T \hat{u}(k+j-1|k) \le q_l^u + M_u \sum_{m=1}^{j-1} b(m),\ l = 1, \ldots, N_u \end{aligned} \tag{9}$$

which makes the constraints inactive for $j > N(k)$ as $b(N(k)) = 1$. For this purpose, $M_x$ must be such that $M_x > r_{x,i}^T x - q_i^x$, $\forall i$, for all $x$ reachable in up to $\bar{N}$ steps from the terminal set with null control. $M_u$ is a scalar that renders the inequalities inactive for all admissible values of $u$.

Therefore the problem is defined with a fixed horizon $\bar{N}$ and a linear cost involving real and integer variables subject to linear constraints. Thus, algorithms for MILP can be used to obtain the optimal control sequence.

### *B. Obstacle avoidance*

Obstacles such as buildings, hills and dangerous areas to be avoided are commonly present in problems of vehicle guidance. The obstacle avoidance constraints lead to the loss of convexity of the optimization problem that has to be solved in order to calculate the control sequence. The present work adopts the formulation for the avoidance of obstacles presented in [5] and [3], which introduces a set of binary variables for each obstacle.

The constraint that the trajectory in space does not cross an obstacle can be written as $r = C_r x \notin \mathcal{Z}_m$, in which $\mathcal{Z}_m = \{r | P_m^{obs} r \le q_m^{obs}\}$. Without loss of generality, all obstacles will be assumed to have the same number of sides $N_f$. It is therefore required that the position $r$ is not in the sets $\mathcal{Z}_m$, $1 \le m \le N_{obs}$ at each sampling time, which is equivalent to imposing that the sets $\mathcal{I}_m = \{i \in \{1, \ldots, N_f\} : P_{i,m}^{obs} r > q_{i,m}^{obs}\} \ne \varnothing$, where $P_{i,m}$ is the $i$-th row of $P_m^{obs}$ and $q_{i,m}$, the $i$-th element of $q_m^{obs}$. To this end, binary variables can be used as follows:

$$\begin{aligned} & -P_{i,m}^{obs} r(k+j) \le -q_{i,m}^{obs} + M_{obs}[1 - b_{i,m}^{obs}(k+j)] - \epsilon \\ & \sum_{i=1}^{N_f} b_{i,m}^{obs}(k+j) \ge 1,\ b_{i,m}^{obs} \in \{0, 1\}, \\ & 1 \le j \le \bar{N},\ 1 \le m \le N_{obs} \end{aligned}$$

Thus, with a large enough scalar $M_{obs}$, when $b_{i,m}^{obs}(k+j) = 0$, the constraint becomes inactive. If $b_{i,m}^{obs}(k+j) = 1$, the constraint is effectively enforced. The condition $\sum_{i=1}^{N_f} b_{i,m}^{obs}(k+j) \ge 1$ requires that at least one of the constraints is active at every sampling time, ensuring that the position $r$ is "outside" the $m$-th obstacle. $\epsilon > 0$ is chosen arbitrarily small so that the inequality "$\le$" becomes "$<$", thus removing the border of the obstacle from the set of allowed positions.

## III. Trajectory planning Architecture

Path planning refers to the search for a curve in two or three dimensions connecting the starting point to the goal point or terminal set and avoiding obstacles. If the planning is successful, a set of positions that the vehicle must occupy to reach the destination is produced. However, the dynamic constraints of the vehicle are not taken into account. In contrast, the problem of trajectory planning includes dynamic constraints. So the result must also include a sequence of velocity vectors associated to the position of the vehicle.

In the context of aircraft guidance and control, the path planning involves a number of issues in addition to the avoidance of obstacles. Such issues include the presence of dynamic constraints, usually in the form of velocity and acceleration limits, the need for a feedback control strategy in real time in order to make the system robust to atmospheric disturbances, and constraints on the amount of fuel available to execute the maneuver. These factors contribute to increase the complexity of trajectory planning and control of aircraft in the presence of obstacles, often making the problem computationally intractable. This limits the application of established algorithms that have been developed in robotics and path planning for land vehicles [6].

Among the possible solutions for this problem, one that enjoys relative success divides the planning and control in hierarchical levels, counting often with layers that employ heuristics to reduce the computational load [6]. Thus, on the upper level, planning is carried out, in which dynamic constraints may be included and which may rely on some optimization criterion. Then, if the dynamic constraints have not yet been considered, it proceeds to a smoothing of the path to adapt to these constraints when possible and discarding it otherwise. The next step is the addition of time tags to the path, obtaining a trajectory. At this stage, one can employ some kind of optimality criterion to define the trajectory. Finally, this trajectory is used to generate references to the feedback controller. Also, criteria for an optimal control solution can be adopted. In this context, [6] presents a thorough review of the literature.

The technique proposed in the present paper involves three layers, namely:

1) A path planner which produces a path composed of the connection of successive straight-line segments connecting the initial position to the target set, while avoiding obstacles. Dynamics constraints are not considered in this layer.
2) A trajectory planner which determines waypoints along the planned path obtained from the first layer. The determination of the waypoints is done considering the dynamic constraints of the vehicle, the existence of obstacles, the arrival at the target set in finite time and the capacity to reach each waypoint from the previous one within a fixed small horizon.
3) A Predictive Control layer which employs the waypoints determined during the second phase as targets of predictive control problems with small horizon, until the last one is reached and the target set can be reached within the small horizon. In this phase, the dynamic and obstacle avoidance constraints are again enforced.

In the present work, the path planner is not addressed and a path which satisfies the conditions described above is assumed available. For the purpose of obtaining such a path, many techniques may be used, such as Voronoi graphs, probabilistic roadmaps, $A^*$ search [7], and RRTs (Rapidly-exploring Random Trees) [8]. It is further assumed that the path is provided in the form of a sequence of vertices connected by straight-line segments.

The trajectory planning and control architecture adopted herein is depicted in Fig. 2. The dashed lines mark the blocks addressed in the present work. The MPC controller was discussed in the previous section. The trajectory planner provides a list of target waypoints in the order that should be followed to reach the final target set. The "Active target selection logic" simply checks whether the position of the vehicle is equal to the waypoint (up to a certain numerical tolerance); if true, the active target is the next waypoint in the sequence; otherwise, the active target remains the same. After the last waypoint is reached, the logic commutes to the final target set. Since the "Trajectory planner" passes only the waypoints to the control loop, and not every position, velocity and control signal used to reach them, and since the controller cost function and the planner one can be different, the planned trajectory and the one that is actually followed may in general present differences.

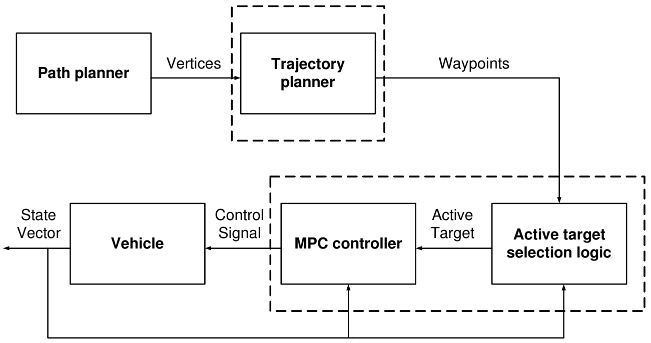

Fig. 2. Trajectory planning and control architecture used in this work.

## IV. Proposed trajectory planning technique

The technique proposed in this paper for trajectory planning involves the determination of a preset number of waypoints. These are scattered between the initial position of the vehicle and the terminal set. Their determination considers a horizon shorter than the one necessary to reach the terminal set from the initial state. Therefore, computational burden is expected to be lighter.

In order to limit the search space of solutions, the waypoints are constrained to a previously planned path, given in terms of the vertices of a sequence of straight-line segments which constitute a collision-free path from the initial position of the vehicle to the target set. This turns the problem of searching a two-dimensional space for a solution to a one-dimensional search over a piecewise linear curve.

In addition, the obstacle avoidance constraints are enforced in the optimal determination of the positions of the waypoints along the planned path in order to ensure the existence of collision-free trajectories between the waypoints. The problem of determining waypoint positions along the planned path composed of straight-line segments, avoiding obstacles and leading to the terminal set can be posed as follows:

*Problem 4.1:* Let $N_{WP}$, $\bar{N}_P$, $N_{obs}$, $N_f$, and $\{V_i\}$, $i = 1, \ldots, N_V + 1$ be the preset number of waypoints, the maximal horizon to reach an waypoint from the previous one, the number of obstacles, the number of sides of each obstacle, and the ordered sequence of vertices whose connection via straight-line segments produces the collision-free path ($V_1$ is the initial position of the vehicle), respectively. The waypoint determination problem is stated as

$$\min_{\hat{u}(k+j|k),\, \alpha_i,\, b_l^{obs},\, b_{i,j}^{WP}} \sum_{i=1}^{N_{WP}} \alpha_i + \mu \sum_{i=1}^{N_{WP}} \sum_{j=1}^{N_V} j b_{i,j}^{WP} \tag{10}$$

s.t.

$$\begin{aligned} &\hat{r}(k+i\bar{N}_P|k) \leq (\alpha_i - N_V + j)V_{j+1} + \\ &+ \left[1 - (\alpha_i - N_V + j)\right] V_j + M_{WP}(1 - b_{i,j}^{WP}), \\ &1 \leq i \leq N_{WP},\ 1 \leq j \leq N_V \end{aligned} \tag{11a}$$

$$\begin{aligned} &-\hat{r}(k+i\bar{N}_P|k) \leq -\left\{(\alpha_i - N_V + j)V_{j+1} + \right. \\ &\left. + \left[1 - (\alpha_i - N_V + j)\right] V_j + M_{WP}(1 - b_{i,j}^{WP})\right\}, \\ &1 \leq i \leq N_{WP},\ 1 \leq j \leq N_V \end{aligned} \tag{11b}$$

$$\sum_{j=1}^{N_V} (N_V - j) b_{i,j}^{WP} \leq \alpha_i,\ 1 \leq i \leq N_{WP} \tag{11c}$$

$$\begin{aligned} &\sum_{j=1}^{N_V} b_{i,j}^{WP} = 1,\ 1 \leq i \leq N_{WP} \\ &b_{i,j}^{WP} \in \{0,1\},\ 1 \leq i \leq N_{WP},\ 1 \leq j \leq N_V \end{aligned} \tag{11d}$$

$$0 \leq \alpha_{N_{WP}} \leq \alpha_{N_{WP}-1} \leq \cdots \leq \alpha_1 \leq N_V \tag{11e}$$

$$\hat{x}(k + (N_{WP}+1)\bar{N}_P|k) \in \mathbb{Q} \tag{11f}$$

$$\hat{u}(k+j|k) \in \mathbb{U},\ 0 \leq j \leq (N_{WP}+1)\bar{N}_P - 1 \tag{11g}$$

$$\hat{x}(k+j|k) \in \mathbb{X},\ 1 \leq j \leq (N_{WP}+1)\bar{N}_P - 1 \tag{11h}$$

$$P_m^{obs}\hat{x}(k+j|k) \leq -q_m^{obs} + M_{obs}(\mathbf{1}_{N_f} - b_m^{obs}(k+j|k)) \tag{11i}$$

$$\begin{aligned} &\sum_{l=1}^{N_f} b_{l,m}^{obs}(k+j|k) \geq 1,\ b_{l,m}^{obs}(k+j|k) \in \{0,1\}, \\ &1 \leq j \leq (N_{WP}+1)\bar{N}_P,\ 1 \leq m \leq N_{obs} \end{aligned} \tag{11j}$$

where $\mu > 0$ is a scalar, $\hat{r}(k+i\bar{N}_P|k) = C_r\hat{x}(k+i\bar{N}_P|k)$ is the predicted position at the sampling time $(k+i\bar{N}_P)$, and $P_m^{obs}$, $q_m^{obs}$, and $M_{obs}$ are defined as in section II-B.

The binary variables $b_{i,j}^{WP}$ are used to make the constraints in Eqs. (11a) and (11b) active or inactive. If $b_{i,j}^{WP} = 1$, then the inequalities (11a) and (11b) are active, which imposes an equality constraint restricting the position of the $i$-th waypoint to the straight-line segment between the $j$-th and $(j+1)$-th vertices. Otherwise, if $b_{i,j}^{WP} = 0$, the inequalities (11a) and (11b) are inactive for the particular values of $i$ and $j$, meaning that the $i$-th waypoint is not located in the straight-line segment between the $j$-th and $(j+1)$-th vertices. For this purpose, the scalar $M_{WP}$ is chosen large enough to render the constraints in Eqs. (11a) and (11b) inactive.

The inequalities in Eqs. (11a), (11b), (11c) and (11e) along with the equality in Eq. (11d) impose that the positions of the waypoints remain in one of the straight-line segments that compose the planned path. If $N_V - j \leq \alpha_i \leq N_V - j + 1$, then the $i$-th waypoint is located in the straight-line segment between vertices $V_j$ and $V_{j+1}$. For instance, if $\alpha_i = N_V - j$, then the $i$-th waypoint is exactly at the $j$-th vertex of the planned path.

The first term of the cost function in Eq. (10) aims at minimizing the values of $\alpha_i$, $1 \leq i \leq N_{WP}$, which prioritizes solutions that locate the waypoints farther from the initial position and closer to the terminal set, in order to avoid low initial speeds. The second term is introduced in order to obtain the maximal possible value to the term $(N_V - j)b_{i,j}^{WP}$, $1 \leq j \leq N_V$. As a consequence, the value of $(N_V - j)b_{i,j}^{WP}$ resulting from the minimization of this term subject to the constraint in Eq. (11c) is the greatest integer which is smaller or equal to $\alpha_i$ for any positive value of the scalar $\mu$. This, in turn, means that the term $(\alpha_i - N_V + j)$ in the constraints (11a) and (11b) is restricted to the set $[0, 1)$, thus resulting in a position between $V_j$ and $V_{j+1}$ for the $i$-th waypoint.

The resulting values of $\alpha_i$, $1 \leq i \leq N_{WP}$ correspond to the positions of the waypoints between the initial position and the last vertex, each farther from the initial position than the one before. The last waypoint is chosen so that it is possible to reach the terminal set $\mathbb{Q}$ from this position within the horizon $\bar{N}_P$.

An example is presented in Fig. 3, in which two waypoints were used with a horizon $\bar{N}_P = 10$ for the system dynamics that will be described in Section V. The planned path contains three vertices ($N_V = 2$, since the initial position is an additional vertex): $V_1 = [0\ \ 0]^T$ (initial position), $V_2 = [1.2\ \ 0.4]^T$ (intermediate vertex) and $V_3 = [1.6\ \ 1.5]^T$ (vertex in the border of the target set). The values for $\alpha_1$ and $\alpha_2$ were 1.583 and 0.385, respectively. This means that the first waypoint should be between the vertices $V_1$ and $V_2$ and the second, between $V_2$ and $V_3$, which can be corroborated by the resulting positions of the waypoints depicted in Fig. 3.

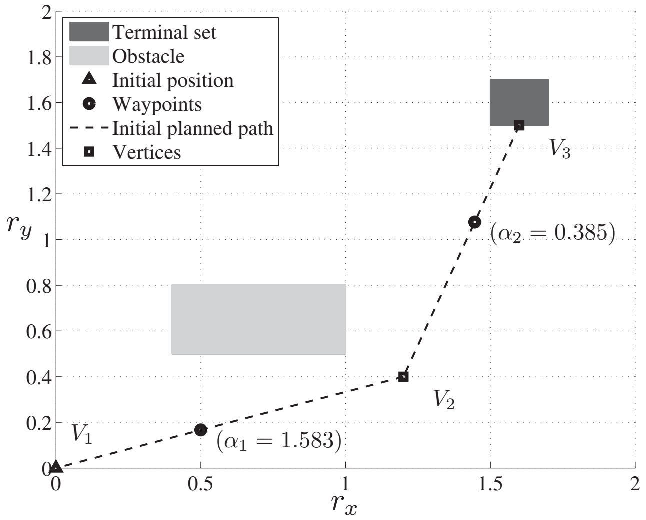

Fig. 3. Example of determination of the waypoints.

## V. Simulation scenarios

A kinematic model describing the movement of a vehicle in two dimensions was employed for simulation. The continuous-time model equations are:

$$\dot{r}_x = v_x,\ \dot{v}_x = a_x,\ \dot{r}_y = v_y,\ \dot{v}_y = a_y \tag{12}$$

where $r_x$ and $r_y$ define the position of the vehicle in a horizontal plane with respect to an arbitrary origin. This equation can be recast in state-space form ($\dot{x} = A_c x + B_c u$) by defining the state and control vectors as $x = [r_x \quad v_x \quad r_y \quad v_y]^T$, $u = [a_x \quad a_y]^T$. For use in the proposed MPC approach with trajectory planning, a discrete-time model of the form $x(k+1) = Ax(k) + Bu(k)$ was obtained with

$$A = \begin{bmatrix} 1 & T & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & T \\ 0 & 0 & 0 & 1 \end{bmatrix}, B = \begin{bmatrix} 0.5T^2 & 0 \\ T & 0 \\ 0 & 0.5T^2 \\ 0 & T \end{bmatrix} \tag{13}$$

in which $T$ is the sampling period. For the simulations in this paper $T$ was normalized to one time unit.

The dynamical constraints imposed on the velocities are $-1 \leq x_2,\, x_4 \leq 1$. As for the accelerations, $-1 \leq u_1,\, u_2 \leq 1$. Constraints $0 \leq x_1,\, x_3 \leq 2$ were also imposed on the position in order to limit it to the known terrain, over which information was assumed to be available.

The initial state of the vehicle was arbitrarily set to $x_0^T = [0\ 0\ 0\ 0]^T$, i. e., it started at rest. The goal was to reach a terminal set in the form of a rectangle described by the following inequalities on the positions $1.5 \leq x_1,\, x_3 \leq 1.7$.

As for the obstacles, they were also represented as rectangles with $0.6 \leq x_1^1, x_1^2 \leq 1$, $0.1 \leq x_3^1 \leq 0.8$, and $1.2 \leq x_3^1 \leq 1.6$, where the superscript refers to each of the two obstacles present in the simulations. It is worth noting that, since only the discrete-time predictions of the position are considered in the inequalities, this does not avoid stretches of the continuous-time trajectory crossing the obstacle. One alternative to handle this issue is proposed in [9], which involves incorporating restrictions on the transition of the vehicle to each region of the space defined by obstacle inequalities. However, it involves the introduction of more binary variables, increasing the complexity of the MILP problem. In this work, the length and width of the obstacle were expanded. To this end, an amount determined through the maximal admissible absolute value of the velocity in each axis was used to expand the borders of the obstacles. Therefore, the adopted avoidance constraints were constructed based on the following expanded obstacles: $0.5 \leq x_1^1, x_1^2 \leq 1.1$, $0 \leq x_3^1 \leq 0.9$, and $1.1 \leq x_3^1 \leq 1.7$.

The weight $\gamma$ of the fuel in the cost function was set to $0.1$. For the one-step solution, the maximal horizon was set to $\bar{N}_{OS} = 35$. Meanwhile, for the planner solution $\bar{N}_P = 8$ was adopted and the number of waypoints was set to $\bar{N}_{WP} = 3$. The computation times were taken as an average of 10 runs of each simulation, in order to eliminate fluctuations due to external factors. All simulations were carried out in a personal computer equipped with a Pentium$^{®}$ Dual-Core E5400 processor with $2.7GHz$ clock. For solution of the MILP, the CPLEX toolbox from IBM ILOG was used in Matlab environment, under an academic license.

## VI. Results and discussion

Initially, the simulation was carried out with the controller employing the one-step solution, i. e., trying to reach the terminal set from the beginning. The resulting path is presented in Fig. 4. The terminal set (dark gray rectangle) was reached successfully and the obstacles (light gray rectangles) were avoided. Moreover, as shown in Fig. 5, the accelerations $a_x$ and $a_y$ (which correspond to the controls $u_1$ and $u_2$, respectively) remained within the ±1 bounds. It took 24 sample periods to reach the terminal set from the starting position. The fuel cost was 28.4 and the average computation time was $17.72s$. The highest computational time was $4.22s$ and the mean computational time was $0.74s$. It can also be noted that a stretch of the continuous-time path crosses the prohibited region (black rectangle), but not the original obstacle. This justifies the choice to expand the original obstacle as means to avoid collisions.

The second simulation introduces the waypoint guidance using a previously planned path. An arbitrary path that connects the initial position to the terminal set while avoiding obstacles was employed for illustration, as shown in Fig. 6. The terminal set was reached successfully and the obstacles were avoided. Again, as shown in Fig. 7, the accelerations $a_x$ and $a_y$ remained within the ±1 bounds. It took 32 sample periods from the initial position to the terminal set. The planning phase lasted $0.33s$. The maximal computational time in the control phase was $0.18s$ and the mean was $0.08s$. Therefore, the total time to plan and execute the trajectory was about $3.03s$, which is much smaller than the time required by the one-step planner. The fuel cost was 52.57, which is larger than the one obtained with the one-step solution. In fact, since the waypoints are restricted to the previously planned

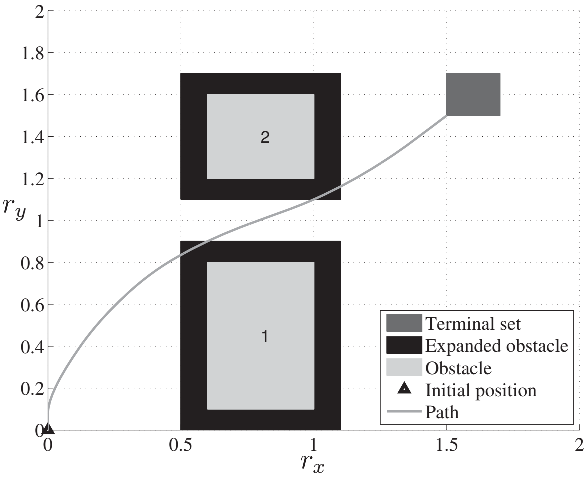

Fig. 4. Path obtained with one-step solution.

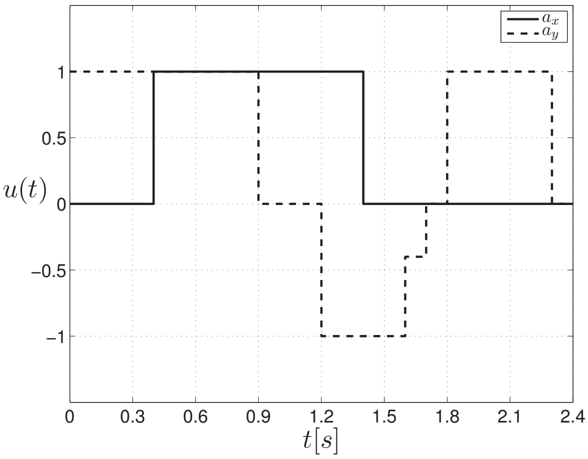

Fig. 5. Control signal obtained with one-step solution.

path that avoids the obstacles, and the horizon is shorter, the minimization of the fuel expense is compromised. It is interesting to note that the path does not cross the prohibited region, due to the fact that the waypoints steer the trajectory to the planned path, which is distant from the expanded obstacles. If the path planner emphasizes a safe path instead of the one that demands less fuel or the shortest one, it is likely to obtain a safer trajectory at the cost of a larger fuel consumption.

## VII. Conclusions

The proposed trajectory planning approach conduced to a feasible trajectory and reduced considerably the computational burden. The results showed also that a compromise between optimality and computation time can be inferred. This is suggested by the greater fuel cost and maneuver time obtained with the proposed approach as compared to the one-step MILP approach.

Future works could include a formulation which provides robustness to an unknown but limited disturbance in the trajectory planning phase, as was done in [3] for the MPC MILP formulation.

***Abstract*—In this work, a Predictive Control formulation for trajectory planning with multiple target sets is proposed, which solves the problem of performing all tasks in finite time via minimization of a weighted-time-fuel cost function, generating a feasible trajectory. An approach involving a procedure to order the list of the target sets to be visited in terms of the distance between them is used for comparison and it is shown that the proposed technique outperforms this approach in terms of time and fuel spent to accomplish the mission.**

***Index Terms*—Predictive control, trajectory planning, target set.**

## I. Introduction

In the context of aircraft guidance and control, the path planning problem becomes more complex than the simple search for a curve that connects the starting point to the goal while avoiding obstacles. Some of the reasons for that include the presence of dynamic constraints, usually in the form of velocity and acceleration limits, the need for a feedback control strategy in real time in order to make the system robust to atmospheric disturbances, and constraints on the amount of fuel available to execute the maneuver [1].

Model-based Predictive Control (MPC) techniques have been increasingly employed in the aeronautical industry [2] due to their ability to handle constraints on inputs and states of the plant [3]. More recently, MPC formulations as the one proposed in [4] have been used to perform trajectory planning for autonomous vehicles. Many particularities of the trajectory planning problem have been addressed in [4], namely the task of reaching a terminal set in finite time, while avoiding obstacles. Through the introduction of a variable horizon, it is possible to calculate the smallest horizon needed to reach the terminal set by solving a *Mixed Integer Linear Programming* (MILP) problem. Thus, a minimum time trajectory between a source point and a target set can be determined by using a kinematic model of the vehicle. Moreover, by enhancing the model with rigid body dynamics and characteristics of actuators, this problem can be extended to a more elaborate guidance and vehicle control framework. The MILP formulation also circumvents the difficulties brought about by the introduction of obstacles, particularly the loss of convexity of the set of admissible solutions.

However, a mission may require that the vehicle visits a number of sets. In this scenario, it may be convenient to consider all sets in the trajectory planning in order to minimize the total time to carry out all the tasks (visit all the target sets), instead of setting a single target set to be reached at every step.

In the present work a formulation to solve the trajectory planning problem with multiple target sets (termed Multitask Trajectory Planning) in the presence of obstacles is proposed. Simulation results with a fictional vehicle are presented in order to illustrate the success of the proposed technique. For comparison, the formulation presented in [4] with a single terminal target set was used with a list of sets to be visited, which was updated upon reaching each one of them. This list was ordered according to a criterion based on minimal distance between the initial position of the vehicle and the first target set as well as between the current target set and the next one.

The remainder of this paper is organized as follows. In Section II, the Predictive Control formulation adopted in the present work and proposed in [4] is presented, which involves minimizing a weighted-time-fuel cost function that penalizes the time to reach a given terminal set in the presence of obstacles. The approach for trajectory planning with multiple target sets is proposed later in Section III. Section IV presents the set ordering technique used for comparison. Simulation results of the application of both approaches are presented and discussed in Section V. Finally, conclusions are drawn and suggestions for future work are given in Section VI.

## II. MPC Formulation

The formulation employed in this work is similar to the one adopted in [4], with exception of the contribution related to the inclusion of multiple target sets, which will be introduced in Section III. The problem is recast in a *Mixed-Integer Linear Programming* (MILP) form much in the same way as in [4], again with exception of the inclusion of multiple target sets in Section III.

Figure 1 presents the basic elements of a predictive controller operating in discrete time, namely:

- A model used to predict the state of the plant over a horizon of $N$ steps in the future, based on the current state $x(k)$ and the control sequence $\{\hat{u}(k+j|k)\},\ j = 0, \ldots, N-1$ to be applied.
- An algorithm to optimize the control sequence regarding the cost function specified for the problem and the existing constraints on inputs and states of the plant.

The notation used is as follows: $u \in \mathbb{R}^p$ and $x \in \mathbb{R}^n$ denote the input and state variables of the plant, respectively. $\hat{\Diamond}(k +$

$j|k)$ denotes the predicted value of variable $\diamondsuit$ at time $k+j$ ($j \geq 1$) based on information available up to time $k$. The optimal control to be applied to the plant at time $k$ is denoted by $\hat{u}^*(k|k)$.

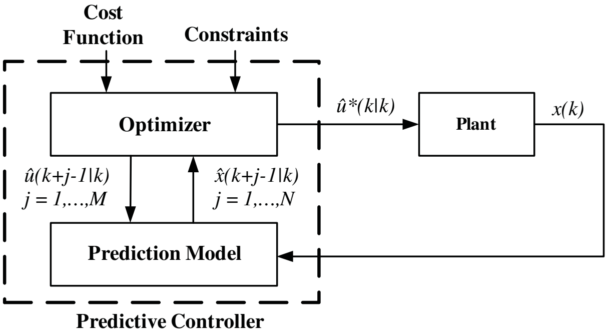

Fig. 1. Predictive control loop using state feedback.

In [4] the cost function is of the form:

$$J\left[\hat{x}(\cdot|k),\hat{u}(\cdot|k),N(k)\right] = \sum_{j=0}^{N(k)} \left(1 + \gamma \left\|\hat{u}(k+j|k)\right\|_1\right), \ \ \gamma > 0 \tag{1}$$

subject to

$$\hat{x}(k+j|k) = \begin{cases} x(k), \ j = 0 \\ A\hat{x}(k+j-1|k) + B\hat{u}(k+j-1|k), \ j > 0 \end{cases} \tag{2a}$$

$$\hat{x}(k+j|k) \in \mathbb{X}(j), \ \ j = 1, \ldots, N(k) \tag{2b}$$

$$\hat{u}(k+j|k) \in \mathbb{U}(j), \ \ j = 0, \ldots, N(k) \tag{2c}$$

$$\hat{x}(k+N(k)+1|k) \in \mathbb{Q}(N(k)+1) \tag{2d}$$

where $\mathbb{U}(j)$ and $\mathbb{X}(j)$ are the sets of admissible controls and states, respectively, and $\mathbb{Q}(N(k)+1)$ is the terminal set. In [4] the dependence of the sets $\mathbb{X}$, $\mathbb{U}$ and $\mathbb{Q}$ in terms of $j$ and $N(k)$ is inserted in order to provide robustness to an unknown but limited disturbance input. If this disturbance is disregarded, the sets are independent of time.

The first term of the cost function in Eq. (1) penalizes the time necessary to reach the target set. The second term, involving the norm of the control vector at each sampling time, penalizes the fuel spent. Thus, such a formulation provides a compromise between minimizing the time to achieve the goal and the fuel spent, which can be adjusted by the weight $\gamma$.

With a small abuse of notation, this cost is usually denoted simply by $J(k)$ in order to clarify that it is a function to be optimized at the $k$-th sampling time.

Optimization algorithms should be employed to obtain the optimal control sequence $\{\hat{u}^*(k+j|k), j = 0, \ldots, N(k)\}$ that minimizes the cost given by Eq. (1) subject to the constraints of Eqs. (2a), (2b), (2c) and (2d). The first element of such a sequence is applied to the plant (i. e., $u(k) = \hat{u}^*(k|k)$) and the optimization is repeated at the next sampling time, making $u(k{+}1) = \hat{u}^*(k{+}1|k{+}1)$. This strategy is known as "receding horizon" [5].

### A. Horizon minimization

If the terminal set is given in terms of linear inequalities

$$\begin{array}{c} \mathbb{Q} = \{x : p_i^T x \leq q_i, \, i = 1, \ldots, N_Q\}, \\ p_i \in \mathbb{R}^n, \, q_i \in \mathbb{R}, \, i = 1, \ldots, N_Q \end{array} \tag{3}$$

then the terminal constraints can be rewritten as:

$$p_i^T \hat{x}(k+j+1|k) \leq q_i + M[1 - b(j)], \, i = 1, \ldots, N_Q \tag{4}$$

where $M > 0$ is a constant and $b(j)$ is a binary decision variable defined as

$$b(j) = \begin{cases} 1, \text{ if } j = N(k), \\ 0, \text{ if } j \neq N(k) \end{cases} \tag{5}$$

The scalar $M$ must be taken so that $M > p_i^T x - q_i$, $\forall i$ for all admissible $x$ [6].

Thus, the cost can be recast in terms of a maximum preset value $\bar{N}$ for the horizon, that is

$$J(k) = \sum_{j=0}^{\bar{N}} \left(jb(j) + \gamma \left\|\hat{u}(k+j|k)\right\|_1\right) \tag{6}$$

subject to additional constraints

$$\sum_{j=0}^{\bar{N}} b(j) = 1 \tag{7}$$

The cost expressed in Eq. (6) coincides with the one in Eq. (1) if the optimal value $N^*(k)$ for the horizon is less than or equal to $\bar{N}$ and the optimal control is null after $N^*(k)$, i. e., $\hat{u}^*(k+j|k) = 0, \, j > N^*(k)$. This last condition is guaranteed as the constraints of equations (2b) and (2c) are imposed only up to the horizon $N^*(k)$. After this horizon, there is no constraint to be satisfied and thus the minimization of $\left\|\hat{u}(k+j|k)\right\|_1$ for $j > N^*(k)$ results in a zero control.

In [4] the state and control constraints are also rewritten up to the horizon $\bar{N}$ using scalars large enough so that they become inactive after $N(k)$. Indeed, let the sets of admissible states and controls be

$$\begin{array}{c} \mathbb{X} = \{x : r_{i,x}^T x \leq q_i^x, \, i = 1, \ldots, N_x\}, \\ \mathbb{U} = \{u : r_{l,u}^T u \leq q_l^u, \, l = 1, \ldots, N_u\}, \\ r_{i,x} \in \mathbb{R}^n, \, r_{l,u} \in \mathbb{R}^p, \, q_i^x, \, q_l^u \in \mathbb{R}, \\ i = 1, \ldots, N_x, \, l = 1, \ldots, N_u \end{array} \tag{8}$$

The constraints on the states and controls can then be rewritten as

$$\begin{array}{c} r_{i,x}^T \hat{x}(k+j|k) \leq q_i^x + M_x \displaystyle\sum_{m=1}^{j-1} b(m), \, i = 1, \ldots, N_x \\ r_{l,u}^T \hat{u}(k+j-1|k) \leq q_l^u + M_u \displaystyle\sum_{m=1}^{j-1} b(m), \, l = 1, \ldots, N_u \end{array} \tag{9}$$

which makes the constraints inactive for $j > N(k)$ as $b(N(k)) = 1$. $M_x \in \mathbb{R}$ must be such that $M_x > r_{x,i}^T x - q_i^x$, $\forall i$, for all $x$ reachable in up to $\bar{N}$ steps from the terminal set with null control. $M_u > 0$ is a scalar large enough to render the control constraints inactive for all admissible values of $u$.

Therefore the problem is defined with a fixed horizon $\bar{N}$ and a linear cost involving real and integer variables subject to linear constraints. Thus, algorithms for MILP can be used to obtain the optimal control sequence.

### *B. Obstacle avoidance*

In problems involving the guidance of vehicles, the presence of obstacles is usual, such as buildings, hills, dangerous areas to avoid, among others. In the presence of such obstacles the set of admissible states will no longer be convex. In [7], a form of dealing with polygonal obstacles through the use of MILP was proposed.

The constraint that the trajectory in space does not cross the obstacle can be written as $r = C_r x \notin \mathcal{Z}$, in which matrix $C_r$ extracts the position information from the state vector and $\mathcal{Z} = \{r | P^o r \le q^o\}$ defines an obstacle in the form of a polygon with $N_f$ sides. It is therefore required that the position $r$ is not in the set $\mathcal{Z}$ at each sampling time, which is equivalent to imposing that the set $\mathcal{I} = \{i \in \{1, \ldots, N_f\} : P_i^o r > q_i^o\} \neq \varnothing$ where $P_i$ is the $i$-th row of $P^o$ and $q_i$, the $i$-th element of $q^o$. To this end, binary variables can be used as follows:

$$\begin{gathered} -P_i^o r(k+j) \le -q_i^o + M_o[1 - b_i^o(k+j)] - \epsilon \\ \sum_{i=1}^{N_f} b_i^o(k+j) \ge 1,\ b_i^o \in \{0,1\},\ 1 \le j \le N \end{gathered}$$

Thus, when $b_i^o(k+j) = 1$, the constraint is effectively enforced. If $b_i^o(k+j) = 0$, with a large enough scalar $M_o > 0$, the constraint becomes inactive. The condition $\sum_{i=1}^{N_f} b_i^o(k+j) \ge 1$ requires that at least one of the constraints is active at every sampling time, ensuring that the position $r$ is "outside" the obstacle. $\epsilon > 0$ is chosen arbitrarily small so that the inequality "$\le$" becomes "$<$", thus removing the border of the obstacle from the set of allowed positions.

## III. Proposed Multitask Trajectory Planning Technique

The contribution of the present paper is the proposition of a novel method to enhance the capability of the trajectory planning technique proposed in [4] to visit $N_{ts} \ge 1$ target sets $\mathbb{Q}_1, \mathbb{Q}_2, \ldots \mathbb{Q}_{N_{ts}}$. This inclusion is in accordance with real-world mission demands, which usually require that the autonomous vehicle visits more than one target. In this context, one alternative is to arrange all target sets in a sequence to be visited. This arrangement may be performed by considering some optimization criteria, such as minimal distance from the starting position of the vehicle to define the first set and then, minimal distance between sets, choosing the next set to be visited as the closest to the last visited one, until all sets have been included in the sequence. With this sequence at hand, one can divide the problem in $N_{ts}$ single-target trajectory planning problems and solve each of them using the framework proposed in [4]. Upon reaching the target set for the current problem, it is replaced with the subsequent one in the pre-established order. This procedure is repeated until the final target set is reached. However, this may not yield the minimum time or minimum fuel solution, since the criteria employed to order the list of target sets do not consider the dynamics of the vehicle and constraints over the variables. Therefore, a framework which is capable of considering multiple target sets within the solution of the Predictive Control trajectory planning problem may bring about interesting results regarding the optimal solution to the trajectory planning problem.

It is assumed that the $N_{ts}$ target sets are defined as in Eq. (3), in terms of linear inequalities:

$$\begin{gathered} \mathbb{Q}_h = \{x : p_{h,i}^T x \le q_{h,i},\ i = 1, \ldots, N_{Q_h}\}, \\ p_{h,i} \in \mathbb{R}^n,\ q_{h,i} \in \mathbb{R},\ i = 1, \ldots, N_{Q_h}, \\ h = 1, \ldots, N_{ts} \end{gathered} \tag{10}$$

in which $\mathbb{Q}_h$ is the $h$-th target set and $N_{Q_h}$ is the number of inequalities used to describe it.

Since the vehicle only needs to visit each target set at one sample time, the constraints can be rewritten as:

$$\begin{gathered} p_{h,i}^T \hat{x}(k+j+1|k) \le q_{h,i} + M[1 - b_h(j)], \\ i = 1, \ldots, N_{Q_h},\ h = 1, \ldots, N_{ts}. \end{gathered} \tag{11}$$

where $M > 0$ is a constant and $b_h(j)$ is a binary decision variable defined as

$$b_h(j) = \begin{cases} 1, \text{ if } j = N_h, \\ 0, \text{ if } j \neq N_h \end{cases} \tag{12}$$

in which $N_h$ is the number of sample times that the vehicle takes to reach the $h$-th target set from the current position. For example, if the vehicle takes 2 sample times to reach the first target set from the starting position and 3 more to go from the first target set to the second, then $N_1 = 2$ and $N_2 = 5$.

An auxiliary variable has to be introduced in order to consider the minimization of the horizon to visit all of the target sets. This variable in be defined as:

$$N_f = \max(N_h),\ h = 1, \ldots, N_{ts} \tag{13}$$

Through the introduction of a new sequence of binary variables $\{b_f(j),\ j = 1, \ldots, \bar{N}\}$, it is possible to penalize this horizon $N_f$ to visit all of the target sets by rewriting the cost function in Eq. (6) as:

$$J(k) = \sum_{j=0}^{\bar{N}} \left( j b_f(j) + \gamma \left\| \hat{u}(k+j|k) \right\|_1 \right) \tag{14}$$

with

$$b_f(j) = \begin{cases} 1, \text{ if } j = N_f, \\ 0, \text{ if } j \neq N_f \end{cases} \tag{15}$$

subject to additional constraints

$$\sum_{j=0}^{\bar{N}} b_h(j) = 1,\ h = 1, \ldots, N_{ts} \tag{16}$$

$$\sum_{j=0}^{\bar{N}} b_f(j) = 1, \tag{17}$$

$$b_f(j) \le \frac{\sum_{h=1}^{N_{ts}} \sum_{i=0}^{j} b_h(i)}{N_{ts}} \tag{18}$$

The constraint in Eq. (16) ensures that each target set is visited at least once, whereas the ones in Eqs. (17) and (18) make sure that the definitions of Eqs. (13) and (15) are applied.

The only step left is to remove the state and control constraints after $N_f$. This is performed by replacing $b(m)$ in Eq. (9) by $b_f(m)$:

$$\begin{aligned} r_{i,x}^T \hat{x}(k+j|k) &\leq q_i^x + M_x \sum_{m=1}^{j-1} b_f(m),\ i = 1,\ldots,N_x \\ r_{l,u}^T \hat{u}(k+j-1|k) &\leq q_l^u + M_u \sum_{m=1}^{j-1} b_f(m),\ l = 1,\ldots,N_u \end{aligned} \tag{19}$$

The formulation presented in this section allows for planning a trajectory which visits all the sets while minimizing the cost function penalizing the overall time taken to perform the mission and the amount of fuel spent. However, when receding horizon feedback control has to be implemented, it is important to have a logic which removes a set that has already been visited, in order to avoid visiting the same sets over and over. The algorithm described bellow is proposed to circumvent this issue. This algorithm has to be run at every sampling time before calculating the control sequence:

**Algorithm 1:** Remove a set from the list after visiting it

```
for $i = 1 \rightarrow N_{ts}$ do
    if $x(k) \in SetList(i)$ then
        $SetList \leftarrow SetList \backslash SetList(i)$
        $N_{ts} \leftarrow N_{ts} - 1$
    end if
end for
```

□

in which the list of sets to be visited is given by $SetList$. The $\diamondsuit\backslash\spadesuit$ operator removes a set $\spadesuit$ from a set list $\diamondsuit$. After removing a set from the list, the number of binary variables can be reduced, since there are less sets to visit, which in turn means less constraints to be imposed.

## IV. Minimum-distance Trajectory Planning Algorithm

In this Section a trajectory planning algorithm which divides the mission in several tasks is presented. This algorithm will be used for comparison with the technique proposed in Section III. It is basically composed of two parts:

1) Order the list of sets to visit according to the distance, i. e., the first set to be visited is the closest to the initial position, the second is the closest to the first, and so on.
2) Apply the formulation presented in [4] with the terminal set as the next to be visited in the ordered list, starting by the first and changing to the next subsequently after the current target is reached.

In the following, the first part will be detailed, as it is the most cumbersome one, since the second involves only a test of pertinence of a point to a set and an update to the list of target sets.

The first part can be divided into two main algorithms, requiring only a list of the $N_{ts}$ target sets ($SetList$) in arbitrary order. In the first algorithm (Algorithm 2), $x_0$ is the initial state and $C_r$, a matrix that extracts position information from the state vector, thus $C_r x_0$ is the initial position of the vehicle. $dist(\alpha,\Omega)$ is a function that returns the minimal distance between a point $\alpha$ and a set $\Omega$ (employing 2-norm):

$$\begin{aligned} dist(\alpha,\Omega) = \quad & \min\nolimits_{\alpha,\beta} \|\alpha - \beta\|_2 \\ & s.t.\ \beta \in \Omega \end{aligned} \tag{20}$$

If $\Omega$ is a convex polygon, $dist(\alpha,\Omega)$ can be evaluated by using a quadratic programming solver.

**Algorithm 2:** Determine the closest set to the initial position

```
$d \leftarrow \infty$
for $i = 1 \rightarrow N_{ts}$ do
    if $d \geq dist(C_r x_0, SetList(i))$ then
        $d \leftarrow dist(C_r x_0, SetList(i))$
        $ClosestSet \leftarrow i$
    end if
end for
$OrdList(1) \leftarrow SetList(ClosestSet)$
$SetList \leftarrow SetList \backslash SetList(ClosestSet)$
```

□

In the second algorithm (Algorithm 3), $N_{elem}(\diamondsuit)$ returns the number of target sets in the list $\diamondsuit$ and $dist(\Gamma,\Omega)$ is a function that returns the minimal distance (employing the 2-norm) between two sets $\Gamma$ and $\Omega$ (notice that the use of $dist(\cdot,\cdot)$ in the previous algorithm is a particular case in which the point $\alpha$ is the only element of the set $\Gamma$).

$$\begin{aligned} dist(\Gamma,\Omega) = \quad & \min\nolimits_{\alpha,\beta} \|\alpha - \beta\|_2 \\ & s.t.\ \alpha \in \Gamma,\ \beta \in \Omega \end{aligned} \tag{21}$$

If $\Gamma$ and $\Omega$ are convex polygons, $dist(\Gamma,\Omega)$ can be again evaluated by using a quadratic programming solver.

Figure 2 shows two examples of the use of $dist(\cdot,\cdot)$ to calculate the minimal distance between a point and a set (a) and between two sets (b).

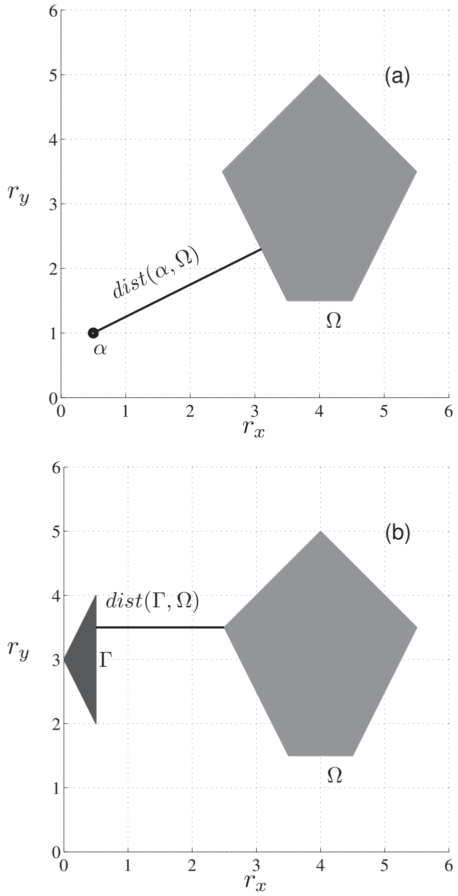

Fig. 2. Illustration of function $dist(\cdot,\cdot)$ involving (a) a point $\alpha$ and a set $\Omega$ and (b) two sets $\Gamma$ and $\Omega$.

**Algorithm 3:** Order the sets from the first to the last, based on smallest distance between them

```
$N_o \leftarrow 1$
while $N_{elem}(SetList) \neq 0$ do
    $d \leftarrow \infty$
    for $i = 1 \rightarrow N_{elem}(SetList)$ do
        if $d \geq dist(OrdList(N_o),SetList(i))$ then
            $d \leftarrow dist(OrdList(N_o),SetList(i))$
            $ClosestSet \leftarrow i$
        end if
    end for
    $OrdList(N_o + 1) \leftarrow SetList(ClosestSet)$
    $SetList \leftarrow SetList \backslash SetList(ClosestSet)$
    $N_o \leftarrow N_o + 1$
end while
```

□

By employing Algorithms 2 and 3, the result is an ordered list of the target sets $OrdList$ containing the set which is the closest to the initial position of the vehicle as its first element and the set that is the closest to the $i$-th set as the $(i+1)$-th element, for $i = 1,\ldots,N_{ts}-1$. This list may be used to provide the terminal target set for the trajectory planner formulation presented in [4]. An algorithm similar to Algorithm 1 may then be used to update the ordered list of sets to be visited ($OrdList$).

## V. RESULTS

This Section contains two subsections: the simulation scenario is described in Subsection V-A and the simulation results are presented and discussed in Subsection V-B.

### A. Simulation Scenario

A kinematic model describing the movement of a vehicle in two dimensions was employed for simulation. The continuous-time model equations are:

$$\dot{r}_x = v_x,\, \dot{v}_x = a_x,\, \dot{r}_y = v_y,\, \dot{v}_y = a_y \tag{22}$$

where $r_x$ and $r_y$ define the position of the vehicle in a horizontal plane with respect to an arbitrary origin. This equation can be recast in state-space form ($\dot{x} = A_c x + B_c u$) by defining the state and control vectors as

$$x = [r_x \quad v_x \quad r_y \quad v_y]^T, \quad u = [a_x \quad a_y]^T \tag{23}$$

For use in the proposed MPC approach with trajectory planning, a discrete-time model of the form $x(k+1) = Ax(k) + Bu(k)$ was obtained with

$$A = \begin{bmatrix} 1 & T & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & T \\ 0 & 0 & 0 & 1 \end{bmatrix}, B = \begin{bmatrix} 0.5T^2 & 0 \\ T & 0 \\ 0 & 0.5T^2 \\ 0 & T \end{bmatrix} \tag{24}$$

in which $T$ is the sampling period. For the simulations in this paper $T$ was normalized to one time unit.

The dynamical constraints imposed on the velocities were $-1 \leq x_2,\, x_4 \leq 1$. As for the accelerations, the imposed limits were $-5 \leq u_1,\, u_2 \leq 5$.

Constraints $0 \leq x_1,\, x_3 \leq 2$ were also imposed on the position in order to limit it to the known terrain, over which information was assumed to be available.

The initial state of the vehicle was arbitrarily set to $x_0^T = [0\ 0\ 0\ 0]^T$, i. e., it started at rest. The obstacle region was represented as a rectangle with $0.6 \leq x_1, x_3 \leq 1$. It is worth noting that, since only the discrete-time predictions of the position are considered in the inequalities, this does not avoid stretches of the continuous-time trajectory crossing the obstacle. One alternative to handle this issue is proposed in [8], which involves incorporating restrictions on the transition of the vehicle to each region of the space defined by obstacle inequalities. However, it entails the introduction of more binary variables, increasing the complexity of the MILP problem. As an alternative, in this work, the length and width of the obstacle were expanded. To this end, an amount determined through the maximal admissible absolute value of the velocity in each axis was used to expand the borders of the obstacle. Therefore, the adopted avoidance constraints were constructed based on the following expanded obstacle: $0.5 \leq x_1, x_3 \leq 1.1$.

The weight $\gamma$ of the fuel in the cost function was set to $0.1$. The maximal horizon was set to $\bar{N} = 35$. Two missions were simulated, each containing $N_{ts} = 3$ rectangular target sets. The inequalities describing the target sets are presented in Table I.

TABLE I
TARGET SETS OF THE TWO SIMULATED EXAMPLES

| Target set | Example | |
|---|---|---|
| | 1 | 2 |
| 1 | $0.2 \leq x_1 \leq 0.3$<br>$0.9 \leq x_3 \leq 1.0$ | $1.2 \leq x_1 \leq 1.3$<br>$0.8 \leq x_3 \leq 0.9$ |
| 2 | $0.5 \leq x_1 \leq 0.6$<br>$0.2 \leq x_3 \leq 0.3$ | $0.8 \leq x_1 \leq 0.9$<br>$1.7 \leq x_3 \leq 1.8$ |
| 3 | $1.2 \leq x_1 \leq 1.3$<br>$0.9 \leq x_3 \leq 1.0$ | $0.2 \leq x_1 \leq 0.3$<br>$0.7 \leq x_3 \leq 0.8$ |

All simulations were carried out in a personal computer equipped with a Pentium® Dual-Core E5400 processor with $2.7GHz$ clock. For solution of the MILP, the CPLEX toolbox from IBM ILOG was used in Matlab environment, under an academic license. The MPT toolbox [9] was employed to evaluate the $dist(\cdot,\cdot)$ function in Algorithms 2 and 3.

### B. Simulation Results

Figure 3 shows the trajectory in the horizontal plane obtained by employing the multitask planning technique with the target sets of Example 1 in Table I. It can be seen that all targets were visited once and the obstacle region was not crossed. It is worth remarking that the expanded obstacle region is crossed, but not the original obstacle, in agreement with the policy of expanding the obstacle in order to avoid collisions. From Table I, it is possible to note that the first visited target was target set number 2, the second was number 1 and the last, number 3. This shows that the order in which the targets are visited does not depend on the order that they are informed to the planner, because it chooses the visiting order in terms of the solution which provides the minimum cost as a compromise between the overall mission accomplishment time and the fuel spent. Moreover, as shown in Fig. 4, the accelerations $a_x$ and $a_y$ (which correspond to the controls $u_1$ and $u_2$, respectively) remained within the $\pm 5$ bounds.

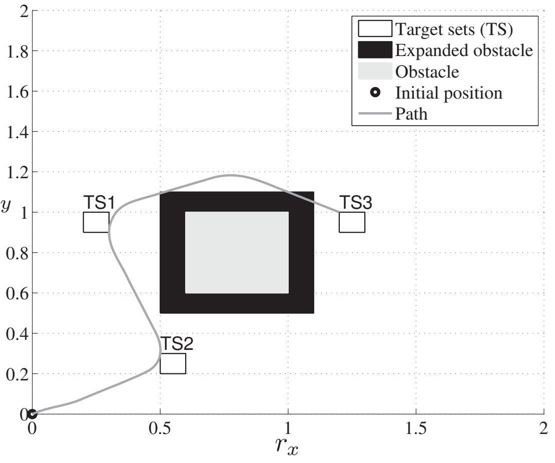

Fig. 3. Trajectory resulting from the use of the proposed multitask planning and control for Example 1.

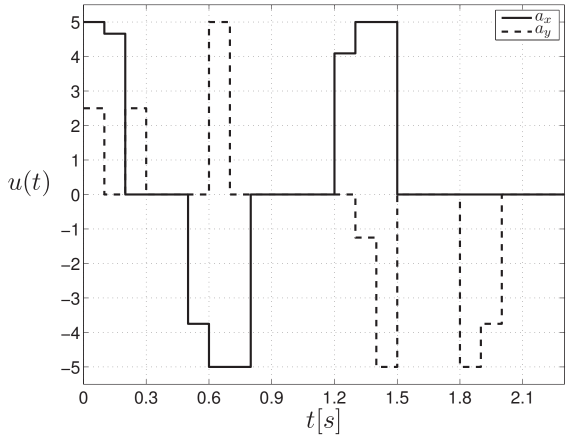

Fig. 4. Control action resulting from the use of the proposed multitask planning and control for Example 1.

The target sets were reached at times: $k = 7$, $k = 13$ and $k = 23$. The fuel cost was $62.50$ and the overall cost, $29.25$.

For comparison, Fig. 5 shows the trajectory in the horizontal plane generated by the minimum-distance trajectory planning algorithm described in Section IV. It can be seen that the minimum-distance choice for ordering the sets to be visited resulted in the same order as that of the multitask receding horizon planning and control shown in Fig. 3. However, the vehicle is now required to make a sharper turn after reaching the first target set and passes closer to the obstacle as compared to the first case, which is a result of the fact that the optimization is not global in this case, since the presence of a second target set is only informed for the planner/controller at the time the vehicle reaches the first target set. Again, as shown in Fig. 6, the accelerations $a_x$ and $a_y$ remained within the $\pm 5$ bounds.

The target sets were reached at times $k = 6$, $k = 14$ and $k = 26$. As can be seen, the overall time to accomplish the mission (26 sampling times) was three sampling times larger than the one observed with the multitask planning and control technique (23 sampling times). The fuel cost was $65.47$ and the overall cost was $32.55$, both larger than the corresponding values obtained with the multitask planning.

Figure 7 shows the trajectory in the horizontal plane obtained by using the multitask planning technique in Example 2. Again, the obstacle was not crossed and all targets were visited once. The first visited target was target set number 3, the second was number 2 and the last, number 1. It can be seen in Fig. 8 that the accelerations $a_x$ and $a_y$ remained within

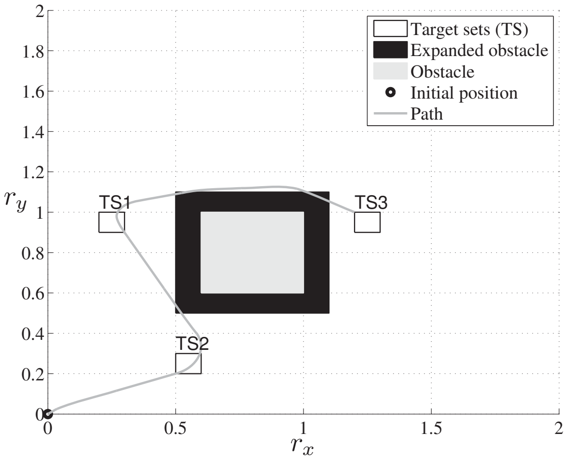

Fig. 5. Trajectory resulting from the use of the minimum-distance target ordering for Example 1.

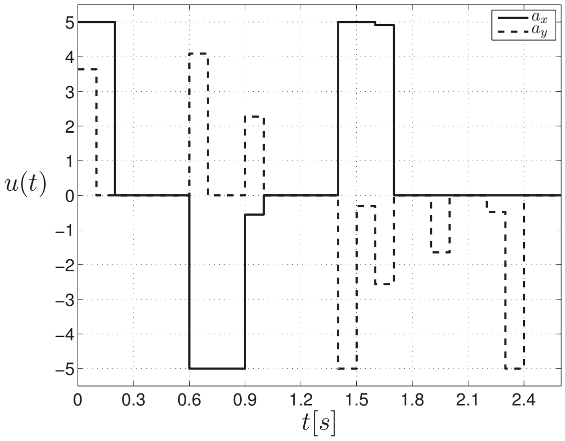

Fig. 6. Control action resulting from the use of the minimum-distance target ordering for Example 1.

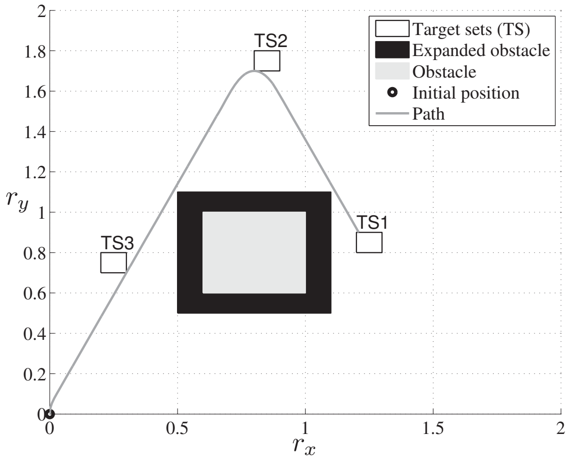

Fig. 7. Trajectory resulting from the use of the proposed multitask planning and control for Example 2.

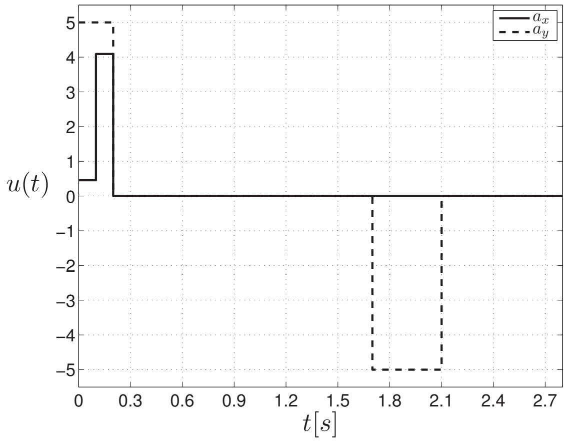

Fig. 8. Control action resulting from the use of the proposed multitask planning and control for Example 2.

the $\pm 5$ bounds.

The target sets were reached at times $k = 8$, $k = 19$ and $k = 28$. The fuel cost was $34.55$, which is smaller than the corresponding value obtained in Example 1. This can be explained by the fact that the resulting trajectory in this case is composed of two straight lines connected by a curve. The straight lines are more economic regarding the sum of the absolute values of the control signals, since no increment is necessary in these signals in order to travel along straight lines. The overall cost was $31.46$, larger than the one obtained in Example 1 due to the larger time necessary to accomplish the maneuver in this case.

For comparison, Fig. 9 depicts the trajectory in the horizontal plane resulting of the employment of the minimum-distance trajectory planning algorithm described in Section IV. It can be seen that the minimum-distance choice for ordering the sets to be visited resulted in a different order as that of the multitask receding horizon planning and control shown in Fig. 7. The first visited target was target set number 3, the second was number 1 and the last, number 2. Figure 10 shows the accelerations $a_x$ and $a_y$, which once again remained within the bounds $\pm 5$.

The target sets were reached at times $k = 8$, $k = 19$ and $k = 31$ sampling times, which gives an overall time to accomplish the mission three sampling times larger than the one observed with the multitask receding horizon planning and control. The fuel cost was $73.26$ and the overall cost was $38.33$, both larger than the ones obtained with the multitask planning. It is interesting to note that the trajectory in this case involves more curves than the one in Fig. 7, and even a reversion in the direction after reaching the target set number 1. This explains the larger fuel cost obtained with the minimum-distance order algorithm $(73.26)$ as compared to the one obtained with the multitask algorithm $(34.55)$.

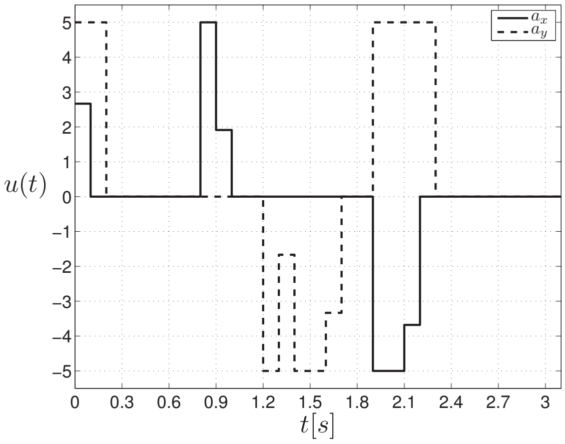

Fig. 10. Control action resulting from the use of the minimum-distance target ordering for Example 2.

## VI. Conclusions

This work proposed a novel formulation of a Predictive Control framework which builds upon the one presented in [4] in order to include multiple target sets in the optimization problem. In the context of autonomous vehicles, this is important due to the fact that some missions require the vehicle to visit a number of target sets.

Simulations were employed to validate the proposed technique. Another approach that first orders the list of sets to be visited based on a minimum-distance criterion and then uses each of them as a terminal target set in the formulation presented in [4] was used for comparison. The approach proposed in the present work outperformed the last one in terms of overall cost of the resulting trajectory.

Future works could include robustness regarding an unknown but limited disturbance to this multitask framework by using an adequate constraint tightening approach, as in [4].

***Abstract*—This article discusses the connectivity of autonomous mobile robots that do not have communication capabilities. We show that if the group members follow the proposed Local Steering Strategy, which utilizes information only about the relative positions of neighbor robots, they can sustain their connectivity, even in the case of bounded position measurement errors and the occultation of robots by other robots in the group. To reduce the computational burden in the implementation of the proposed methodology, we used sub-optimal solutions.**

***Index Terms*—Mobile robots, autonomous motion, connectivity**

## I. Introduction

One important aspect of the navigation of multiple autonomous mobile agents is how they maintain connectivity. Loosely speaking, the connectivity of a robot group means that each robot can be contacted by any other robot in the group, either directly or via other robots. The method of making contact may differ according to the characteristics of the individual agents. For instance, being able to establish communications via a standard channel of communication, being visible, or being detected by ultrasonic waves are various ways of being contacted, and thus of being connected.

The navigation of autonomous agents may be the primary or secondary task of a group, depending on the application. The transportation of a group of mine-digging robots from one site to another is an example of the latter, in which navigation is a secondary task. However, navigation is the primary task of robots in such missions as defense patrols or underwater exploring. In both cases, connectivity is of vital importance, since it reflects the unity of the group. Thus, connectivity and its maintainability are fundamental concepts in almost any study regarding the decentralized group motion of autonomous agents.

In this paper, we present a methodology for the navigation of autonomous robot groups which maintain group connectivity. We assume that the robots have position sensors of limited range and with bounded measurement errors, but no communication capabilities. In studies related to connected navigation and the group behavior of mobile robots, many authors *assume* group connectivity or communication within the group during the period of motion as a prerequisite for the success of their methods. For example, graph theory or potential field techniques are employed in this way in [1]–[10].

Graph theoretic approaches to maintain the connectivity of mobile agents are mainly based on the maximization of the second smallest eigenvalue (Fiedler value) of the Laplacian matrix of the graph [5]–[8], [11]. Even if this maximization can be accomplished in a distributed manner as suggested in [5], this does not eliminate the necessity of communications between the robots. For example, the method introduced in [5] requires some data to be obtained from neighbor robots to update components of the supergradient of the Laplacian which are computed locally, and [8] provides an extensive literature survey about group connectivity. Only a few studies, however, have focused on the maintenance of connectivity without relying on information exchange or communication between robots [12]–[14]. The algorithmic methodologies in these studies assume that the robots are points, and are designed to work only in $\mathbb{R}^2$ with perfect measurements via sensors.

The approach proposed in a recent work by the authors [15] results in the navigation of a robot group having dynamic topology using only limited-range position sensors with guaranteed connectivity. In [16], an ad hoc method was proposed to resolve possible deadlock cases. In this study, we present an extension of these results by including measurement errors and the occultation of the robots as well as a modification of the navigation strategy to eliminate any deadlock problems.

In the following section, we describe the agents in the group and define the related navigation problems. Section III gives an overview of our theorem on connectivity and discusses a local steering strategy used for maintaining connectivity. A sub-optimal approach to the implementation of this strategy is given in Section IV and tested by simulations in Section V. Lastly, Section VI offers concluding remarks on the study.

## II. Problem Formulation

The robots in this study are assumed to be physically identical, and each robot has the capability of moving in all directions and is equipped with limited-range position sensors. These sensors have a known degree of accuracy. We assume that the sensing capability is omnidirectional, but the sensor results can bear both angular and radial measurement errors.

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

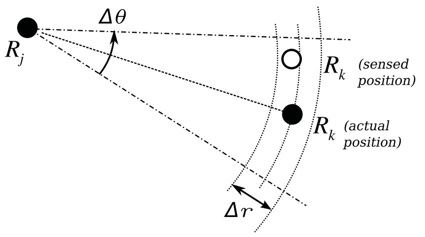

Fig. 1. Angular and radial measurement errors in $\mathbb{R}^2$

Fig. 1 depicts the bounds on the radial and angular components of position errors, $\Delta\theta$ and $\Delta r$, respectively.

It is important to note that sensing other robots means obtaining information about the position of the robots in the neighborhood via position sensors. We shall refer to such a mutual visibility between robots as a *link*. However, we should also note that such a link does not imply any communication or information exchange between the robots. As the robots move around, as long as they maintain visibility with their neighboring agents, they can avoid separating from the other robots, even if they do not communicate with them. Also, it should be pointed out that the robots have no labels, and as a result, sensing the other robots does not imply recognizing a specific robot.

Let us denote a group of autonomous mobile robots that are connected by links as discussed above as $\mathcal{G}$ and the robots in the group as $R_i$, $i = 1, \ldots, N$. Note that the subscripts are arbitrary and for the sake of analysis only. If we consider the robots $R_i, \ldots, R_N$ as vertices and the links between them as the edges of an undirected graph, group $\mathcal{G}$ will be *connected* if there is a path from any robot to any other robot in the group through the links [11]. A group which has at least one pair of robots without a path between them is therefore *disconnected.*

Since the range of the position sensors is limited, a robot may not sense all of the other robots in the group, especially when the total number of robots in the group is large. We refer to the set of robots sensed by $R_i$ as the subgroup $\mathcal{S}_i$. In this way, there are $N$ such subgroups of $\mathcal{G}$, and if $\mathcal{G}$ is connected, $\mathcal{S}_i$ $(i = 1, \ldots, N)$ are nonempty sets.

We denote the radius of the spherical region with $R_i$ at its center and which contains robots in $\mathcal{S}_i$ as $d_{max}$. In other words, $d_{max}$ is the maximum sensing distance for each robot. On the other hand, if the largest distance between the robots in $\mathcal{G}$ is denoted as $D_{max}$, $\mathcal{G}$ will be connected if $d_{max} \geq D_{max}$. However, nontrivial and more interesting cases emerge whenever $d_{max} \ll D_{max}$, which corresponds to groups of relatively large number of agents which have limited sensing ranges.

Fig. 2 depicts a group consisting of three robots. It is seen that $R_2 \in \mathcal{S}_1$, and $R_1 \in \mathcal{S}_2$, which means that $R_1$ and $R_2$ are linked. The links between $R_2$ and $R_3$ are formed likewise. Note that the robot $R_2$ has the position information of both $R_1$ and $R_3$, but $R_1$ and $R_3$ cannot sense each other, as the distance between them is larger than $d_{max}$.

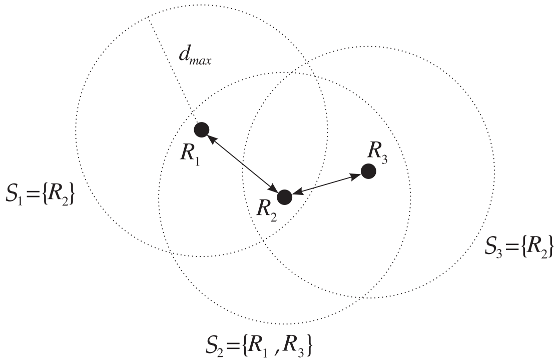

Fig. 2. A group of three robots and their subgroups

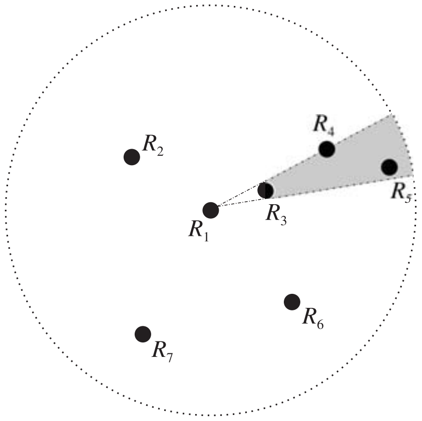

Fig. 3. $R_3$ occults $R_4$ and $R_5$ from $R_1$

In implementing position measurements, which could be performed using any kind of ultrasonic, laser or vision-based sensors, it is inevitable that some robots might occult others. In such a case, occulted robots are not sensed by another robot, say $R_1$ (and hence, are not in $\mathcal{S}_1$) although their distances to $R_1$ are less than $d_{max}$. Fig. 3 depicts an example of occulting in which the position measurements of $R_4$ and $R_5$ cannot be accomplished since $R_3$ prevents $R_4$ and $R_5$ from being "in sight" of $R_1$. Consequently, whenever occultation occurs, the positions of the occulted robots cannot be taken into account in the computation of local movement at that time instant.

Taking into account these sensory limitations and assuming that a set of mobile agents initially represents a connected group, our objective in this work is to develop a decentralized steering methodology that allows for the navigation of the group while preserving its connectivity without requiring any exchange of information between the robots.

In fact, once connectivity is assured, the target or navigation trajectory of the mission need not be known by all group members. It suffices if only one agent has this information [13]. We shall call this robot the *leader* of the group and denote it as $R_N$. Nevertheless, the leader has the same physical properties and capabilities as the other robots. The only difference is that the trajectory to be followed by the group is given to $R_N$. In fact, the leadership of the group is *hidden*. None of the robots recognize the leader as a distinguished group member. In other words, if $R_N$ is sensed by robot $R_j$, i.e. $R_N \in \mathcal{S}_j$, $R_j$ can only see it as one of its neighbors and the leadership of $R_N$ does not affect the local steering strategy of $R_j$.

In the following section, we consider the group of $N$ robots as having one leader, $R_N$, and $N-1$ *followers*, $R_j$ ($j = 1, \ldots, N-1$). Note that the indexing of robots is irrelevant as regards the problem under discussion and the solution we propose. Nonetheless, we utilize such a numbering of robots for the sake of notational simplicity.

## III. Autonomous Motion

Our goal is to develop a methodology for simple autonomous agents, such that a large group of them could navigate as a connected group. We assume that the robots update their information concerning the position of other robots within range of their sensors at every $\Delta t$ seconds. Also, to take into account measurement errors regarding distance, we define a positive scalar $d_m$ as

$$d_m \overset{def}{=} d_{max} - \Delta r$$

where $\Delta r$ is the bound of the distance measurement error with $d_{max} > \Delta r > 0$. We will denote the position of a robot $R_i$ at time $t$, as $X_i(t)$, $i = 1, \ldots, N$. Since all robots in the group move autonomously, we will set up local moving rules for each robot.

The motion of each robot is most conveniently described in terms of a coordinate system referring to itself, since each robot is at the center of its own local coordinate system. We denote the position vector in the local coordinates as $x(t)$ and use a notation such that the superscripts in $x$ indicate the robot to which the coordinate frame is attached, and the subscripts indicate which robot's position it represents. For example, $x_k^j$ represents the position vector of $R_k$ in the coordinate frame of $R_j$. For the robots in $\mathcal{S}_i$, $i = 1, \ldots, N$, we have

$$\|x_k^i(t)\| = \|X_k(t) - X_i(t)\| \leq d_m, \qquad k = 1, \ldots, M$$

where $M$ is the number of robots in $\mathcal{S}_i$. In the next section, we present a result on the sufficient conditions for the maintainability of connectivity.

### A. Main Theorem

According to the notation given above, $x_i^i(t+\Delta t)$ is the location, which $R_i$ targets (for the time instant $t+\Delta t$), in $R_i$'s own coordinate system at time $t$. For any $x_i^i(t+\Delta t)$, let us define two complementary subsets of $\mathcal{S}_i$ as

$$\begin{aligned}\mathcal{S}_{ip} &= \left\{R_p \in \mathcal{S}_i \mid [x_i^i(t+\Delta t)]^{\mathrm{T}} x_p^i(t) \leq 0\right\} \\ \mathcal{S}_{iq} &= \left\{R_q \in \mathcal{S}_i \mid [x_i^i(t+\Delta t)]^{\mathrm{T}} x_q^i(t) > 0\right\}.\end{aligned}$$

This means that if a displacement of $R_i$ to $x_i^i(t+\Delta t)$ will take $R_i$ closer to a robot, then this robot will appear in $\mathcal{S}_{iq}$. Otherwise, it will be a member of $\mathcal{S}_{ip}$. Using, $\mathcal{S}_{ip}$, $\mathcal{S}_{iq}$ and also the notation defined above, we can state the following theorem on group connectivity.

*Theorem 1:* Consider a group $\mathcal{G}$ of $N$ autonomous mobile robots which are connected at $t = 0$. If the motion of the robots is subject to the constraints

$$\|x_i^i(t+\Delta t)\| \;\leq\; \frac{1}{2}\left(d_m - \max_{R_p \in \mathcal{S}_{ip}} \|x_p^i(t)\|\right) \qquad (1)$$

and

$$\|x_i^i(t+\Delta t)\|^2 \;\leq\; \min_{R_q \in \mathcal{S}_{iq}} \left\{[x_i^i(t+\Delta t)]^{\mathrm{T}} x_q^i(t)\right\} \qquad (2)$$

for $i = 1, \ldots, N$, the group preserves its connectivity for $t > 0$.

*Proof:* Note that the position of each robot in $\mathcal{S}_i$ can constrain the motion of $R_i$ either via (1) or via (2), based on whether this robot appears in $\mathcal{S}_{ip}$ or $\mathcal{S}_{iq}$. Let $R_a$ and $R_b$ be any two robots within their mutual sensing range, that is, $R_a \in \mathcal{S}_b$ and $R_b \in \mathcal{S}_a$ at time $t$.

First, suppose that $R_b \in \mathcal{S}_{ap}$ and $R_a \in \mathcal{S}_{bp}$. Then, it follows from (1)

$$2\|x_a^a(t+\Delta t)\| + \max_p \|x_p^a(t)\| \leq d_m \qquad (3)$$

and

$$2\|x_b^b(t+\Delta t)\| + \max_p \|x_p^b(t)\| \leq d_m. \qquad (4)$$

Noting that $\max_p \|x_p^a(t)\| \geq \|x_b^a(t)\|$, $\max_p \|x_p^b(t)\| \geq \|x_a^b(t)\|$, and $\|x_b^a(t)\| = \|x_a^b(t)\|$, we obtain from (3) and (4),

$$\|x_a^a(t+\Delta t)\| + \|x_b^b(t+\Delta t)\| + \|x_b^a(t)\| \leq d_m.$$

Further, by triangle inequality, we get

$$\|x_a^a(t+\Delta t) - [x_b^a(t) + x_b^b(t+\Delta t)]\| \leq d_m. \qquad (5)$$

Note that the term $x_b^a(t) + x_b^b(t+\Delta t)$ is the position of $R_b$ at time $t+\Delta t$ as expressed in the local coordinate frame attached to $R_a$ at time $t$. Therefore, (5) shows that the distance between the robots $R_a$and $R_b$ will not be larger than $d_m$ at time $t+\Delta t$.

Next, we assume that $R_b \in \mathcal{S}_{aq}$ and $R_a \in \mathcal{S}_{bq}$. In this case, we have to proceed using the constraint in (2). Namely,

$$\|x_a^a(t+\Delta t)\|^2 \leq [x_a^a(t+\Delta t)]^{\mathrm{T}} x_b^a(t). \qquad (6)$$

Since

$$\left\|x_a^a(t+\Delta t) - \frac{x_b^a(t)}{2}\right\|^2 = \|x_a^a(t+\Delta t)\|^2 + \left\|\frac{x_b^a(t)}{2}\right\|^2 - [x_a^a(t+\Delta t)]^{\mathrm{T}} x_b^a(t), \qquad (7)$$

using (6), we obtain

$$\left\|x_a^a(t+\Delta t) - \frac{x_b^a(t)}{2}\right\| \leq \frac{\|x_b^a(t)\|}{2}. \qquad (8)$$

Noting that $x_b^a(t) = -x_a^b(t)$ and using the triangle inequality along with (8), it follows that

$$\begin{aligned}
&\|x_a^a(t+\Delta t) - [x_b^a(t) + x_b^b(t+\Delta t)]\| \\
&\quad = \left\| \left( x_a^a(t+\Delta t) - \frac{x_b^a(t)}{2} \right) - \left( x_b^b(t+\Delta t) - \frac{x_a^b(t)}{2} \right) \right\| \\
&\quad \le \left\| x_a^a(t+\Delta t) - \frac{x_b^a(t)}{2} \right\| + \left\| x_b^b(t+\Delta t) - \frac{x_a^b(t)}{2} \right\| \\
&\quad \le \|x_b^a(t)\| \\
&\quad \le d_m,
\end{aligned} \tag{9}$$

which asserts the link between $R_a$ and $R_b$ at time $t + \Delta t$ in the same way as (5).

To complete the proof, we also must analyze cases where $R_b \in \mathcal{S}_{aq}$ while $R_a \in \mathcal{S}_{bp}$, and $R_b \in \mathcal{S}_{ap}$ while $R_a \in \mathcal{S}_{bq}$. Without loss of generality, we consider only the former, since the proof for the latter can be obtained by an interchange of subscripts $a$ and $b$ only.

In other words, the motion of $R_a$ and $R_b$ will be constrained by (6) and (4), respectively. Similar to (7), we can state:

$$\begin{aligned}
&\|x_a^a(t+\Delta t) - x_b^a(t)\|^2 \\
&\quad = \ \|x_a^a(t+\Delta t)\|^2 + \|x_b^a(t)\|^2 - 2[x_a^a(t+\Delta t)]^{\mathrm{T}} x_b^a(t).
\end{aligned}$$

In light of (6), we get

$$\|x_a^a(t+\Delta t) - x_b^a(t)\| \le \|x_b^a(t)\|. \tag{10}$$

Therefore, (4) with (10) yields

$$2\|x_b^b(t+\Delta t)\| + \|x_a^a(t+\Delta t) - x_b^a(t)\| \le d_m$$

or

$$\|x_a^a(t+\Delta t) - x_b^a(t) - x_b^b(t+\Delta t)\| \le d_m - \|x_b^b(t+\Delta t)\|. \tag{11}$$

Hence, the validity of (5) is maintained in this case as well.

The results in (5), (9) and (11) show that any two robots $R_a \in \mathcal{S}_b$ and $R_b \in \mathcal{S}_a$ sensing each other at time $t$ will still be linked when they move to their new locations at $t + \Delta t$. Hence, we conclude that if the group is connected at $t = 0$, it will also be connected for $t > 0$. ■

Note that if a robot $R_i$ is occulted by another robot in $\mathcal{S}_i$, the number of robots in $\mathcal{S}_i$ might decrease. Nevertheless, this does not disturb the overall connectivity, as the existence of the occulting robot itself is the evidence of the connection between $R_i$ and the occulted robot.

### *B. Local Steering Strategy*

As long as the constraints in (1) and (2) are satisfied when a given navigation trajectory is followed, formation control and other mission-oriented tasks can be accomplished by minimizing suitable cost functions. Therefore, in view of Theorem 1, once group connectivity is assured by (1) and (2), the following Local Steering Strategy can be applied for navigation by a group which is composed of follower robots and a leader.

*Local Steering Strategy:* Subject to the constraints (1) and (2)

- The follower robots $R_j$ ($j = 1, \ldots, N-1$) move towards a target location $x_j^j(t+\Delta t)$, which minimizes the cost function $J(x_j^j(t+\Delta t))$ related to the positions of the robots in $\mathcal{S}_j$.
- The leader $R_N$ follows the navigation trajectory.

Several types of cost functions can be used in implementing the local steering strategy. An example may be given as

$$J(x_j^j(t+\Delta t)) = \max_k \|x_j^j(t+\Delta t) - x_k^j(t)\|, \tag{12}$$

which makes the $j^{\text{th}}$ robot try to decrease the distance to the farthest robot that it senses. Another possible approach could be to employ

$$J(x_j^j(t+\Delta t)) = \sum_{k=1}^{M} \Big( \|x_j^j(t+\Delta t) - x_k^j(t)\| - d_0 \Big)^2 \tag{13}$$

as the cost function in order to force the robots to keep their distances with the robots in their subgroups as close to a desired distance as possible. Here, $d_0$ ($d_0 < d_m$) denotes the desired distance.

Note that both (12) and (13) are defined in terms of local coordinates to ensure a distributed algorithm. The choice of suitable cost functions will depend on the requirements of the mission. It is possible to take into account fixed as well as time-varying cost functions, and these can incorporate the position information of all or only some of the neighbor agents. Furthermore, it is possible for each agent to minimize a different cost function.

Note that the constraint in (1) delimits the distance to be travelled by each robot at every sampling interval. It is a direct consequence of the requirement that the distance between any two robots that are connected at time $t$ must be less than $d_m$ at $t+\Delta t$, even in the worst case, which happens when the robots are moving in opposite directions. Therefore, (1) alone is sufficient to maintain connectivity. Nevertheless, it was shown in [15] and [16] that if the motion of the robots is constrained only by (1), the group may get stuck in situations where none of the robots can move. Such situations are called *deadlock*. A typical example of a deadlock is when all inter-robot distances are $d_{max}$, so that $\|x_i^i(t+\Delta t)\| = 0$, $i = 1, \ldots, N$ and, hence, none of the robots can move. In avoiding deadlocks, it is essential to allow the outermost robots in the group to move towards their neighbors. However, (1) depends only on the magnitude of $x_i^i(t+\Delta t)$ and does not account for its direction. The direction of $x_i^i(t+\Delta t)$ can be utilized by considering the neighbor robots in two distinct subsets as implied by (1) and (2). In fact, it is shown in [17] that the constraints (1) and (2) prevent deadlocks under reasonably mild conditions as regards the cost functions, which are fulfilled by, for example, those in (12) and (13).

## IV. A SUBOPTIMAL SOLUTION TO A LOCAL STEERING PROBLEM

The robots in this study are quite simple and limited devices especially from the computational point of view. Our purpose is to provide a decentralized control methodology which can be applied to such simple robots yet still lead to satisfactorily good group navigation. Below, we propose a gradient-descent-based iterative method to reduce the computational burden in the implementation of the Local Steering Strategy with the cost function in (13).

The minimum of the cost function given in (13) is the location to which follower robot $R_j$ aims to arrive at each sampling time. In a general case, the minimization of (13) subject to the constraints in (1) and (2) requires solving a set of nonlinear equations and this approach may result in several local minima, which should be further checked to ensure they are the absolute minimum. In other words, it requires high computational power, especially when the number of the robots in $\mathcal{S}_j$ increases.

It should be noted that the optimal points are computed for each follower robot $R_j$ at every sampling time. The location of the optimal points depends on the positions of the robots in the subgroup $\mathcal{S}_j$. Since the sensed robots in $\mathcal{S}_j$ also move autonomously, these local targets will be updated every $\Delta t$ sec, possibly before reaching them. Since (1) and (2) constrain the magnitude of $x_i^i(t+\Delta t)$, they will not be violated as the robots are moving towards their local targets. Hence, the solution will only provide a direction to the optimal points, because the solution will be updated before $R_j$ arrives at that location.

This fact can be exploited to introduce an iterative method to implement the Local Steering Strategy in a sub-optimal way. Rather than solving for the minimum points of the cost function, each robot $R_j$ can move in the direction of the negative gradient of the cost function, evaluated at the position of $R_j$ for each sampling instant. That is,

$$x_j^j(t+\Delta t) = x_j^j(t) - \gamma \left. \frac{\partial J(x_j^j(t+\Delta t))}{\partial x_j^j(t+\Delta t)} \right|_{x_j^j(t+\Delta t) = x_j^j(t)} \qquad (14)$$

where $\gamma > 0$ is a positive gain, and $x_j^j$ is the position vector of $R_j$ in its local coordinates. From (13), (14) and the fact that $x_j^j(t) = 0$, it follows that

$$x_j^j(t+\Delta t) = 2\gamma \sum_{k=1}^{M} \left( \|x_k^j(t)\| - d_0 \right) \frac{x_k^j(t)}{\|x_k^j(t)\|}. \qquad (15)$$

The gain $\gamma$ in (15) should be treated as a parameter by which one can choose the distance of the local target so as to satisfy the constraints in (1) and (2), rather than as a constant to be determined a priori. In that respect, there is no reason why $\gamma$ must be kept constant during navigation. Therefore, the direction of the next movement can be obtained by (15) and then implemented in this direction with a magnitude so as to satisfy the inequalities (1) and (2).

## V. Simulation Results

In this section, we present our computer simulations to verify the theoretical results of the previous sections. In the simulations, the working space was taken as a section of $xy$-plane in $\mathbb{R}^2$. The sensor range ($d_{max}$) was 15 units. The bounds on the measurement errors were $\Delta\theta = 12°$ for angle and $\Delta r = 0.03 d_{max}$ for distance measurements. The following scenario was applied: The leader was given a trajectory and as the leader started navigation, the rest of the group also moved so as to stay connected under the Local Steering Strategy. The simulation was done for a group consisting of 20 robots where (15) is used with $\gamma = 0.2$.

The snapshots of the simulation can be seen in Fig. 4. With the initial locations shown in Fig. 4 and $d_{max} = 15$, the group was connected and accommodated 62 links at the beginning. The trajectory of the leader is shown by the solid line through the graph. As soon as the simulation started with $d_0 = 11$, the group widened but kept its connectivity. Occulting happened rarely. For 20 robots, the maximum possible number of links is $20 \cdot (20-1)/2 = 190$. Fig. 5 indicates that at least 63 of 190 possible links were preserved until the end of the navigation. The sharp turns in the trajectory of the leader are important, as they could disrupt the shape of the group.

Also, the impact of $d_0$ on connectivity can be assessed by Fig. 5, in which the number of links in the group throughout the entire simulation is plotted for three different values of $d_0$. It is seen that for $d_0 = 5$, the number of links lies between those for $d_0 = 11$ and $d_0 = 8$. This is an interesting result and deserves some interpretation. Whenever $d_0$ is small, the group is dense and occupies a smaller area. Conversely, the group widens with increasing $d_0$. However, when the robots are confined to a smaller volume due to a low value in $d_0$, the number of occulted robots increases significantly. Hence, the number of links decreases because visibility is reduced by occulting. However, as was noted in Section III, this does not imply any weakness for overall group connectivity.

## VI. Conclusions

This work examined the navigation of mobile robot groups and the methodology presented does not require communication between the robots. Rather, a local steering strategy, which uses only information regarding the position of neighbor agents, is employed to sustain the connectivity of group members. The limited-range sensors are modeled in such a way that they produce angular and radial position measurement errors to better reflect a realistic situation. Moreover, robots may be occulted by other robots. In this way, the methodology accounts for all of the fundamental difficulties that can arise in real-life implementation.

This study demonstrates that once the robots start their motion as a connected group, the steering strategy assures their connectivity without any risk of deadlock. Also, the fact that no communication or hierarchy among the robots is required makes it possible for new members to be easily accepted into the group. The simulations verified the success of the methodology.

## Abstract

This paper presents a new low cost obstacle detection system for wheeled mobile robot. The hardware implementation of the proposed detection system uses two Sharp GP2D02 infra-red range sensors which are placed cross over each other in front of the robot in order to detect any object and avoid collisions. The software implementation of the proposed detection system is implemented using timer with the overflow interrupt for generating the required waveform for driving the Sharp GP2D02 infra-red range sensor. As a result, the mobile robot is able to execute different tasks without a delay on the processing time, for example driving the robot wheels and drive the Sharp sensors for detecting an object. Experimental results show that the proposed detection system successfully detect an object placed in a path of the mobile robot.

**Keywords-** Obstacle, Detection system, Mobile robot, Sharp Infra-red Range Sensors.

## 1. Introduction

Robots are very powerful elements of today's life. They are widely used in many industries due to the high level of performance, reliability, capability of performing many different tasks and operations. Recently, mobile robots are more and more involved in our daily lives. They can be employed in several missions such as cleaning rooms, taking care of patients, playing with kids, etc. It is important for many mobile robots to have ability for understanding and be aware of their environment such as the ability to detect an object and avoid collisions. To achieve this, mobile robots have used several types of sensing sensors, such as ultrasonic, infra-red, laser rang finder, charge-coupled device (CCD), web camera, mini-radar and bump sensors [1, 2,3]. The visual sensors can provide the richer source of useful information about the surroundings. However, they are slow in computing data and more expensive [4]. The infrared sensors have widely used for object detection and avoidance collisions due to their low cost and ranging capability [5]. Authors in [5] presented a software implementation of an obstacle detection and avoidance system. In this system, three sharp GP2D12 infra-red range sensors were used to cover the large area in the front of the mobile robot. This type of the infrared sensor offers a analogue voltage corresponding to the distance measured. Therefore, an analogue to digital converter (ADC) is required using such this sensor, so extra cost is required for this system. Authors in [6] designed and developed a low cost mobile robot that designed in as a circle–shaped and five sharp GP2D12 Infra-red Range Sensors were used in order to cover the large area.

In this paper, a new low cost obstacle detection system for wheeled mobile robot is proposed. In comparison with existing approaches, the proposed system possesses the following advantage: (i) the proposed detection system requires only two infra-red range sensors to cover a large area. By contrast, method in [5] uses three infra-red range sensors and method in [6] uses five infra-red range sensors. (ii) The proposed detection system is implemented using the Sharp GP2D02 infra-red range sensor which is a digital sensor and does not required an analogue to digital converter (ADC). By contrast, methods in [5, 6] are implemented using the Sharp GP2D12 infra-red range sensors which is an analogue sensor and required an analogue to digital converter (ADC) and therefore, extra cost is required using such this sensor.

The rest of this paper is structured as follows. Section 2 describes the interfacing between the Sharp GP2D02 infra-red range sensors and the PIC microcontroller. Section 3 covers the details of the proposed obstacle detection system. Section 4 presents experimental results. Conclusions are drawn in Section 5.

## 2. Interfacing the Sharp GP2D02 Infra-red Range Sensor to the PIC microcontroller

The Sharp GP2D02 infra-red range sensor uses an open-drain input which means it can not be interfaced directly to the PIC microcontroller due to the maximum characteristics of the open drain input which is in range -0.3 to 3 voltages. Therefore, a diode is used to only enable the current to flow when I/O pin is low [7]. Figure 1 shows the Interface between PIC and the sharp GP2D02 infra-red range sensor. As shown, this sensor requires two lines from the PIC in order to be controlled. One line provides the signal to begin a measurement and also is used to provide clock pluses, this line is called $V_{in}$ and the other line is called $V_{out}$ which is used to transmit the measurement back to the PIC microcontroller. The output of this sensor is 8 bit serial measured.

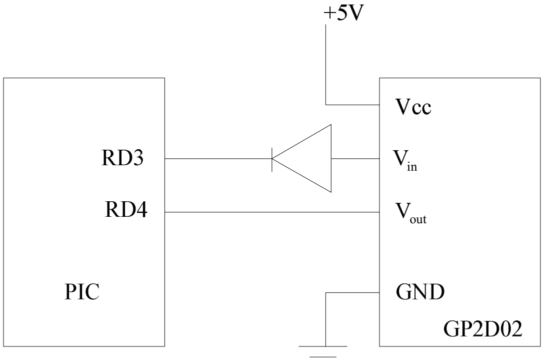

Fig. 1 Interfacing PIC with GP2D02

### 2.1 Driving the Sharp GP2D02 Infra-red Range Sensor

The sharp GP2D02 infra-red range sensor is driven according to the timing diagram which illustrates in figure 2. As shown, the measurement is initiated by forcing the $V_{in}$ signal to logic low for at least 70 ms or until the $V_{out}$ signal from GP2D02 sensor becomes logic high. Once that occurs, $V_{in}$ signal is toggled at the rate of 0.2 ms or less to start clocking in the serial bits from the sensor. Once the entire byte is read, $V_{in}$ is floated high for at least 1.5ms in order to reset the sensor for another reading.

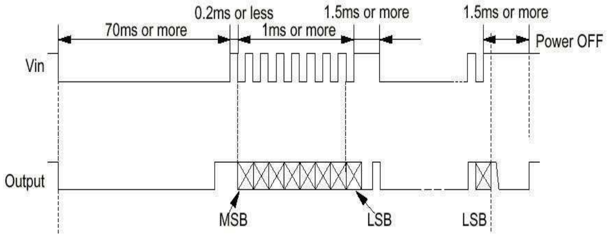

Fig. 2 the timing diagram for GP2D02 infra-red sensor

## 3. The proposed obstacle detection system

The proposed obstacle detection system uses two sharp GP2D02 infra-red range sensors that are mounted in front of the mobile robot cross over each other in order to provide coverage for a large area as shown in figure 3. The sharp GP2D02 sensors can measure a distance to an object by emitting infra-red pulses and then receives back the reflected signal. It can measure distances in the range 10cm – 80cm.

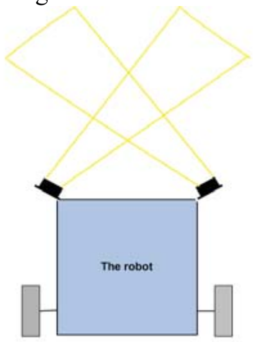

Fig. 3 Block the diagram of the mobile robot with two Sharp infra-red range sensors.

## 3.1 The implementation of the detection system

The implementation of the proposed detection system is divided into two stages: The first stage covers the hardware implementation and the second covers the software implementation. In the hardware implementation, two Sharp GP2D02 infra-red range sensors are used to implement the hardware part of the proposed detection system as shown in figure 4; RD3 pin of the PIC 18F452 is used as the output pin for controlling both of the Sharp sensors. Therefore, one timing waveform is used to initiate, read a byte from each sensor and reset both of the Sharp sensors. RD1 and RD2 are used as input pins in order to read a byte from each sensor.

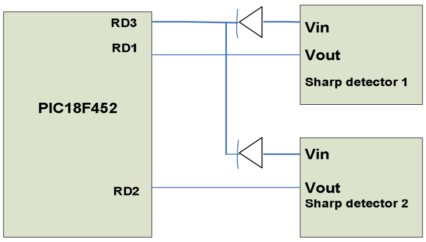

Fig. 4 the hardware implementation of the detection system

In the software implementation, the required waveform is generated for driving the Sharp GP2D02 Infra-red sensor as described in section 2. This required waveform can be implemented by using a delay function. However, this will take about 74ms, and will slow down the processing time on the PIC 18F452 microcontroller. If the required waveform is implemented using a delay function; the robot will be unable to execute different tasks without a delay on the processing time, for example driving the robot wheels and drive the Sharp Infra-red sensors to detect an object. To overcome this, the proposed detection system uses a timer with the overflow interrupt to generate the required waveform for driving the Sharp GP2D02 sensors. The software implementation is divided into three functions that are described as follows.

- **Initial function**

The aim of this function is to initiate the general and the overflow timer 0 interrupt. Also timer 0 is initiated as 16- bit timer/count. Two flags are used to distinguish between the first interrupt which should occur after the timer 0 reaches 70ms and other interrupts that should occur after the timer 0 reaches 0.2 ms and 1.5 ms as shown in figure 5.

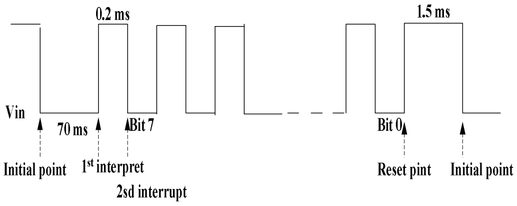

Fig. 5 Timing waveform and interrupt edges

The following Pseudo-codes describe the implementation of the initiate function.

```
void initGP2D02(void)
{
  Enable the interrupt (GIE& timer 0
   overflow INT)
   OpenTimer0( as 16BIT &  256 prescale value);
   WriteTimer0(TIMER_VAL_70MS);
   timer to overflow after 70 ms
   Set timer0_70ms_flag;
   Vin= 0;
   Clear timer0_15ms_flag;
   sensor value=0;
 }
```

- **Read byte from Sharp sensor**

The aim of this function is to read the distance information from the sensors. This information is serial bits and it is converted into a distance of centimeters. The sensors are calibrated using a linearization formula. The sensors output has an inverse relationship to the distance of an object. That is the further the object, the output values of the sensor will be small. The output values of the sensors are converted into distances using the equation (1) [8].

$$D = Kg/(X\text{-}Ko) \qquad (1)$$

Where D denotes a distance and it is given in units of centimeters (cm), X is the sensor output, Kg is the gain and Ko is an offset. The values of Kg and Ko can be determined as follows:

Let D and X be the distance and output, respectively of the first measurement. Let D' and X' be the distance and output, respectively, of the second measurement.

$$Kg = (X'-X)\, D'D \,/\, (D-D') \qquad (2)$$
$$Ko = (D'X' - DX) \,/\, (D' - D) \qquad (3)$$

The Pseudo-codes of this function is described as follows.

```
int readGP2D02(void)
{
 int ret_val = sensor_value;
 Disable Timer 0 interrupt
 ret_val =1560/(ret_val-82);
 Enable Timer 0 interrupt
 return ret_val;
}
```

The 'sensor_value' stores the output byte from the Sharp sensor. This value is updated via the interrupt function. The timer 0 overflow interrupt is disabled at the begging of this function and it is enabled at end by clear or set the timer 0 enable bit in the interrupt control register (INTCON) respectively.

- **Interrupt function**

The aim of this function is to deal with the timer 0 interrupt by generating the required waveform on the $V_{in}$ input pin of the Sharp sensor in order to initiate and read a byte from the output of the Sharp sensors also after the eight bits output from the Sharp sensors are read, it will generate the reset pulse to initiate the sensors to be ready for next measurement. This waveform is generated according to the waveform shown in figure 2. The design of the interrupt function is illustrated in figure 6.

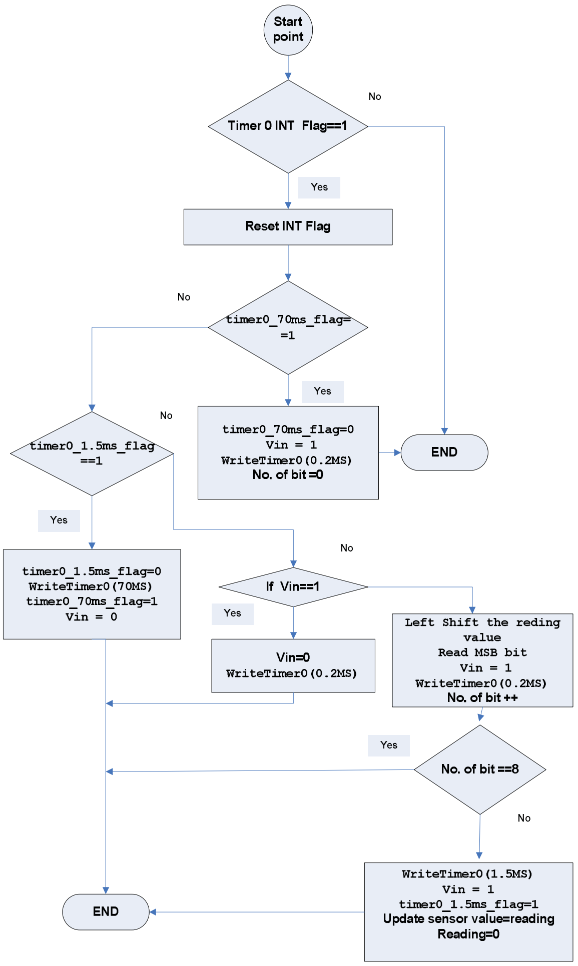

Fig. 6 flowchart of the interrupt function

## 4. Experimental Results

The experiments were organized in two phases. The first phase evaluated the relation between the output of the Sharp GP2D02 Infra-red sensor and the distance to the reflective object. The second phase evaluated the performance of the proposed detection system. To complete the first experimental phase, the Sharp Infra-red sensor was mounted as shown in figure 7 and a reflective object was placed in the front of the sensor in different distances in order to find out the relation between the output of the sensor and the distance to the reflective object.

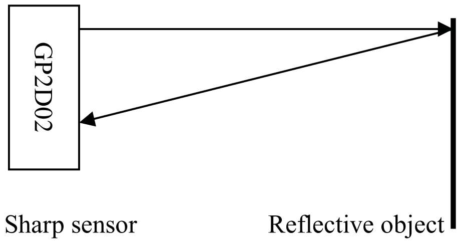

Fig. 7 the first experimental phase

The results of the first experimental phase are shown in figure 8. As shown, the output of the Sharp detector within the range 10 cm - 80 cm. The sensor gives a wrong value for distances less than 10 cm or more than 80cm [7] therefore, an object closer than 10 cm will appear to be further away. The measurement unit of the distance is centimeter and the outputs of the sensors are decimal values.

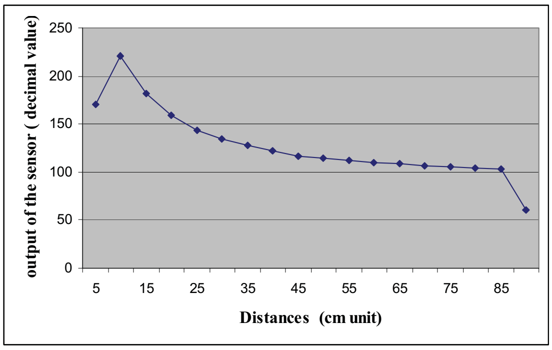

Fig. 8 the results of the first experimental phase

The second experimental phase is divided into two stages; the aim of the first stage is to test each Sharp sensor individually in order to find out if the beam of one sensor affects other sensor. The first stage was achieved by recording the output of each sensor according to the distance to the object without driving the robot; in case one  by activating one sensor and record its output; and in the case two by activating both sensors and record the output of one sensor. This was achieved by using the PORTB as output port and using an oscilloscope to read the output of the sensor from PORTB. The results of these tests are shown in table 1 and table 2. As shown in table 1 and table 2, the output of the Sharp sensor 1 is affected by the beam of the Sharp sensor 2. As a result of this, the output of the Sharp sensor returns a wrong distance measurement to an object. To overcome this problem, extensive experiments were carried out to find the best position for mounting the Sharp sensor. It has been found that the best angle for mounting the position of the Sharp sensors should be 5 degree. If this angle is increased, the sensors will affect each other and they will return wrong distance measurements to an object.

The aim of the second stage is to find out if the proposed detection system is able to detect different types of objects place in deferent positions in the front of the robot; this test was achieved by driving the robot and using a different type of object in different position in front of the robot.  The result of this test is carried out that the robot is able to detect any object even if a small object For example, a pen or a wire.

Table 1 Result of testing sensor 1

| sensor 1 is activated<br>Output of sensor 1 (Decimal) | Both sensors are activated<br>Output of sensor 1 (Decimal) | Distance in cm |
|---|---|---|
| 226 | 226 | 10 |
| 157 | 218 | 20 |
| 135 | 27 | 30 |
| 133 | 14 | 40 |
| 134 | 124 | 50 |
| 95 | 94 | No object |

Table 2 Result of testing sensor 2

| sensor 2 is activated<br>Output of sensor 2 (Decimal) | Both sensor are activated<br>Output of sensor 2 (Decimal) | Distance in cm |
|---|---|---|
| 212 | 212 | 10 |
| 145 | 145 | 20 |
| 126 | 125 | 30 |
| 111 | 110 | 40 |
| 97 | 98 | 50 |
| 32 | 39 | No object |

## 4. Conclusion

A new mobile robot detection system based on two Sharp GP2D02 infrared range sensors is presented. To detect an object in front of the mobile robot, the proposed detection system is implemented using two sharp sensors cross each other in order to cover all the area in front of the mobile robot. The experimental results show that the best angle for mounting the position of the Sharp sensors should be 5 degree. Moreover, experimental results show that the proposed detection system is able to detect any object placed in front of the mobile robot.

***Abstract*—This paper proposes an airborne monitoring methodology of ground vehicle behaviour based on a fuzzy logic to identify suspicious or abnormal behaviour reducing the workload of human analysts. With the target information acquired by unmanned aerial vehicles, ground vehicle behaviour is firstly classified into representative driving modes and then a string pattern matching theory is applied to detect pre-defined suspicious behaviours. Furthermore, to systematically exploit all available information from a complex environment and confirm the characteristic of behaviour, a fuzzy rule-based decision making is developed considering spatiotemporal environment factors as well as behaviour itself. To verify the feasibility and benefits of the proposed approach, numerical simulations on moving ground vehicles are performed using both synthetic and realistic car trajectory data.**

## I. Introduction

Recently, autonomous airborne surveillance and reconnaissance systems become a challenging and emerging problem in the area of aerospace and robotics with the rapid improvement of the UAV (unmanned aerial vehicle) operation and sensing technology. Airborne monitoring allows suspicious or unusual behaviour to be identified and investigated promptly so that situational awareness can be increased in support of border patrol, law enforcement and protecting infrastructure. For this, many researchers have investigated a swarm of autonomous airborne sensor platforms having a long endurance as well as good spatial coverage with an appropriate level of decision making. In particular, surveillance by UAVs equipped with a MTIR (Moving Target Indicator Radar) sensor can provide a certain level of accurate estimation of a large number of moving targets as well as capability to respond possible threats from the air. However, for detection of suspicious behaviours, the operators have to manually analyse the gathered mass data and construct a coherent picture of events. With these backgrounds, this paper focuses on the development of a high-level analysis algorithm to process target information acquired by UAVs which provide awareness of abnormal behaviour.

In general, detecting anomalous behaviour can be classified into two categories: The first approach codifies the behaviours using experience and domain knowledge of experts and the behaviours are learned from data in the second approach [1]. Purely learning based approaches can provide a good performance [2], [3], however, they require massive data set in advance or tend to suffer from the high computation burden for real-time applications. On the other hand, there are several algorithms to deal with behaviour or activity analysis in the context of codified (or classified) behaviour model with the aid of learning. Srivastava *et. al.* [4] introduced the method to detect anomalies of the ground vehicle by observing the patterns in its velocity called as velocity trajectory using hypothetical co-ordinated system in which the axes are specified with respect to the road segment. Besides, Fraile and Maybank [5] proposed the idea of dividing the trajectories of the ground vehicle into several driving modes using video images which can be exploited for ground traffic surveillance. However, this classification is limited to car manoeuvres in an urban parking space with slow speed. Similarly, Kim *et. al.* [6], [7] proposed the trajectory classification codified with more detailed driving modes, and applied it to string matching theory to detect suspicious behaviour defined from expert knowledge.

This paper proposes a fuzzy expert rule-based airborne monitoring methodology of ground vehicle behaviour as an extension of our previous works mentioned above [6], [7]. In those works, a primary source for the behaviour recognition is a single deterministic cost obtained from the string matching. Although this cost can provide the measure of suspiciousness computing similarity between pre-defined suspicious strings and driving mode history from trajectory classification within a certain time window, additional information needs to be considered to finally confirm the characteristic of behaviour while avoiding frequent false alarms. Therefore, in this study, to systematically exploit all available information interconnected and influenced by each other obtained from complex environment, a fuzzy system is applied considering its ability to classify complex sources into simple and intuitive form resulting in the final decision with some degree of confidence through expert rules. The proposed fuzzy expert rule-based decision making allows to concurrently accommodate several aspects of behaviour as well as spatiotemporal environment factors providing a level of alert to operator monitoring complex scenes.

The overall structure of this paper is given as: Section

II briefly introduces a target tracking filter, trajectory classification, and behaviour recognition algorithm using string matching. Section III introduces rule-based decision making algorithm to find suspicious behaviour based on a fuzzy logic. Section IV presents numerical simulation results of behaviour monitoring for both synthetic and civilian traffic scenario using realistic ground vehicle trajectory data. Lastly, conclusions and future works are addressed in Section V. An overall flow chart the technique presented in this paper is shown in Fig. 1.

## II. Behaviour Modelling and Recognition

This section briefly introduces our previous works on airborne monitoring of ground vehicle behaviour based on [6], [7]. Ground target tracking filter using UAVs is firstly explained. Trajectory classification is followed to model the behaviour of ground vehicles, and lastly behaviour recognition algorithm using string matching theory is presented.

### A. Target tracking

This study considers acceleration dynamics to apply it to tracking of the moving ground vehicle. This model regards the target acceleration as a process correlated and exponentially decreasing in time, which means if there is a certain acceleration rate at a time $t$, then it is likely to be the same jerk also at a time instant $t+\tau$ as:

$$\mathbf{x}_k^t = F_k \mathbf{x}_{k-1}^t + \eta_k \tag{1}$$

where $\mathbf{x}_k^t = (x_k^t, \dot{x}_k^t, \ddot{x}_k^t, y_k^t, \dot{y}_k^t, \ddot{y}_k^t)^T$, $\eta_k$ is a process noise which represents the acceleration characteristics of the target, and the state transition matrix $F_k$ can be represented as:

$$F_k = \begin{bmatrix} 1 & T_s & \Phi & 0 & 0 & 0 \\ 0 & 1 & \frac{(1-e^{-\alpha T_s})}{\alpha} & 0 & 0 & 0 \\ 0 & 0 & e^{-\alpha T_s} & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & T_s & \Phi \\ 0 & 0 & 0 & 0 & 1 & \frac{(1-e^{-\alpha T_s})}{\alpha} \\ 0 & 0 & 0 & 0 & 0 & e^{-\alpha T_s} \end{bmatrix} \tag{2}$$

where $\Phi = (e^{-\alpha T_s} + \alpha T_s - 1)/\alpha^2$, and $\alpha$ is a correlation parameter which allows for the modelling of the different classes of targets. The details of the covariance matrix $Q_k$ of the process noise $\eta_k$ can be found in [8].

Besides, this study assumes the UAV are equipped with a MTIR to localise the position of target. Because the measurement of MTIR is composed of range and azimuth of the target with respect to the radar location, the actual measurements are the relative range and azimuth with respect to the position of the UAV airborne. The radar measurement $(r, \phi)^T$ can be defined as the following nonlinear relation using the target position $(x_k^t, y_k^t)^T$ and the UAV position $(x_k, y_k)^T$ as:

$$\begin{aligned} \mathbf{z}_k &= \begin{pmatrix} r_k \\ \phi_k \end{pmatrix} = h(\mathbf{x}_k^t) + \nu_k \\ &= \begin{pmatrix} \sqrt{(x_k^t - x_k)^2 + (y_k^t - y_k)^2} \\ \tan^{-1} \frac{y_k^t - y_k}{x_k^t - x_k} \end{pmatrix} + \nu_k \end{aligned} \tag{3}$$

where $\nu_k$ is a measurement noise vector, and its noise covariance matrix is defined as:

$$V[\nu_k] = R_k = \begin{bmatrix} \sigma_r^2 & 0 \\ 0 & \sigma_\phi^2 \end{bmatrix}. \tag{4}$$

Considering that the measurement equation is nonlinear, the localisation of target is designed using the EKF (Extended Kalman filter). In addition, assuming a pair of UAVs track the same targets, sensor fusion technique using a Covariance Intersection algorithm is applied. Lastly, as the behaviour of ground vehicle will be analysed with a moving horizon history, the optimal fixed-interval smoother is used to improve the accuracy of past state estimation of the target. The details for sensor fusion and optimal smoother can be found in [6].

### B. Trajectory classification

To model a driver's behaviour, the trajectory is classified into driving modes. The purpose of the classification is to categorise characteristics of manoeuvres associated with forward or lateral driving by assigning them to driving modes as will be explained in the following. This allows not only to recognise characteristic fragments of the trajectories, but also to enable recognition of ground traffic behaviour in an intuitive, computationally-efficient and flexible way.

Since the driving manoeuvre does not happen for a single sampling time, the trajectories for a certain length of time need to be considered. For this, a moving-window-based trajectory approximation [6] is applied using a polynomial function which generates trajectory with a virtually increased sampling time for a certain time interval. Let us assume a new time sequence within a moving window, $0 < T_n < 2T_n < \ldots < (N_T - 1)cT_n = (N_T - 1)T_s$ where $T_s$ is an original sampling time of tracking filter, $T_n$ is a new virtual sampling time, and $N_T$ is the number of samplings for a moving window. In this study, it is assumed that $N_T = 4$, $T_s = 0.5$, and $c = 5$, and thus the new virtual sampling time is 0.1 seconds. The selection of $N_T = 4$, i.e. 1.5 seconds' moving window reflects that the bandwidth for lane changing is at least 1.0Hz according to the reference [9]. Then, velocity $(\dot{x}^t(i), \dot{y}^t(i))$ and acceleration $(\ddot{x}^t(i), \ddot{y}^t(i))$ histories with a new time sequence are used to compute the minimum speed $U$, the rate change of orientation $\theta(i)$, and forward acceleration $a_f(i)$ of the vehicle at current time step $k$ for each $i$ in a moving window (i.e. $k-c(N-1)+1 \leq i \leq k$) as:

$$
\begin{aligned}
U &= \min v(i) = \min \sqrt{\dot{x}^t(i)^2 + \dot{y}^t(i)^2} && (5)\\
\theta(i) &= v(i)\kappa(i) \\
&= \sqrt{\dot{x}^t(i)^2 + \dot{y}^t(i)^2}\frac{\dot{x}^t(i)\ddot{y}^t(i) - \dot{y}^t(i)\ddot{x}^t(i)}{(\dot{x}^t(i)^2 + \dot{y}^t(i)^2)^{3/2}} && (6)\\
a_f(i) &= \ddot{x}^t(i)\cos\psi(i) + \ddot{y}^t(i)\sin\psi(i) && (7)
\end{aligned}
$$

where $\kappa$ is a curvature, and $\psi = \tan^{-1}(\dot{x}^t/\dot{y}^t)$ is the heading angle from the North. Using above equations, a driving mode $m_k^d$ among driving mode set $M^d = \{0, \cdots, 8\}$ at time step $k$ can be obtained for each moving window with a frequency of $1/T_s$ as:

- **Stopping (0)**, $U < 1$: Since 1 m/s equals to 3.6 km/h, it can be assumed that the car does not move or is about to stop or start moving.
- **Left turn (1)**, $\max(\theta)\min(\theta) > 0$ and $\max(\theta) > \theta_{th}$: The inspection of sign change of $\theta$ is used to distinguish the pure turning maneuver from the lane changing.
- **Right turn (8)** $\max(\theta)\min(\theta) > 0$ and $\max(\theta) < -\theta_{th}$
- **Left lane change (2)** $\max(\theta)\min(\theta) < 0$, $\max(|\theta|) > \theta_{th}$, and $\theta(0) > 0$: The difference to the left turn of this condition is the sign change of the rate of orientation change. The sign of curvature transits from positive to negative in case of the left lane change.
- **Right lane change (7)** $\max(\theta)\min(\theta) < 0$, $\max(|\theta|) > \theta_{th}$, and $\theta(0) < 0$: The sign of curvature transits from negative to positive in case of the right lane change.
- **Closing gap (6)** $\max(a_f)\min(a_f) < 0$, and $a_f(0) > 0$: When the driver wants to close gap to the preceding vehicle, the sign of acceleration transits from positive to negative.
- **Widening gap (3)** $\max(a_f)\min(a_f) < 0$, and $a_f(0) \leq 0$: Contrary to the case of closing gap, the sign of acceleration transits from negative to positive.
- **Accelerating ahead (5)** $\max(a_f)\min(a_f) > 0$, and $a_f(0) > 0$: The sign of acceleration keeps positive.
- **Decelerating ahead (4)** $\max(a_f)\min(a_f) > 0$, and $a_f(0) \leq 0$: The sign of acceleration keeps negative contrary to the case of the accelerating ahead.

### C. Behaviour detection

This section introduces behaviour detection scheme to find suspicious behaviour using driving mode histories of ground vehicles. The key tools for this detection scheme are symbolic dynamics and string matching. The mathematical subject of symbolic dynamics originally arose in the theory of dynamical systems and was motivated by the qualitative approach to dynamics in which the character of trajectories is more important than their numerical values. String matching theory is a well-developed area of text processing. String matching consists in finding all the occurrences of a string (called a pattern) in a text where the pattern is a string $x$ of length $m$, while the text is a string $y$ of length $n$. In this study, using the driving mode set $M^d = \{0, \cdots, 8\}$, a symbolic time series of driving modes $y_k^d = \{m_l^d \in M^d | l = 1, \ldots, N_{sm}\}$ is generated by trajectory classification for each time step $k$, where $N_{sm}$ represents a moving window length for string matching. The suspicious behaviour is also expressed as strings $x_s$ consisting of nine numbers.

Intuitive string matching method we can apply is the exact matching which detects exactly the same pattern in the driving mode history as the pre-defined suspicious string. However, assuming a reference suspicious string of '145048', '145548' or '145448' cannot be ignored as well in the detection scheme, whose fourth element of the string might be one of the following forward driving modes: '3'; '4', '5', '6', instead of '0'. To tackle this, an approximate matching is applied by defining a cost which is called as Edit distance measuring distance or similarity between reference and test patterns. The Edit distance $D(S_1, S_2)$ [10] between two string patterns $S_1$ and $S_2$ is defined as the minimum number of editions including changes $C$, insertions $I$, and deletions $R$ required to change pattern $S_1$ into $S_2$. The details of approximate string matching can be found in [6].

Although above edit distance can provide the measure of suspiciousness computing similarity between pre-defined suspicious strings and current driving mode history within a certain time window, additional information needs to be considered to finally confirm characteristic of behaviour while avoiding frequent false alarms. From the following section, what types of information can be used and how to combine them will be dealt with.

## III. Fuzzy Expert Rule-Based Decision Making

For airborne behaviour monitoring, this section proposes a decision making algorithm to find suspicious or anomalous vehicle based on a fuzzy logic. To systematically exploit all available information interconnected and influenced by each other obtained from complex environment, fuzzy system is applied considering its ability to classify complex sources into simple and intuitive form (fuzzification) resulting in the final decision (defuzzification) with some degree of confidence (rather than single certain decision) through expert rules (fuzzy inference). The proposed fuzzy expert rule-based decision making allows to concurrently accommodate several aspects of behaviour as well as spatiotemporal environment factors with supervision of human providing a level of alert to operator monitoring complex scene. Fuzzy system used in this study consists of four fuzzy membership functions for inputs and one output with 36 expert inference rules.

### A. Fuzzification

A fuzzy input for behaviour monitoring includes four aspects: location, behaviour cost, speed of the vehicle, and environmental aspect as:

- **Location:** A time history of the location which is a relative position of the suspicious ground vehicle to the critical area (e.g. the centre of complex activities and the base walls of military facilities) or an index of road

that the ground vehicle has moved along is an important source for behaviour monitoring. Assuming that the local roadmap information is readily available in advance, the indexes of the local roads in region of interest can be annotated by a sequence of road numbers. If the vehicle travelling on one of identified roads of interest, the location is categorised as ’Region of interest (R)’; otherwise is ’General (G)’ as shown in Fig. 2(a).
- **Behaviour cost:** As a key factor for the behaviour monitoring, the edit distance $D$ is used resulting in time history of a behaviour cost. Let $X_s = \{x_s^1, \cdots, x_s^{N_{su}}\}$ be the set of pre-defined suspicious behaviours. Then, the behaviour cost $C_k^b$ with respect to current time series of driving modes $y_k^d$ and suspicious behaviours at time step $k$ can be defined as:

  $$C_k^b = \frac{1}{\min_{i \in X_s} D\left(x_S^i, y_k^d\right) + 1} \tag{8}$$

  Three fuzzy membership functions with linguistic variable ’Normal (N)’, ’Suspicious (Su)’, and ’Worrying (W)’ are used to categorise the behaviour cost as shown in Fig. 2(b).
- **Speed:** The velocity profile of the vehicle with respect to its position or time step also needs to be investigated since it can provide the measures of the suspicious or abnormal behaviour inherently. Three functions with ’Slow (Sl)’, ’Moderate (M)’, and ’Fast (F)’ are used as shown in Fig. 2(c).
- **Environment:** The last input considers an environmental condition with a human interaction for the behaviour decision process. Depending on the traffic flow density, two functions with ’Normal traffic (Nt)’ and ’Congestion (C)’ are used as membership functions as shown in Fig. 2(d). Even though only traffic flow is used in this study, it can be easily replaced with time zone such as day/night or weekday/weekend or any other environmental aspects. This input allows for incorporating human supervision on a certain environment into decision making instead of relying only fully autonomous decision process which can be vulnerable to unexpected and dynamic environments.

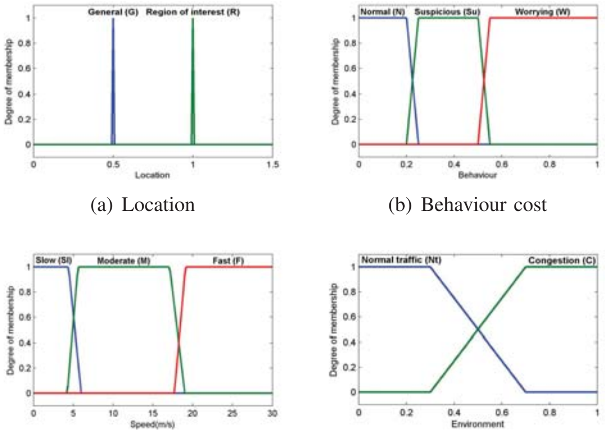
A fuzzy output for behaviour monitoring is the level of alert of each ground vehicle consisting of four membership functions with linguistic variable ’Allow’, ’Monitor’, ’Investigate’, and ’Respond’ as shown in Fig. 3.

### B. Fuzzy inference

In this study, a fuzzy inference system is designed by using a Mamdani model [11]. Inhere, expert knowledge can be expressed in a natural way using linguistic variables defined above as Table. I∼II. In the table, rules can be interpreted as:

- Rule 1: If Location is ’G’ and Behaviour is ’N’ and Speed is ’Sl’ and Environment is ’Nt’, then Alert is ’Allow’.

Note that depending on the location and environment, rules are changed slightly. For instance, if location of the vehicle is ’G’ (i.e. general area), speed ’Sl’ does not mean something significant leading to alert ’Allow’, whereas if the location is ’R’ (i.e. region of interest), slow speed or stopping of the vehicle can be identified as suspicious one (monitoring the specific facility or placing of improvised explosive devices) leading to alert ’Investigate’ as Rule 1 and 19. However, even though the location is ’R’ and speed is ’Sl’, if the environment is ’C’ (i.e. congestion), its alert level should be alleviated as Rule 20 since slow speed is more likely to be observed.



(a) Location

(b) Behaviour cost

(c) Speed

(d) Environment (Traffic flow)

Fig. 2. Membership functions for fuzzy inputs

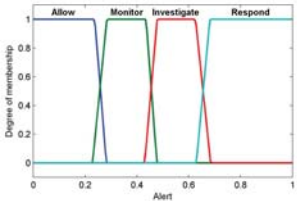


Fig. 3. Membership function for fuzzy output

### C. Deffuzification

By using input variables and defined fuzzy rules, the fuzzy outputs for all rules are then aggregated to one output fuzzy set. Finally, to obtain a crisp decision value for level of alert, a defuzzification process needs to be performed. Even though there are several algorithms for this defuzzification,

TABLE I
FUZZY RULE 1∼18: LOCATION IS ’G’ (GENERAL ROAD)

| *Rule No.* | *Behaviour* | *Speed* | *Environment* | *Alert* |
|---|---|---|---|---|
| 1 / 2: | N | Sl | Nt / C | Allow / Allow |
| 3 / 4: | N | M | Nt / C | Allow / Allow |
| 5 / 6: | N | F | Nt / C | Monitor / Investigate |
| 7 / 8: | Su | Sl | Nt / C | Monitor / Allow |
| 9 / 10: | Su | M | Nt / C | Monitor / Allow |
| 11 / 12: | Su | F | Nt / C | Investigate / Investigate |
| 13 / 14: | W | Sl | Nt / C | Investigate / Monitor |
| 15 / 16: | W | M | Nt / C | Investigate / Monitor |
| 17 / 18: | W | F | Nt / C | Respond / Respond |

TABLE II
FUZZY RULE 19∼36: LOCATION IS 'R' (REGION OF INTEREST)

| *Rule No.* | *Behaviour* | *Speed* | *Environment* | *Alert* |
|---|---|---|---|---|
| 19 / 20: | N | Sl | Nt / C | Investigate / Monitor |
| 21 / 22: | N | M | Nt / C | Allow / Allow |
| 23 / 24: | N | F | Nt / C | Investigate / Monitor |
| 25 / 26: | Su | Sl | Nt / C | Investigate / Monitor |
| 27 / 28: | Su | M | Nt / C | Monitor / Monitor |
| 29 / 30: | Su | F | Nt / C | Investigate / Investigate |
| 31 / 32: | W | Sl | Nt / C | Respond / Investigate |
| 33 / 34: | W | M | Nt / C | Investigate / Investigate |
| 35 / 36: | W | F | Nt / C | Respond / Respond |

this study uses the method of taking the centre of gravity of the aggregated output fuzzy set [12].

## IV. NUMERICAL SIMULATIONS

This section carries out a numerical simulation for both synthetic and civilian traffic scenario using the proposed fuzzy expert rule-based airborne monitoring algorithm for moving ground targets using UAVs loitering over a certain area.

### A. Synthetic scenario

Figure 4 shows the scenario description where a ground vehicle is moving around region of interest. In the map, at the southern area of a river, there is a stadium of strategic importance to be protected, which has a surrounding roadmap to be passed by a civilian ground vehicle near the base wall. A ground vehicle considered in this scenario circles clockwise round the stadium twice. During that time, the vehicle stops for ten seconds on the mid of road 3 near 420s. After that it crosses on the bridge and then travelling on the general road network. The vehicle trajectory data are used to generate virtual MTIR measurements composed of the relative range and azimuth angle adding the white Gaussian noise having the standard deviation of $(\sigma_r, \sigma_\phi) = (10m, 3deg)$.

The trajectory classification histories shows a reasonable performance capturing the turning or stopping manoeuvre timely as shown in Fig. 5 in conjunction with the trajectory estimation result with blue lines and numbered time history in Fig. 4. In this scenario, only road 3 and 4 are assumed to be of interest (i.e. location is 'R') as red line in Fig. 6(a), and suspicious behaviour $x_s$ is selected as '4 4 0 0 0 0' (which means deceleration and then stopping) to detect the vehicle which stops around stadium suspiciously. In addition, the size of driving mode history $y^D$ is set to $N_{sm} = 6$ which is the same as that of $x_s$.

Figure 6 shows the fuzzy rule-based decision making result including location information, behaviour cost and speed of the vehicle. Note that even if $y^D$ and $x_s$ are totally different, since edit distance $D$ between them is six in this case, the lowest behaviour cost would be 1/7 instead of zero according to Eq. (8) as shown in Fig. 6(b). In normal traffic shown as blue line in Fig. 6(d), level of alert has high value when the location is 'R', behaviour cost is high as well as speed is slow. Besides, if there is congestion in the traffic, the effect of the behaviour cost and slow speed on level of alert is reduced as red line in Fig. 6(d) since those conditions are more likely to happen due to the congestion.

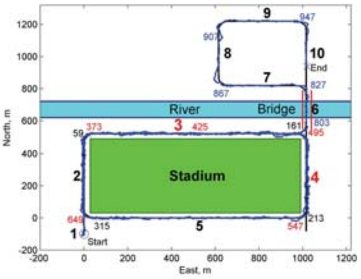

Fig. 4. Trajectory estimation for synthetic scenario

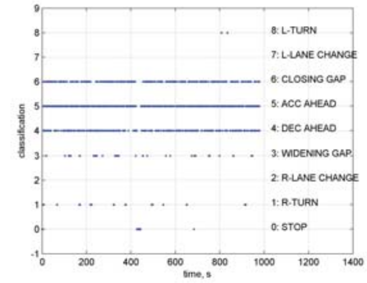

Fig. 5. Trajectory classification for synthetic scenario

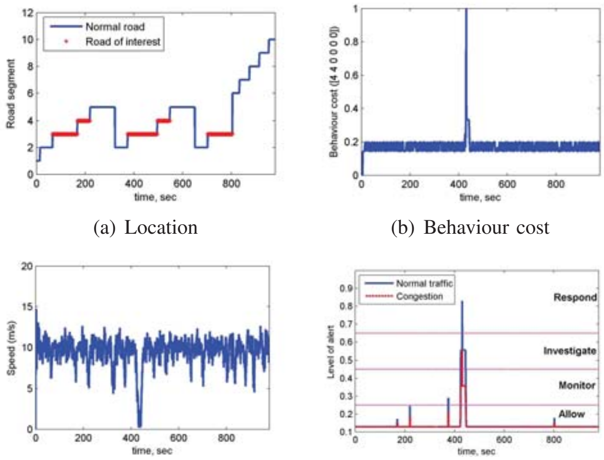

(a) Location (b) Behaviour cost

(c) Speed (d) Level of alert

Fig. 6. Fuzzy rule-based decision making results for synthetic scenario

### B. Civilian traffic scenario

The ground target trajectory is obtained from S-Paramics [13] traffic model of Devizes map in the UK at 2 Hz as shown in Fig. 7. Figure 8(a) shows trajectory estimation result of a given S-Paramics data with frequent lane changes inserted artificially (to generate suspicious behaviour) as shown in Fig. 8(b). This manoeuvre is called weaving or evasive, and can be viewed as one of the most dangerous behaviours in civilian traffic. In this scenario, every road is assumed to be general road (i.e. location is ’G’ only), and suspicious behaviour $x_s$ is selected as ’2 7 2 7’ and ’7 2 7 2’ (2: right lane change and 7: left lane change) to detect evasive manoeuvre.

Figure 9 shows the fuzzy rule-based decision making result including behaviour cost with trajectory classification and speed of the vehicle. In normal traffic shown as blue line in Fig. 9(d), level of alert has high value when the behaviour cost is high (which means evasive manoeuvre is likely to be happening) around 20∼40 seconds or velocity is fast around 10 second. In case there is congestion as red line in Fig. 9(d), although level of alert shows the same tendency, the effect of the behaviour cost is reduced as frequent lane change is more likely to happen due to the congestion. On the contrary, the effect of fast speed is enhanced around 10 second since fast ground vehicle in the congested traffic could be regarded as dangerous one.

## V. Conclusions

This paper proposed a fuzzy expert rule-based airborne monitoring methodology of ground vehicle behaviour to identify suspicious or abnormal behaviour considering spatiotemporal environment factors as well as behaviour itself. Numerical simulation results using synthetic scenario and realistic car trajectory data showed the feasibility of the proposed approach successfully providing a recommended level of alert. The study could be applied to various scenarios in view of both military and civil applications: monitoring urban/rural area of interest, detecting unknown intent of terrorists, providing a protective surveillance around military facilities, and enhancing situational awareness of traffic movements both on land and at sea. As a future work, additional relevant aspects of behaviour will be considered as fuzzy inputs such as cultural background related to driving habits and deviation from general behaviour.

***Abstract*-The complex structure of the shaped surface formed by a kind of bars-converging single-layer reticulated shell joints is analysed, and the characteristic of higher precision in production is considered, the patter decomposing – patter processing - patter assembling –patter casting joint processing flow is put forward. According to the joint design data, the joint spatial axis model is built, the spatial orientation description method is proposed, the developed SolidWorks 3D drawing software is used to import the design data to visualize the joints in 3D model. According to the joints splitting and assembling principle, the mathematical model of joint processing is derived, based on the mathematical model, the joint processing equipment based on the TriVariant series robots is developed, the real time control of the joint NC machining system is implemented. The results of this research have been verified in the large complex steel structure building of the Sun Valley for Shanghai World Expo and the roof of Star Mall in Shenyang, now the research is being used in the Cell Wall of the new natural museum in Shanghai which is under construction.**

## I. INTRODUTION

Spatial reticulated shell structure is a kind of architectural structure connected by spatial bars with multiple joints, in order to adapt to the changing space angles, a type of bars-converging joint for single-layer reticulated shell appeared[1].As shown in Fig. 1,this type of joint has many advantages, such as the shape can be changed with the overall surface of the building, and can be connected easily with bars with various special-shaped sections (such as triangle, rectangle, trapezoid), so it can constitute a variety of fashionable spatial curved surface of architectural modeling, it becomes an important development trend of the highly decorative spatial reticulated shell structure building[2] .

In order to satisfy the whole smooth surface and continuous changes, joints for reticulated shells have different shapes and complex space angles. Through topological mesh the single layer netrack is composed by triangular grids, each grid is mutual restricted, each joint has at least four brackets, each bracket is connected with other components[3]. Any bracket has little error, it will affect the installation of the components, so the joint itself requires high machining precision. At present, at home and abroad the production methods of the bars-converging single-layer reticulated shell joint can be put into the following two categories:1）CNC cutting- assembling-processing, this facture process of joints has been applied in the latticed dome of the London Shopping Center called Beispiel Westlife (Fig. 2)by SEELE, a German company. The basic process is firstly steel plate cutting, edge processing and forming different units by pressure,

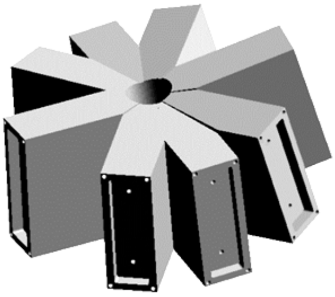

Figure 1. Bars-converging reticulated shell joint

Figure 2. Beispiel Westlife Shopping Center

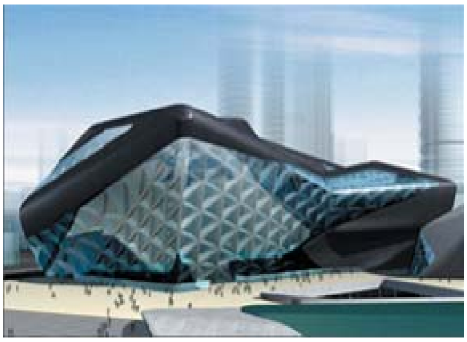

Figure 3. Guangzhou Opera House

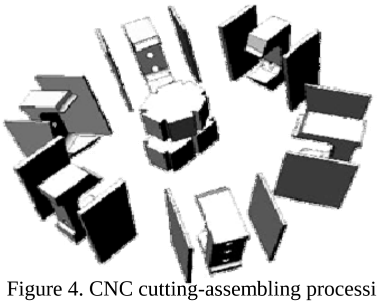

Figure 4. CNC cutting-assembling processing

then the next step is assembling, using clamping fixture for welding, finally the last step is completing the machining of surface / hole combined with bars using 5 axis machining center, as shown in Fig. 4. As the reticulated shell structures often contain thousands of different geometry joints, and each joint is divided into several units, it requires a lot of pressure molding and welding clamping fixture, so it results in high difficulty in joints production，high complexity in information management ， high cost, low processing efficiency. In addition, it is difficult to guarantee the manufacturing accuracy.2 ） Patter processing-casting-processing, this process of joints has been applied in the national stadium Bird’s Nest in Beijing for 2008 Olympic Games and Guangzhou Opera House. First the joint mould is made, then the next step is getting the joints semi-finished products by using precision casting, finally the last step is completing the machining of surface / hole combined with bars using 5 axis machining center[4]. Compared with the first method, this process needs mold making for each joint, if there is no quick, low cost molding technology and equipment available, this process can also lead to low efficiency, high cost, poor precision. In the Guangzhou Opera House project (Fig. 3), the sand casting is used in the step of mold making, as it needs a lot of wood patterns, the working efficiency is low and the production cost is high. It also leads to the difficulty in mold making and complex angles formation. So this research adopts the lost foam casting, which can raise the efficiency, lower the cost and guarantee the required precision.

In order to solve the engineering difficulties and make up for the previous study defects, this paper presents a joint processing method which includes deepen design- patter decomposing – patter processing - patter assembling–patter

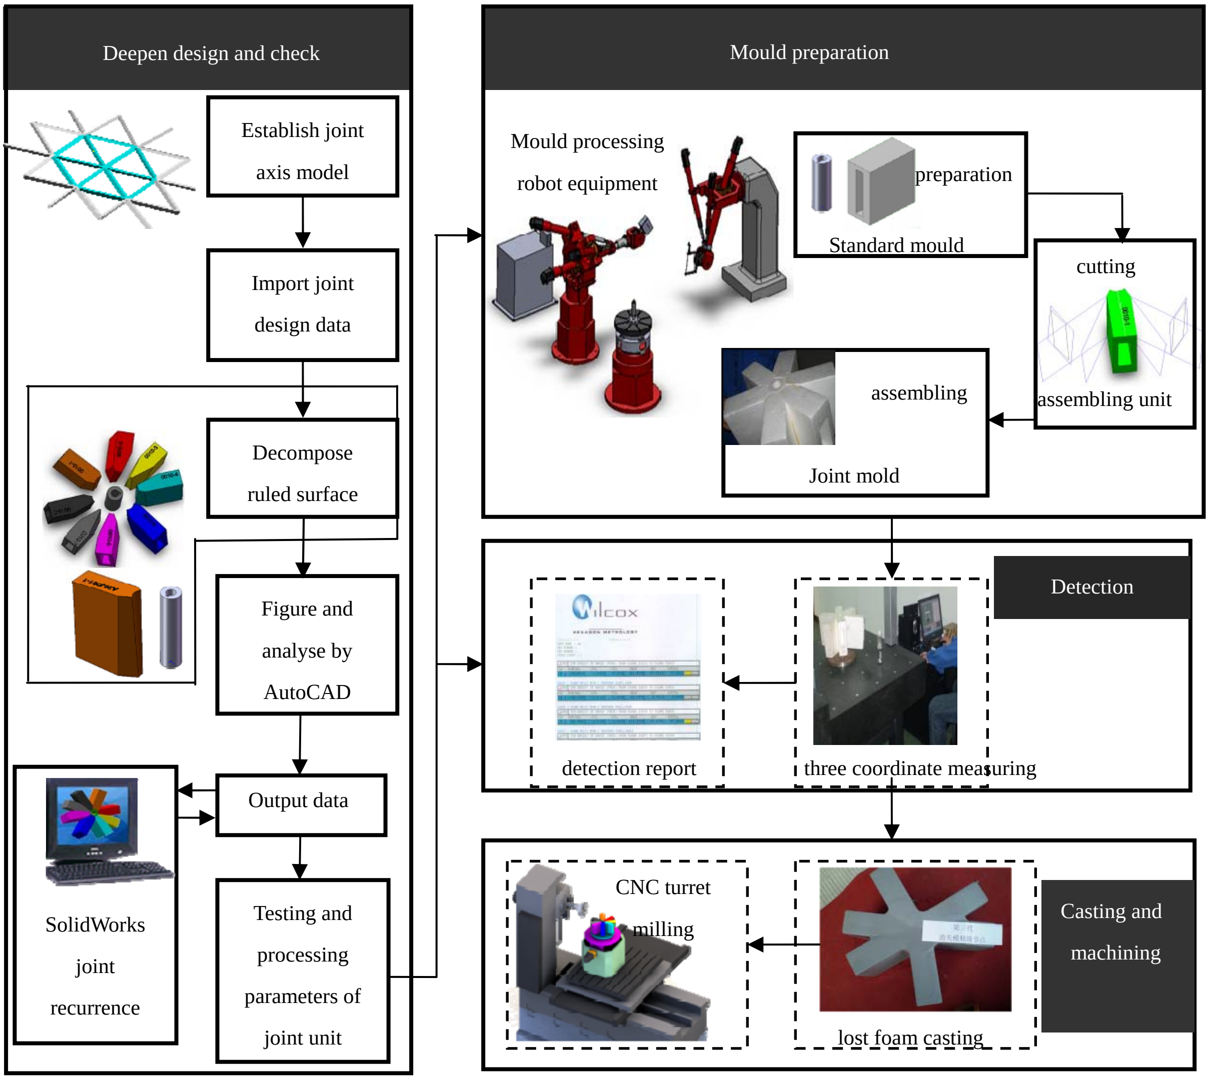

Figure 5. Joint CNC processing flow

casting- machining. At first the key point coordinates of the bracket is extracted from reticulated shell structure axis model, based on the developed SolidWorks software the joints are visualized in 3D model and virtual preassembled to verify the joint deepen data, then according to the principle of joint splitting - assembling, the method of ruled surface for parting and positioning is used, with the 5 degree of freedom TriVariant series hybrid robots as the joint mold processing equipment, the cutting and assembling of joint mould is completed.

## II. JOINT PROCESSSING FLOW

According to the bars-converging single-layer reticulated shell joint processing project, this paper proposed a joint NC machining process based on the multi functional robot.

Steps are as follows: At first the joints are deepen designed, the axis model of bars-converging single-layer reticulated shell structure is set up, the initial designed coordinate parameters and dimension parameters of all joints and bars are input into the computer, and each joint is divided into a number of tectonic units, AutoCAD is used to figure and analyse, the size data and processing parameters of each unit are gotten, by the programming language VC++ , Solidworks 3D drawing software is developed, every joint in 3D model is visualized based on the size data and processing parameters, the correctness of joint deepen data is verified. Then the size data and its processing parameters after testing of each joint structure unit are input into the joint processing robot CNC equipment, the robot is controlled to complete the cutting and assembling of joint mold units, three coordinate measuring instrument is utilized to detect the size and accuracy of the joint mold, the detection report is gained. Finally the qualified joint mold after measuring and testing is obtained, through the lost foam casting process, the molten steel is casted, through machinery processing the prepared products are obtained by using the CNC turret milling.

The process for joint products has many advantages, such as good mechanical properties, low production cost, and it can guarantee the required precision, the joint processing flow is shown in Fig. 5.

## III. JOINT SPACE ATTITUDE

In order to unified describe the spatial different joints, the characteristic that a large number of joints are similar but not identical is used. For every different joint, the joint number of unit N and the pitch angle $\alpha_i$ 、 the torsion angle $\beta_i$ and the angle of circumference between units $\theta_{i,i+1}$ (Where i is the joint unit number)and bracket unit length L and width B are used to describe the joint spatial attitude, as shown in Fig. 6, But in actual machining, in order to be measured and expressed easily, this study uses joint end face point coordinates to describe the spatial attitude. According to the joint spatial attitude, the coordinate system $O-xyz$ is established ,the point $O$ is the point of intersection in the theory diagram model, as $O$ is the origin, the axis of the center column is axis z, upward is positive, according to the clockwise direction ( z upward direction ) to define each joint unit NT-1、NT-2、……、NT-i（determined by the unit quantity）,the bottom center line of the numbered NT-1 unit is the axis x, the direction departs from the central cylindrical axis and points outwards. In accordance with the right-hand rule in Cartesian coordinate system to determine the y axis direction, the joint model is shown in Fig. 7. According to the joint initial designed space attitude angles and the bracket unit parameter data, the three vertices coordinates on every rectangular cross section of the numbered joint in the coordinate system $O-xyz$ are figured out(as $P_{11}, P_{12}, P_{13}$ in NT-1）,a total of 3i vertices coordinates can express the positional relationship between each unit and the space angle relation in the same joint.

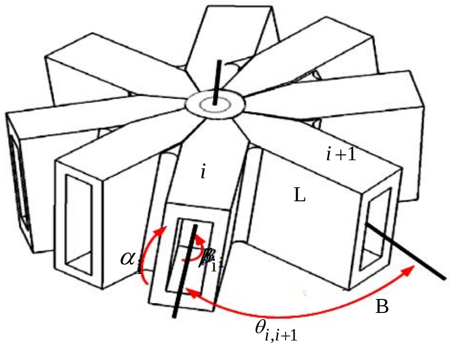

Figure 6. Joint space angle attitude

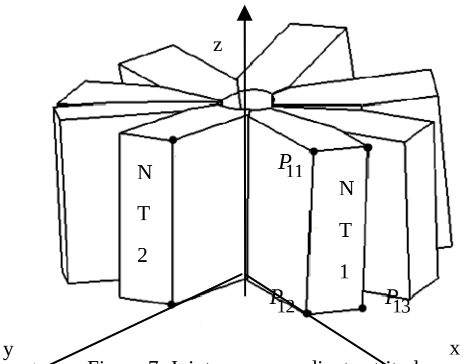

Figure 7. Joint space coordinate attitude

## IV. JOINT THREE-DIMENSIONAL REAPPEARANCE

In order to meet the requirement of high precision of joints, it needs to test and check the deepen design data, the programming language VC++ is used to develop SolidWorks 3D drawing software. According to the characteristics that the joints are similar but not identical, by dimension driving method, the joint model structure is maintained unchanged, all the dimension which affect the model structure are defined as the dimension variables, by means of giving these dimensions variables with different values, it is able to obtain a series of a different sort of junction joints with identical structure and different sizes.

The concrete steps are as followed: In Visual C++ 6 integrated developed environment for programming, through the dynamic link library DLL and SolidWorks API functions

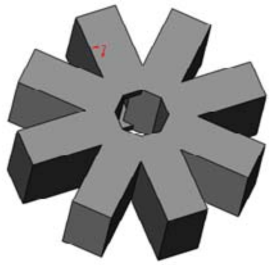

Figure 8. Three-dimensional reappearance results

to develop SolidWorks software, then the data tables which contain batch joint features are imported into the 3D drawing software automatically, automatic batch drawing is carried out, the joint model is reconstructed, at last virtually the reticulated shell structure model is assembled in advance, the initial visual inspection of joint and structure is realized. Because of the visualization and intuitionism of the model, the joint data with obvious errors can be found, reappearance results are shown in Fig. 8.

## V. JOINT SPLITTING-ASSEMBLING PRINCIPLE

Joint splitting - assembling principle which is adopted in this paper is that the joint are split into assembling units and the cylinder which is connected to each unit, the split surface between the unit is the angle bisector plane, the robot is used to cut the standard module into the assembling units, and with circular arc and plane surface to position each unit and the units are combined into complete joint mold.

The processing of each unit of joints is the cutting of the angle bisector plane and cylindrical ruled surface of the standard foam mold, the key technology is the transformation from the ruled surface mathematical expression in space to the trajectory data of the processing equipment. The overall principle of robotic cutting: Through the geometric relationship, the space equation of processing ruled surface in the joint coordinate system can be obtained, the conversion between joint coordinate system, workpiece coordinate system and processing device coordinate system is created, equipment's trajectory control data is gotten by post processing ,the end-effector space pose when cutting ruled surface can be obtained, the track pulse is input into the servo control system, the robot servo control is realized.

Standard module cutting mathematical principle: the center cylindrical surface equation and each unit's two plane equations are united, two arc $\alpha$ and $\beta$ equations can be obtained. Similarly the space plane equations are united, the angle bisector planes $\lambda_1$ and $\lambda_2$ equations can be obtained. Considering that the joint cutting data is easy to use and express, in each unit corresponding vertex the coordinate system $O'-x'y'z'$ is established, as shown in Fig. 9. According to the coordinate system conversion, the rotation matrix can be expressed as ***R***=

$$\begin{bmatrix} \sin\theta_1 \sin\theta_2 & -\cos\theta_2 & \cos\theta_1 \sin\theta_2 \\ \cos\theta_1 & 0 & -\sin\theta_1 \\ \sin\theta_1 \cos\theta_2 & \sin\theta_2 & \cos\theta_1 \cos\theta_2 \end{bmatrix}$$

The $\theta_1$ and $\theta_2$ are the attitude angle of the joint unit. Coordinate translation vector $P = \overrightarrow{OP_{4-2}} = \left[x_0, y_0, z_0\right]^T$ .The coordinate transformation equation is T

$$T = \begin{bmatrix} R & P \\ 0 & 1 \end{bmatrix}$$

So the relation is $T^{-1}\begin{bmatrix} x & y & z \end{bmatrix}^T = \begin{bmatrix} x' & y' & z' \end{bmatrix}^T$

Similarly, with the intersection method the equation of cylindrical surface and each unit plane in a new coordinate system $O'-x'y'z'$ can be obtained, then the equation of intersecting lines between upside and downside section and the cylinder surface $\alpha'$ and $\beta'$ can be obtained, and the equation of $\lambda_1{}'$ and $\lambda_2{}'$ which is the angle bisector planes by adjacent bracket units intersecting in the new coordinate system $O'-x'y'z'$ are achieved. Thus the spatial vector and the position which the robot end effector needs to arrive at in the unit coordinate system $O'-x'y'z'$ can be expressed.

In actual production, in order to control the cutting trajectory of the cutting robot, it needs to transform the measurement of joint mold unit ruled surface for processing (two spatial surfaces and a cylindrical surface) in the unit coordinate system $O'-x'y'z'$ to the same reference coordinate system with the cutting robot, the space relation between the two coordinate systems is shown in Fig. 10, the rotation matrix is R,

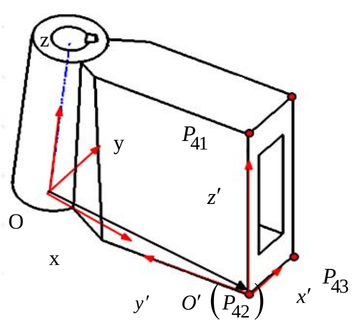

Figure 9. Joint coordinate system conversion

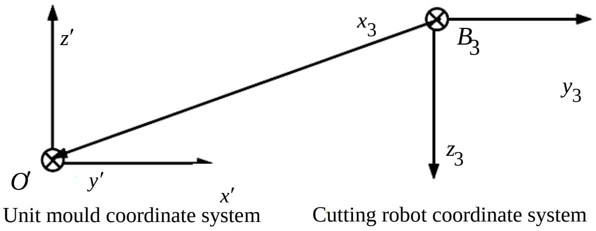

Figure 10. Relation between unit mould coordinate system and cutting robot reference coordinate system

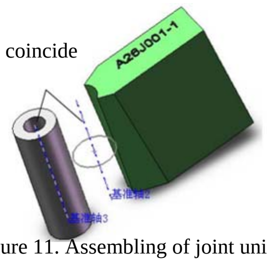

Figure 11. Assembling of joint unit mold

$$R = R(x_3, 180^\circ)R(z_{3'}, -90^\circ) = \begin{bmatrix} 0 & 0 & -1 \\ 0 & -1 & 0 \\ -1 & 0 & 0 \end{bmatrix}$$

Translation vector $P = \overrightarrow{B_3O'}\,BO$, the space vector $L_i$ and position $E_i$ which the end executor needs to reach in the cutting robot reference coordinate system $B_3 - x_3y_3z_3$ respectively are $L_i = RL_i', E_i = RE_i' + P, (i = 1, 2 \ldots n)$ Where n is the number of sampling points, $L_i'$ and $E_i'$ respectively are the space vector and the end position of the end-effector needs to arrive at in the unit coordinate system $O' - x'y'z'$ .

Through this two quantities and the robot inverse kinematics model, the relevant parameters of the branched chains and the joint angle values of TriVariant-A cutting robot can be obtained for completing processing, thereby the robot control during the cutting process is realized[8] .

Unit assembling process is essentially the process that the TriVariant-B robot module terminal control unit axis is coincident with the center cylinder axis by means of the rotary with the single degree of freedom platform to the assembling area, as is shown in Fig. 11. When the center cylinder axis of joint mold is expressed as $S = \begin{bmatrix} 0 & 0 & 1 \end{bmatrix}^T$ in the coordinate system $O$ - $xyz$ ,the vector $\overrightarrow{P_{42}P_{41}}$ is the robot target vector, point $P_{42}$ namely is the target point. Similar with the cutting process of mold unit, in the assembling process, each vector is required to be measured in the robot coordinate system, in order to convert to the robot recognizable data, through the inverse kinematics solution for assembling robot, as is similar with the coordinate system transformation in the cutting process, so is not discussed here.

The joints splitting -cutting - assembling process method not only realizes joint batch production, but also transfers the processing difficulty to the digital cutting of various unit's bisecting planes and curved surfaces, the arc and planes are used for positioning to ensure the precision of the joint shape. Finally through the lost foam casting the joint processing is finished.

## VI. CONCLUSION

This paper presents a method based on the basic idea of joint NC processing process flow which includes deepen design- patter decomposing – patter processing - patter assembling –patter casting- machining, the developed SolidWorks software is used to carry out the batch joints three-dimensional reappearance, and to test the correctness of the deepen data, the joint mold cutting- assembling model is established, on the basis of the mathematical model the

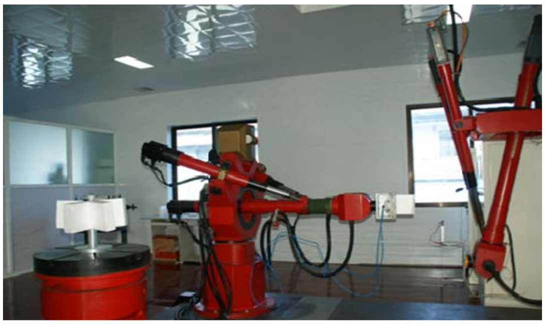

Figure 12. Robot equipment for processing joint mold

Figure 13. Shanghai World Expo Sun Valley

Figure 14. Star Mall in Shenyang

Figure 15. The design sketch of natural museum in Shanghai

control of the robot end-effector pose is realized. The robot NC equipment(Fig. 12) for processing the joint mold is used to complete cutting and assembling. The novelties of this method are as followed:1)The application of the TriVariant series robots in the mold cutting and assembling; 2)The utilization of lost foam casting in producing joints;3)The proposal of the whole process flow for bars-converging joints. Based on the multi functional robot, the digital joint manufacturing process has been successfully applied in the Sun Valley in 2010 [8] (Fig. 13)and the roof structure of Star Mall in Shenyang in 2011(Fig. 14). In addition now the Cell Wall of the new natural museum in Shanghai is under construction by using the results of this research (Fig. 15). It proves that this joint processing method not only reduces the joint production cost, but also improves the production efficiency, and it creates favorable conditions for the development of spatial reticulated shell structure technology.

## ACKNOWLEGMENT

This research is sponsored by the 863 High-Tech Development Program (2009AA04Z219). We would like to thank the anonymous reviewers for their useful comments.

***Abstract*—Two-axis pan and tilt systems are widely used in surveillance applications for high accuracy positioning of sensor payloads such as cameras and laser pointers. In order to develop advanced control algorithms to improve the performance of these systems, a model of the system must be developed. This model should include the dynamics of the system to include effects such as compliance and account for friction effects in the drive. This paper discusses the development of the overall model of the system using National Instruments LabVIEW, and in particular, the models for friction and the drive train that will be used.**

***Keywords-Servo systems; Modelling; Software tools; Harmonic drives***

## I. INTRODUCTION

Chess Dynamics Ltd. is a supplier of high performance Radar and Electro-Optic systems for the defence industry. It designs and manufactures precision two-axis pan & tilt camera systems for land, naval and airborne applications.

The performance demands of these systems are very high; requiring high pointing resolution and high positional accuracy with fast tracking speeds and smooth low speed control.

Research and development is being conducted within the company through a Knowledge Transfer Partnership (KTP) scheme with Kingston University to develop advanced control methods that will improve the accuracy and tracking performance of the company's products.

Initially, simulation models of the system will be developed to allow advanced control and estimation algorithms to be evaluated and tested before being implemented into the actual system. Subsequent stages of the project will develop estimation algorithms to improve the quality of sensor measurements and then control algorithms will be developed and evaluated as to their suitability for increasing system performance.

This paper discusses the models of the system that have been developed and their implementation in National Instruments' LabVIEW software using the Control Design and Simulation toolkit.

Finally, simulation results are compared to results obtained from a representative experimental test rig.

## II. SYSTEM MODELLING

In this section, we will begin by introducing the system to be modelled before going on to discuss the models for the individual components of the system. Finally, the implementation of the overall system model in different forms using LabVIEW is discussed.

### *A. System Overview*

The system to be modelled, shown in Figure 1, is a compact two-axis pan and tilt system designed to carry an optical sensor payload of up to 25kg.

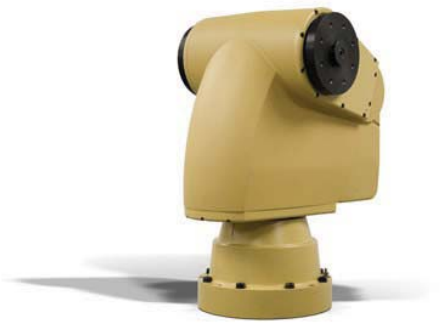

Figure 1 - Cobra Product [1]

The system consists of two identical drive assemblies, with integrated encoders, mounted on the azimuth and elevation axes. Housed within the body of the system are two current-mode servo amplifiers to drive each axis and the main control board to interface to the amplifiers and the outside world via a

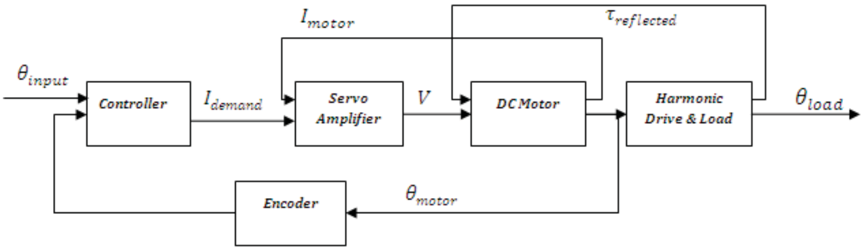

Figure 2 - Single Axis Servo System Control Block Diagram

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

serial interface. The software on this board implements the digital controller that controls the position and rate of the platform.

Initial investigations will consider a single axis only as the dynamics of each axis will be similar due to having the same drive components and electronics. It also provides a simplified system that can be easily tested and used for validating the models. It is, however, understood that the azimuth and elevation dynamics are not independent (for example, the azimuth inertial load will change as the elevation axis rotates).

The overall block diagram showing the feedback relationships between the main components of the system for a single axis is shown in Figure 2.

The details of modelling the components of the servo system from the servo amplifier to the load will now be discussed.

### B. Servo Amplifier

The servo amplifier used is a current-mode linear DC amplifier capable of providing up to 2A of current. The DC relationship was found by experimentation and connecting the amplifier to a large resistive load and measuring the current across it. This provided information on the DC Gain but did not give any information about higher frequency dynamics.

The experiment was conducted using LabVIEW, a CompactRIO and a Fluke 8808a Digital Multimeter (DMM) as shown in Figure 3. The 8808a DMM was connected to the CompactRIO via the serial interface, using plug and play instrument drivers to configure and read the current measurements. Meanwhile, the CompactRIO fed an analogue voltage to drive the servo amplifier across its full range.

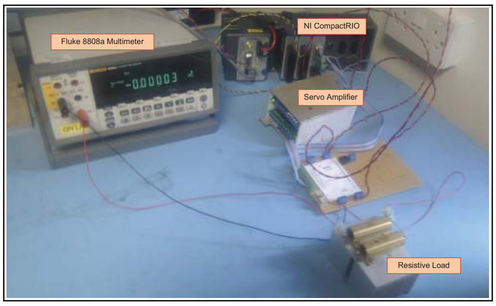

Figure 3 - Servo Amplifier Characterisation Experiment Setup

The servo amplifier was modelled as a proportional current feedback loop with a voltage saturation to represent the maximum voltage supply that can be supplied to the motor.

### C. DC Motor

The DC Motor used in the system is a high performance brushed DC motor. The motor is modelled as a two-input (voltage and load torque) and single output (motor shaft velocity) system. The DC motor model consists of two sub-processes, an electrical and mechanical, as detailed in [1].

The electrical sub-process is described by Equation 1, where $I_a$ is the armature current, $U_a$is the armature voltage, $L_a$ is the armature inductance, $R_a$ is the armature resistance, ω is the angular velocity and Ψ represents the magnetic flux.

$$\begin{aligned} I_a(t) = \frac{1}{L_a}\int_0^t \big(U_a(t) - R_a I_a(t) \\ - \Psi\omega(\mathrm{t})\big)\mathrm{dt} + \mathrm{I_a}(0) \end{aligned} \tag{1}$$

The mechanical process is described by Equation 2, where $J$ is the inertia of the motor, $K_t$ is the motor torque constant from the electrical sub-process, $M_l$ is the load torque and $M_\mathrm{f}$ is the friction torque in the motor.

$$\omega(\mathrm{t}) = \frac{1}{J}\int_0^t (K_t I_a - M_l - M_\mathrm{f})\mathrm{dt} + \omega(0) \tag{2}$$

### D. Harmonic Drive

The gearing used in the system is a harmonic drive, or strain wave gear, developed in the 1950's for the aerospace industry. It is a compact, lightweight gearbox with high gear ratios and zero backlash. Disadvantages of this type of gearing include high static friction, nonlinear compliance and high flexibility. Considerable research has been conducted into the modelling, friction compensation and control of harmonic drives due to their favourable transmission attributes [3][4][5].

From the research conducted in this field, a number of different models have been proposed for harmonic drive gears. Some of these models will now be discussed.

#### 1) Hashimoto & Kiyosawa

The dynamic model proposed in [6] considers two primary nonlinear effects of harmonic drives, Coulomb friction ($\tau_f$) and a linear stiffening spring ($K$). The dynamic equations for the model are shown by Equation 3.

$$\begin{gathered} J_l\ddot{\theta}_l - K\left(\frac{\theta_m}{N} - \theta_l\right) = 0 \\ NJ_m\ddot{\theta}_m + K\left(\frac{\theta_m}{N} - \theta_l\right) + N\tau_f = N\tau_m \\ \tau_l = K\left(\frac{\theta_m}{N} - \theta_l\right) \end{gathered} \tag{3}$$

#### 2) Ghorbel & Gandhi

The models proposed in [7] and [8] are significantly more complex and take into account additional nonlinear effects and more advanced friction models. The model, represented by $\tau_{fr}$ and shown in Equation 4, uses a LuGre friction model that takes into account Stribeck, Dahl, viscous and Coulomb friction effects and an additional position dependent component. Kinematic error in the harmonic drive is represented by $\tilde{\theta}_p$ as a function of the motor position and an additional damping term, caused by the stiffness in the drive, is represented by $B_{sp}$.

$$
\begin{aligned}
J_m\ddot{\theta}_m + K\left(\theta_l - \frac{\theta_m}{N} + \tilde{\theta}_p\right)\left[-\frac{1}{N} + \frac{d\tilde{\theta}_p}{d\theta_m}\right] \\
+ B_{sp}\left(\dot{\theta}_l - \frac{\dot{\theta}_m}{N} \\
+ \dot{\tilde{\theta}}_p\right)\left[-\frac{1}{N} + \frac{d\tilde{\theta}_p}{d\theta_m}\right] + \tau_{fr} \\
= \tau_m
\end{aligned}
\tag{4}
$$

$$
\begin{aligned}
J_l\ddot{\theta}_l + K\left(\theta_l - \frac{\theta_m}{N} + \tilde{\theta}_p\right) + B_l\dot{\theta}_l \\
+ B_{sp}\left(\dot{\theta}_l - \frac{\dot{\theta}_m}{N} + \dot{\tilde{\theta}}_p\right) = 0
\end{aligned}
$$

### 3) *Ghorbel & Dhaouadi*

The model suggested in [9] uses a nonlinear function, represented by $\tau(\dot{\theta}, \theta)$, to model a nonlinear torsional spring with nonlinear viscous damping and a function $\tau_f$ to represent a dry friction torque that includes the static friction, as shown in Equation 5.

$$
\begin{gathered}
J_m\ddot{\theta}_m + B_m\dot{\theta}_m + \tau_f + \frac{\tau(\dot{\theta}, \theta)}{N} = \tau_m \\
J_l\ddot{\theta}_l + B_l\dot{\theta}_l + \tau_l - \tau(\dot{\theta}, \theta) = 0 \\
\tau(\dot{\theta}, \theta) = g^{-1}\left[\frac{\dot{\theta}}{h(\theta)}\right] + f(\theta) \\
\theta = \frac{\theta_m}{N} - \theta_l
\end{gathered}
\tag{5}
$$

### 4) *Taghirad*

A more in-depth analysis of the friction effects in harmonic drives are proposed in [3]. The frictional components of the wave generator bearing ($\tau_{f1}$), gear meshing ($\tau_{f2}$) and output bearing are all considered separately in a friction model comprising velocity-dependant Coulomb, viscous and Stribeck friction. $T_{meas}$ represents the compliance model between the motor and load side positions. In comparison to the other models discussed, the motor and load inertias are considered as an overall effective inertia, $J_{eff}$. The overall model of the harmonic drive was therefore as per Equation 6.

$$
\begin{aligned}
K_m i - \frac{1}{N}(T_{meas}) = J_{eff}\ddot{\theta}_{wg} + (\tau_{fm} + \tau_{f1} \\
+ \tau_{f2})
\end{aligned}
\tag{6}
$$

### 5) *Tjahjowidodo, Al-Bender & Van Brussel*

The work carried out in [10] proposed a model for the torsional compliance of the harmonic drive and then performed identification on the drives in two test setups using a low and high-torque class of harmonic drive. The harmonic drive model was then described by Equation 7, with equations for the input (motor) side and load side dynamics.

$$
\begin{gathered}
J_m\ddot{\theta}_m + \frac{\left[T_b(\Delta\tilde{\theta}) + T_h\left(\Delta\tilde{\theta}, \Delta\dot{\tilde{\theta}}\right)\right]}{N+1} = \tau_m \\
J_l\ddot{\theta}_l + T_h\left(\Delta\tilde{\theta}, \Delta\dot{\tilde{\theta}}\right) + T_f(\Delta\theta_l, \Delta\theta_l) = 0
\end{gathered}
\tag{7}
$$

In Equation 7, $\tilde{\theta}$ is the difference between the motor and load angles, $T_b$ is a third order polynomial function to represent a nonlinear spring, $T_h$ represents the torsional stiffness and $T_f$ is the bearing friction torque of the harmonic drive.

## *E. Overall System Model*

This section deals with the different representations of the overall system model built from the components previously discussed and their implementation in LabVIEW.

The initial model of the system developed encompassed the models of the DC motor and servo amplifier discussed and the harmonic drive model detailed in Section 1) of II.D. It consists of a load inertia and a linear spring to represent the compliance between the motor and load side angles. Friction in the system was considered for each of the motor and harmonic drive separately as a linear damping function. The initial overall model of the mechanical system is shown in Figure 5.

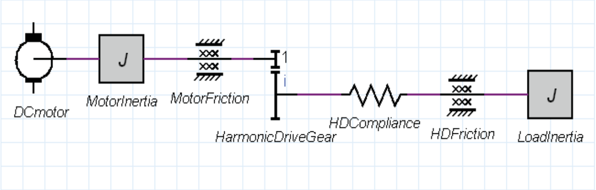

Figure 5 - Overall System Model Diagram

### 1) *Simulation Model*

Firstly, a simulation model was developed to represent the system from the dynamical equations as discussed previously. This simulation model was implemented in LabVIEW using the Control Design and Simulation toolkit as shown in Figure

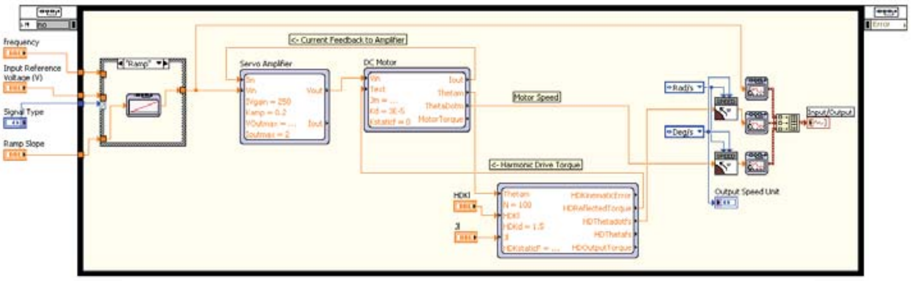

Figure 4 - Simulation Model of System in LabVIEW

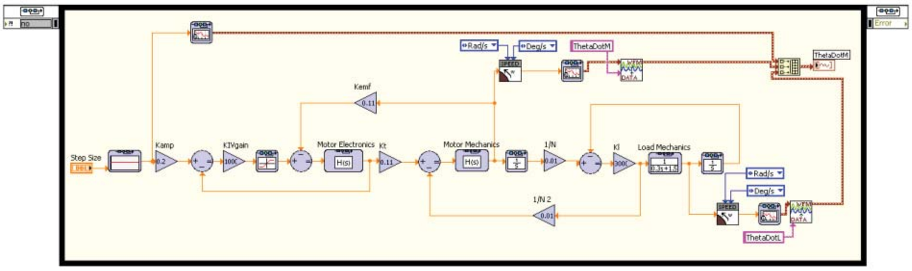

Figure 6 - Transfer Function Representation

4.

*2) Transfer Function Model*

Having a transfer function representation of the system is important to allow the use of classical design and analysis tools. From the system models, a transfer function representation using the Laplace transform was developed and implemented in LabVIEW, as shown in Figure 6.

*3) State Space Model*

The need for a state space model of the system allows for the use of modern control design and analysis tools and estimation algorithms such as the Kalman Filter rely on a state-space model of the system. They are also more suited to multiple-input multiple-output (MIMO) systems.

The state space model was implemented in LabVIEW using a MathScript node, allowing the state space equations, parameters and state space model to be defined in a textual way, as shown in Figure 7.

## III. Simulation Results

To test the correct operation of the model, simulations were run with a range of input signals. Known parameters of the system were used along with values for unknown parameters that demonstrate the operation of the model. Responses of the system to a step and sinusoidal input for the transfer function model are shown in Figure 8 and Figure 10.

Experiments were carried out for a small number of input signals to an experimental test rig containing a drive assembly of the type being modelled connected to a representative inertia for the Cobra product (including payload). This test rig will be used to validate the models and then controllers developed in the simulation will be verified using the physical test rig.

The results of running the experiments for the same input signals as shown in Figure 8 and Figure 10 are shown in Figure 9 and Figure 11.

The linear model proposed in this paper does not take into account the most important non-linear characteristic of the harmonic drive unit, the high static friction. This is shown by the discontinuity around the zero-output crossing point of the sine response, as shown in Figure 11. Current work is looking to include this effect in a future iteration of the model.

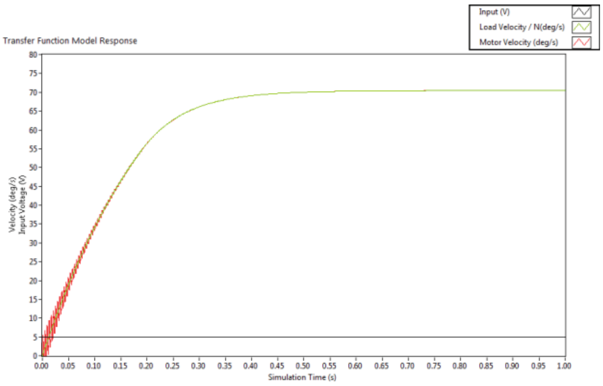

Figure 8 - 5V Step Response – Simulation

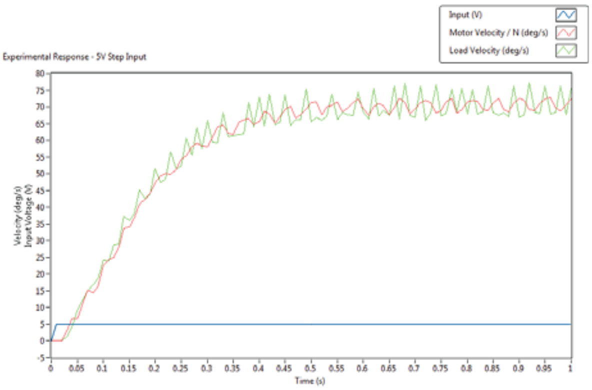

Figure 9 - 5V Step Response – Experiment

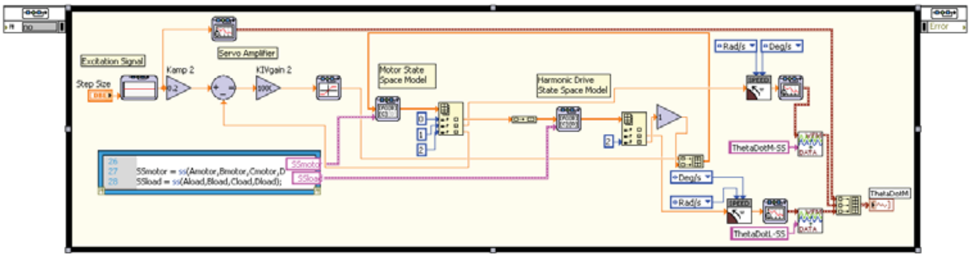

```
SSmotor = ss(Amotor,Bmotor,Cmotor,D
SSload = ss(Aload,Bload,Cload,Dload);
```

Figure 7 - State Space Representation of System Model using MathScript

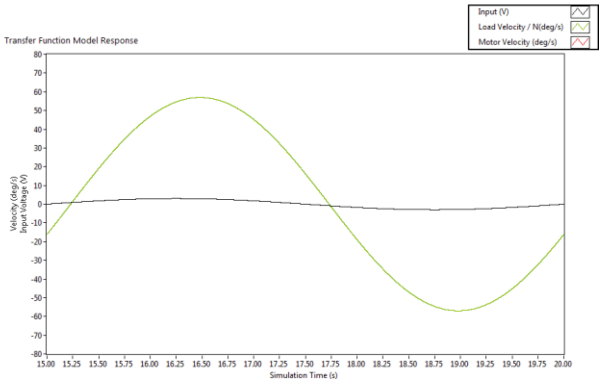

Figure 10 - 3V Low-Frequency Sine Response - Simulation

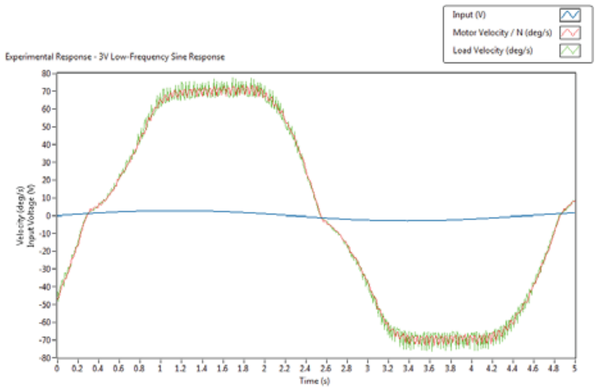

Figure 11 - 3V Low-Frequency Sine Response – Experiment

Comparing the results of the simulation and experiment, the general response of the simulation is similar, however, the experimental results exhibit measurement noise due to the quantisation error in the quadrature encoder. Also, in the experimental sine response, the maximum velocity is reached during the cycle and this limit is not reached in the simulation, as shown by the smooth sine response in Figure 10.

## IV. Further Work

Now that a model of the system has been developed and implemented using LabVIEW, further work will look at validating the model to ensure that it reflects the physical system being modelled. This will be conducted on the experimental test rig to provide a known system with which to test the system. The models can then be enhanced to include further dynamical effects and also to evaluate some of the other harmonic drive models discussed previously.

The initial model included only linear friction models, but it will be possible to extend the model to evaluate some of the nonlinear friction models that incorporate additional effects such as static and Coulomb friction, as surveyed in [11]. One example is the positional dependent friction as discussed in [8]. It was confirmed that this exists within the experimental test rig; this will be quantified and added to a future iteration of the model.

Within the larger scope of the full KTP project, the models developed will be used to test and evaluate control and estimation algorithms to evaluate the potential benefits in terms of increased performance of Chess Dynamics' products.

## V. Conclusions

In this paper, a model for a two axis servo platform has been introduced. Firstly, an outline of the system was presented, followed by models for the individual components of the system with the main area of interest being the harmonic drive gear system.

The overall model of the system was then presented and different representations of the model were then derived (simulation, transfer function and state space).

Results of running the simulation for various input signals were shown and the model was shown to lack one of the key nonlinearities of the physical system which has the most significant impact on its performance. The simulation results were then compared to the results from the physical test rig using the same input signals.

Finally, the direction of further work in the area was discussed as part of the overall KTP project.

*Abstract*—**Development and testing of automotive embedded control systems traditionally depended on the availability of prototype vehicles. Automotive manufactures adopted model based approaches in order to produce quality products faster. Thus, the need of more integrated testing using virtual environment in an automated manner becomes a vital element of product development. The full vehicle simulator aims to provide a fully integrated environment for verification and validation of the embedded automotive software to avoid the dependency of the prototype vehicles. The execution of different automated test scenarios aims to increase the development of the product faster without compromising robustness and quality. This paper deals with both the development of full vehicle simulator and the concept of the automated modelled test cases.**

***Keywords-** Hardare-in-the-loop; full vehicle simulator; automated modeled test cases, automotive control systems.*

## I. Introduction

The embedded software complexity and the number of electronic control units (ECU) integrated in modern luxury vehicles are radically increased due to the increasing distributive functionality, safety requirements and legislation for lower emissions. Today's luxury vehicles include more than 60 interconnected ECUs using various network systems [1]. Four main domains such as body systems, chassis, powe rtrain and infotainment constitute a typical vehicle electrical architecture. Mots vehicle functionality is distributed among these domains as shown in [2],[3] and [4].

The power train and chassis domain contains ECUs responsible to control systems such as engine management, anti-lock brake system, hybrid systems, transmission and vehicle dynamics [5] and [6]. These are generally continuous control systems and are interconnected using the high speed CAN network.

The body system domain, however, is responsible to deal with systems like security, locking, wipers, mirrors, start authorization, etc. These control systems are mainly event driven with response time slower than the powertrain domain. The characteristic of the body domain is that the overall functionality (i.e. locking) is distributed to more than one ECU. These ECUs are located on one or more network buses [7] and [8].

The infotainment domain is one of the most popular systems nowadays due to its human machine interface nature between and the driver and the vehicle. This system usually consists of DVD player, amplifier, human machine interface console, TV modules and navigation. Other infotainment features require communication with the external world using external media such as Bluetooth and Wi-Fi. Typically, the response time of these systems is very slow due to the nature of consumer electronics functionality. The data bandwidth required to run an infotainment system is high compared to powertrain and body domains. The driver interaction with the vehicle makes the infotainment system one of the hottest topics in modern automotive industry.

Distributive functionality shared amongst four domains can impact customer's perception about vehicle quality. Software complexity and programme development cycle substantially reduced due to continuously customer's demand for new features. Competition amongst vehicle manufactures radically increased due to demand for robust and quality vehicle systems. Advanced and sophisticated techniques (i.e. hardware-in-the-loop) commonly employed to validate the embedded software in real time early at the product development [4]. The drive to reduce dependency in prototype vehicles is still an important initiative for most vehicle manufacturers. The usage of prototype vehicles is therefore aimed mainly for verification and validation activities close to mass production data. Automated virtual testing environment promotes more robust, systematic, time efficient and cost effective way for software testing. It has the potential to uncover possible software failure modes and to perform fault diagnostics automated tests prior to development of prototype vehicles [8].

This paper is organised in the following manner: The first section deals with introduction and brief literature review in the area of automotive control system development and test. The second section presents the development of the full vehicle simulator within Jaguar Land Rover (JLR). Two case studies are considered in the next section. The results and benefits of the automated testing are depicted in section four. Section five illustrates the discussion about the main benefits of the automated modelled test cases. The last section gives some concluding remarks of the work presented in this paper.

## II. Full vehicle simulator overview

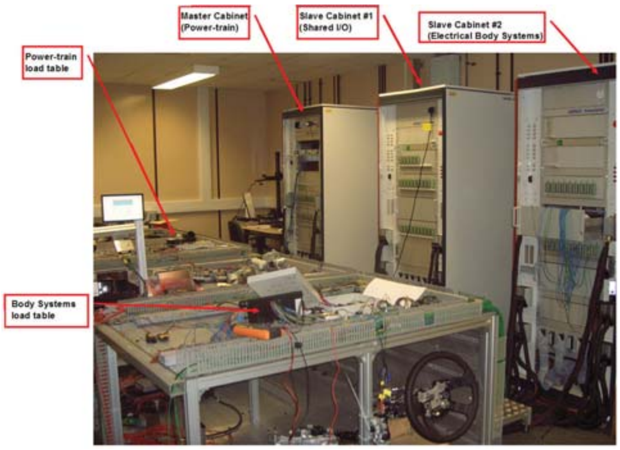
The main scope of this section is to describe the structure of the full vehicle simulator (i.e. fully integrated hardware-in-the-

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

loop platform) suitable for automated functional and non-functional testing.

### *A. Simulator setup and schematics*

The full vehicle simulator consists of three 21 inches cabinets and two load tables. The load tables hold vehicle real loads and ECUs. Figure 1 show the full vehicle simulator which is currently used within the premises of JLR.



Master Cabinet (Power-train)
Slave Cabinet #1 (Shared I/O)
Slave Cabinet #2 (Electrical Body Systems)
Power-train load table
Body Systems load table

Figure 1. Full vehicle simulator at JLR.

In the following sections the high level requirements including the number of input and output (i.e. I/O) channels specified for the full vehicle simulator are given. The amount of the I/O required to interface with the ECUs to form the vehicle architecture clearly demonstrates the complexity of the system.

The main features of this simulation platform can be summarized as follows.

149 ADC; 145 DAC; 275 digital input; 79 PWM , 195 digital out, 126 digital relay output, 88 PWM output, 24 resistive channels, 22 special channels for powertrain simulation, 110 dedicated power lines and GND, 8 CAN channels, 32 LIN channels used to interface with ECU hardware. Quiescent current measurements an all power lines (i.e. 2 power switches), 1 power supply (i.e. 400A@20V), access to CAN and LIN channels for measurements, Serial ports from processors (i.e. 3 DS1006 quad processors), Integration of the low voltage tester (i.e. LVT), On/Off capability on all power lines, Fault insertion and load boards on the input channels w.r.t (with regards to the) simulator, fault insertion capability on all CAN and LIN channels, ABS valve detection unit, colour coding on the on each I/O type, Special software to interact with the simulator (i.e. Control Desk, Automation Desk, Motion Desk, CAN/LIN multi-message), Measuring point for the main power supply (i.e. 4 banana plugs on the front side of the first cabinet).

The first cabinet (i.e. master cabinet) dedicated for the powertrain, chassis and driveline domain (i.e. high speed CAN network domain). For instance, engine management system (i.e. EMS), chassis control and transmission control ECUs are integrated on the master table. Peripheral loads such as electronic throttle, injectors, differential and transmission solenoids interfaced to ECUs via the master load table to the simulator. The aim of load integration is to enable the ECUs to functionally operate in as close as possible to the environment of the vehicle. Thus, the number of logged diagnostic trouble codes substantially reduced. Engine and transmission plant models developed and executed in real time in order to provide dynamic closed loop control between the EMS module and the models of the engine/driveline.

The second cabinet (Figure 1) is known as first slave to the master cabinet. The use of this cabinet is to provide bulk I/O (i.e. input and output) channels to powertrain and body tables. These I/Os are distributed on both load tables to provide enough channels to ECUs for the interface with the simulator.

The third cabinet (i.e. body systems cabinet) dedicated to electronic body systems (i.e. body control module, door modules, keyless vehicle module, etc) and is known as the second slave of the master cabinet. This domain is dedicated to medium speed CAN modules and their LIN slaves (i.e. intrusion monitoring system). The second load table (i.e. body systems table as shown in Figure 1) is used to accommodate all the medium speed ECUs and their peripheral components..

### *B. Integrated model to control the full vehicle simulator*

The VITAL framework is a generic model that built to interface with twelve different core processors (three quad processors DS10006) of the full vehicle simulator. The aim of this framework is to create a structured environment for integration of potentially of vehicle electrical components. Additional features of this model are summarised below:

- The model structure allows integration of three dSPACE Quad core processors or more.
- Enables simulation of Multi-CAN/LIN architectures and other network protocols (i.e. Ethernet)
- Exchange of signals between cores of each processor.
- Selection mechanism for switching between real and modelled ECUs
- Common interface for simulation of ECU loads and actuators.
- Hardware interface between ECUs and simulator arranged per dSPACE IO board..

The above features offer less development time, more optimal model structure resulting in more efficient real time execution. In addition to that the model promotes consistency and reduces the risk for development errors.

Figure 2 show only an example of the VITAL model and the closed loop integration method between the real driver door ECU and the latch plant model. The plant model in this example provides the feedback signals to the driver's door control unit (i.e. DDCU). The door ECU outputs are fed back to the door latch model and the feedback of the door latch is fed back to the door ECU via the simulator IO channels.. The door latch plant model developed in Stateflow® is a true functional representation of the real latch [9].

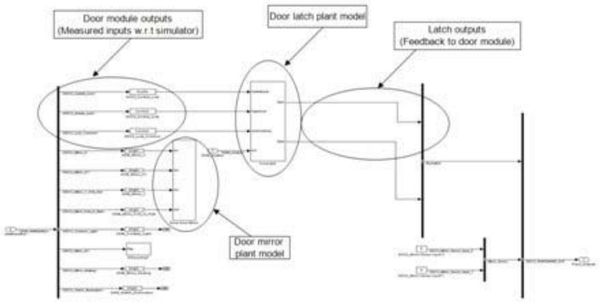


Figure 2. Hardware interface on VITAL framework for closed-loop control

More detailed description about the VITAL framework is presented in [9]

## III. CASE STUDY (CLOSED LOOP CONTROL OF BODY SYSTEM FUNCTIONALITY)

The aim of this section is to demonstrate two automated test scenarios using the fully integrated platform described previously. The first scenario is the drive away door locking and the second one is the valet mode.

The drive away door locking function is a security feature that locks all the doors automatically when the vehicle speed exceeds the threshold speed (i.e. 32Km/h). This feature is selectable by the driver, and any operation of the door locks by any other means (i.e. master locking switch on the facial panel) will unlock the doors [10].

Valet mode is also a security feature that allows the vehicle to be driven with the luggage compartment locked with restricted touch screen functionality. This feature is accessible directly from the home menu on the touch screen or from the vehicle settings screen. The vehicle owner enters a four digit Personal Identification Number (PIN) to a soft key pad displayed on the touch screen. This PIN must be entered twice in order for the valet mode to be enabled. A pop-up screen is displayed, confirming that the vehicle is now in valet mode. To cancel the valet mode operation, the PIN number must be entered once again [10].

### *A. System Overview*

The deployment of the drive away door locking and the valet mode features is depicted in Figure 3. Several ECUs are required to exchange data amongst different domains in order to interpreter the customer's operation into low level software command (i.e. set the threshold of drive away door locking).The simulation environment to deliver these features required the integration of the following ECUs and models, engine controller; gateway controller; door controllers; infotainment control units; engine and driveline real-time models.

The complexity of system integration significantly increases due to the following reasons, number of ECUs; the scale of the system integration; inter-dependencies across functional areas and domains. For instance, the DDCU receives the command from the gateway to lock the door latch when the EMS transmit the correct vehicle speed from the high speed CAN network. An engine model and accurate sensor simulation required for the real EMS hardware to assume that an engine is in operation and the vehicle is in a drive cycle. Although drive away door locking feature appears to the customer to be a simple operation the effort required to develop the automated virtual environment is certainly a challenging engineering task.

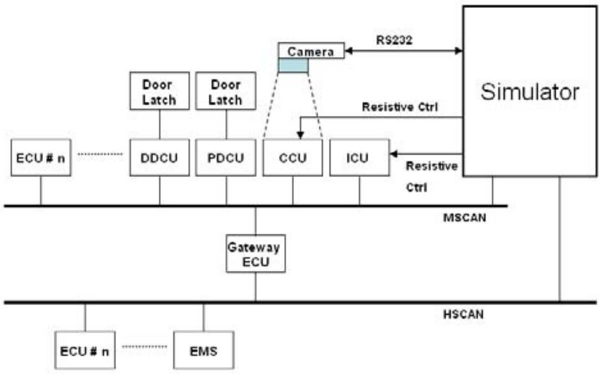

Figure 3. Schamatic of vehicle feature demployment

### *B. System Integration*

The full vehicle simulator is interfacing (Figure 3) the ICU using resistive signals for simulation of the driver switch-pack component which is hardwired back to the ICU (this switch-pack controls the navigation menu shown in the CCU'display). The simulator is also providing resistive signals to the ICU in order to emulate driver touch screen selection. High resolution camera is integrated with the simulator via serial (i.e. RS232) connection to provide feedback acquired by the image processing software. This camera is used as feedback sensor to capture the results from the instrument cluster and infotainment display. Detailed description about multi-camera vision system is out of the scope of this paper.

The two front door modules (i.e. driver and passenger), instrument cluster and infotainment display have an interface to the medium CAN bus. The two door latches are integrated to each door module using hardwire connection. The gateway ECU (i.e. ECU that accommodates the core body system functionality) is used to pass network signals from medium speed CAN bus to high speed. The EMS is interfaced with the engine model to high speed CAN in order to provide engine and vehicle speed to the rest of the vehicle systems. The rear door modules are not assessed on this paper since their behaviour is very similar to front doors.

### *C. Event driven control Logic*

Event driven control logic is a discrete programming method that is based on the conditional transition between operating modes. This method is used in this paper to model the automated control sequence of the infotainment displays selection.

### 1) *Automatic navigation on instrument cluster*

This control logic is employed for automatic selection of the drive away door locking threshold. The model is divided in two main parts.

The first part deals with the simulation of a button (i.e. up, down, left, right and OK button) from the driver's switch pack. Figure 4 shows a snapshot of this model which represents one event of the OK press button. The event sequence is required to alter the simulator's resistive output from idle (X Resistance) to pressed position (Y Resistance). The transition between the two states delayed for 500 milliseconds. This allows the instrument cluster to process the request received from the infotainment control unit. A counter is implemented to capture the complete sequence. It is also used as a transitional condition to another event (i.e. simulation of down button). In addition to counter, the camera feedback is used as an alternative transitional condition. The camera is trained to identify the main menu pattern. This menu is displayed after pressing the OK button. Figure 4 shows that either the camera feedback or the counter conditions must be satisfied in order to continue the sequence.

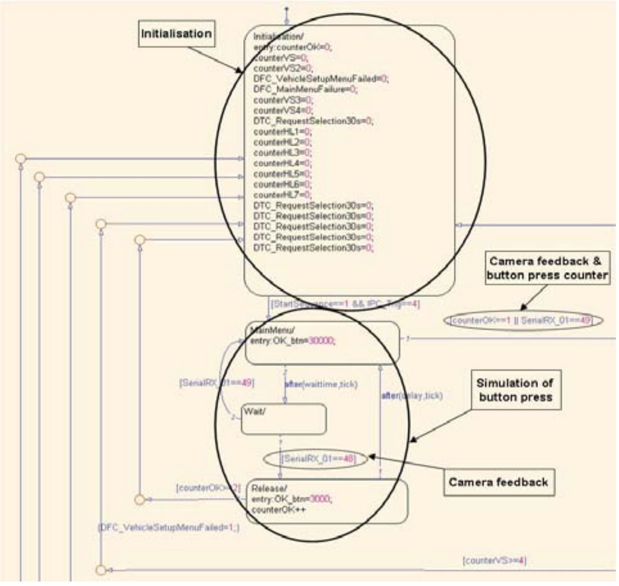

Figure 4. Automatic navigation through the instrument cluster menu

The second part (not shown in this paper) of this control logic is the evaluation of the menu position via the camera's feedback. The camera is placed to point directly the instrument cluster. It is trained to recognise five different positions of the drive away door locking settings menu. The control logic identifies the menu selection and responds to the driver's choice. For instance, different sequence is employed in order to set 32Km/h when the default position is on OFF mode and different sequence when the value is 5Km/h. The difference is due to the number of down or up button event presses. Similar concept is used to control the automatic selection of valet mode.

### 2) *Valet Mode*

The driver inserts twice a predefined four digit code to ICU touch screen in order to set the vehicle to valet mode. The automatic sequence requires selection steps on the ICU menu before the driver enters the PIN number. An event driven control logic is developed using Stateflow® to achieve this automated selection

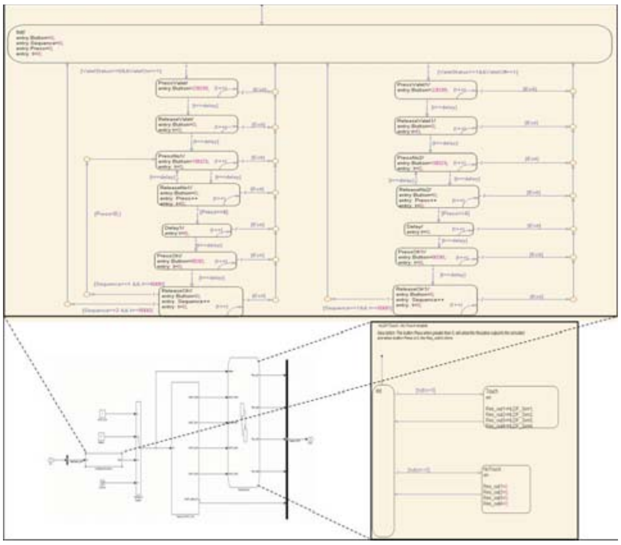

Figure 5. Automatic control of infotaiment display (i.e. valet mode selection)

Figure 5 shows only the sequence to set the valet mode on. The first state defines the initial conditions and determines the idle mode. On this mode the control logic provides the idle resistive output to ICU via the simulator's restive channel. The sequence starts when all the initial transitional conditions are satisfied. Delay of 800ms is implemented between the states after the idle mode. This allows the ICU to process the request from the driver and the infotainment graphics. Exit conditions are implemented on every stage of the sequence to ensure smooth execution avoiding stagnation points. On this particular example a medium speed CAN signal is used to inform about the valet mode status instead of camera feedback.

## *D. Control desk interface*

Control desk layouts are developed in order to control the full vehicle simulator (i.e. 20 controlDesk® tabs) via graphical user interface. Figure 6 shows only a sub-set of the main working layout. This is dedicated to control the automated selection of the drive away door locking. It is also shown that the camera mode and image processing job is controlled from this layout. The manual mode of the driver's switch pack is also part of this interface as shown in Figure 6.

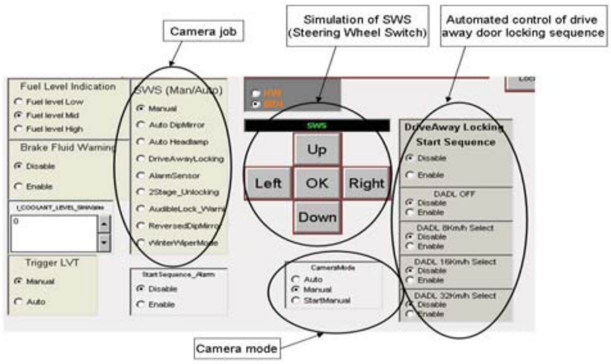

Figure 6. Graphical user interface for automated drive away door locking selection mode.

A Similar graphical user interface is developed to control the automated valet mode selection. However, this is not shown in Figure 6.

### E. *Manual test scenario description*

A manual test scenario is performed to set the drive away door locking threshold from OFF mode to 32Km/h. The flowchart in Figure 7 depicts the manual sequence.

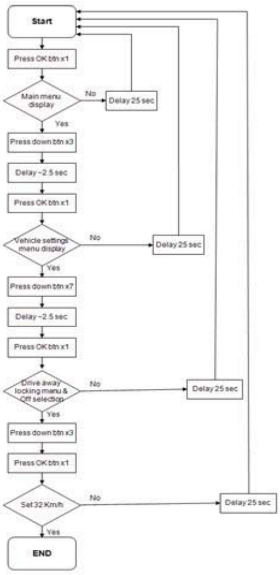

Figure 7. Flowchart of manual drive away door locking from OFF to 32Km/h

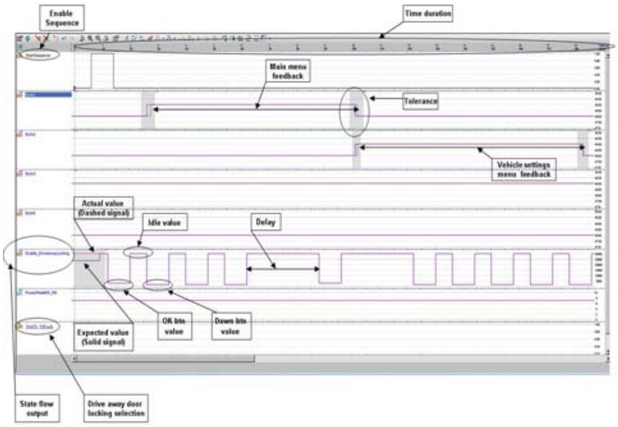
The sequence starts from a warning free instrument cluster. Figure 7 shows the exact sequence required for the instrument cluster to display the driver away door locking settings menu. Since this is a submenu, it is required to navigate three layers below the main menu. An extra delay is introduced on every conditional state (approximately 2.5 seconds) to allow the camera to process the captured image. Based on the camera feedback, the control logic decides about the status and the progress of the automated sequence. Similar manual test scenario is produced for the valet mode. The only difference is that the navigation is through the resistive touch screen of the infotainment display. The flowchart for the valet mode selection is not shown in this paper.

## IV. Test Automation

The purpose of the automated testing is to execute the existing manual test cases in a repeatable manner. MXvDEV® test automation software is used to model the automated test cases.

### A. *Execution of the automated test sequence*

Both automated sequences are executed and the results are captured in a graphical manner. Figure 8 and Figure 9 present the test results for drive away door locking and valet mode, respectively.



Enable Sequence
Time duration
Main menu feedback
Tolerance
Vehicle settings menu feedback
Actual value (Dashed signal)
Idle value
Delay
OK btn value
Down btn value
Expected value (Solid signal)
State flow output
Drive away door locking selection

Figure 8. Automated test results for drive away door locking to 32Km/h

For presentation purposes, only half duration of both scenarios are presented in Figures 8 and 9.

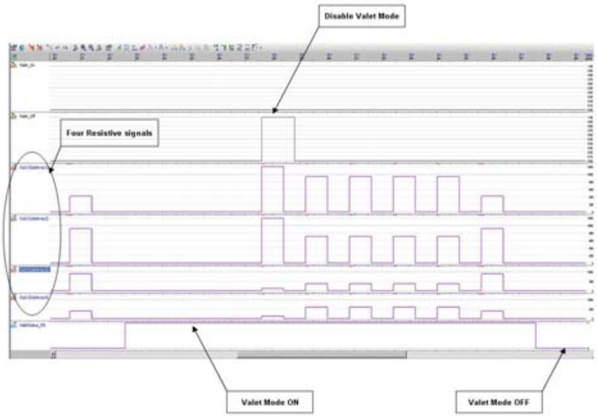


Figure 9. Automated test results to disable the valet mode.

The desired signals are graphically modelled as shown in Figures 8 and 9. It is difficult to distinguish the differences between the actual and desired signal. This is due to exact match of the two signals. For that purpose, the expected signal (i.e. sixth signal in Figure 9) is altered at the start of the sequence. A time delay is implemented on x-axis (time axis) at the first 500 milliseconds of the test in order to deliberately make the test cases result a fail (i.e. a shadowed area).

## V. Discussion

The evaluation of the test results has shown that both case studies (i.e. Figures 8-9) were executed successfully in an automated manner. These scenarios performed with zero tolerance on the y-axis. The expected signal has identically matched the actual measured. Occasional deviations observed on x-axis (i.e. time), where slight time variations (i.e. milliseconds) occurred. This is due to the time delays of the real time processor to fetch and process the results. Thus, signal delay of few milliseconds was introduced in the area of interests (i.e. shadowed areas on x-axis) to avoid failures of the test case.

The benefits of the modelled test cases are summarised below:

- Accurate definition of the test case in terms of time and signal definition.
- Graphical representation of the signal during the test execution.
- Reduced test case duplication due to test case re-use.
- Less specialised knowledge is required to analyse the test results.
- The graphical definition of the test case can uncover failure modes associated with the functional requirements prior to the test execution.
- Test cases can be linked to system requirements.
- Visualisation of signal tolerances (i.e. y-axis).
- The review of the automated test case and scenarios is significantly minimised.

The creation of the modelled test cases require well defined design verification plan and signal specification standards to be in place. This approach of automation helps JLR to move test creation using tabular format to one with graphical representation.

In addition to the above remarks regarding the creation of automated test cases, the deployment of the full vehicle simulator has demonstrated the following potentials.

- Most Electrical functional requirements can be validated prior to prototype build.
- Distributed functionality validation is decoupled from single software release.
- Drive cycles which have functional safety implications, can be executed in a controlled test environment.
- The product design can be evaluated and altered early in the programme before commitment to tier 1 is made.
- Early feature demonstration can help towards concept selection and decision making.
- Enables cross functional team working and explores opportunities towards "what can we do better and how?"

Although the aforementioned characteristics clearly deliver competitive advantage to an OEM, there are points to be considered before full deployment takes place.

- Significant upfront capital investment is required to purchase the hardware and software simulation components.
- Early engineering effort is required to develop product engineering specification.
- Engineering mind set shift from manual vehicle testing to automated simulation based testing.

## VI. Conclusion

The purpose of this paper was to present a fully integrated hardware-in-the-loop environment for validation of distributive vehicle functionality. The automated modelled test cases concept is introduced with the execution of two case studies. The successful execution of both scenarios has proven that the entire vehicle functionality can be modelled and executed on the full vehicle simulator.

***Abstract*—This paper focuses on addressing theoretical and practical considerations in developing a retrofit system for traditional internal combustion engine vehicle. Extensive simulation test results and theoretical analyses are presented and analyzed. Firstly, the basic theory of design is discussed in term of the market needs, target vehicle chosen, system components chosen, etc. A controller algorithm design is discussed in details. The performance test results are simulated later in several drive cycles. The results show that the retrofit kit can improve about 3% fuel consumption in a NEDC and 19% in a real world urban delivery drive cycle.**

***Keywords: mild hybrid, HEV, CVT, matlab/Simulink***

## I. INTRODUCTION

Nowadays, energy consumption and CO2 emissions of road transport are the main issues amongst all impacts. CO2 emissions threaten the world with climate-change. The increasing demand and the tight supply for oil is the problem every country need to face in the next decade, many research believe that the demand for oil will exceed the production capability (Figure 1) [1] Oil reserves will run short within the near future, experts are just arguing about the time. How to maintain the energy supply to catch up with the increase demand become an on-going concern and a high priority.

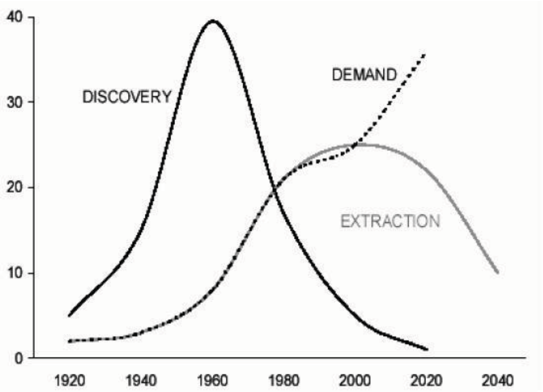

Figure.1 Actual and projected worldwide discovery, extraction and demand for conventional oil (From 1920 to 2040 in billions of barrels). [1]

The transport energy consumption takes a significant part of the oil consumption worldwide and it is continue to rise rapidly. In 2000 it was 25% higher than in 1990 and it is projected to grow by 90% between 2000 and 2030 as shown in Figure 2.[2]

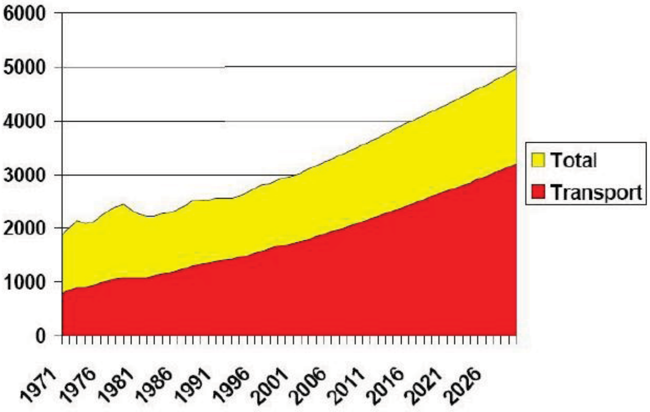

Figure. 2 Globe Oil Consumption Perspective. [2]

Some researchers indicate that Sweden and the UK are large potential markets of the HEV due to the potential energy savings and also California by the exceptionally high incentives. [3] Also the use of HEVs depends on the legislation which either increases the fuel cost or mandates high fuel economy. As a result, France and the UK are good potential markets because of the high fuel price.[4] The Daily Telegraph reported in February 2005 that “The value of home delivery has risen to £36.8bn in 2004, the story continued, with one-seventh of all spending in the retail sector now on items delivered to door”. More and more big retail companies offering the online shopping and home delivery services. This door to door shopping saved a lot of time and money for customers. The accelerating growth of the new retail pattern means that a new pattern of usage needs to be checked. This new pattern of usage of delivery vehicle, door-door and start-stop all the time, is potentially highly wasteful of fuel. Vans are most commonly used in urban areas for delivery and daily commercial use. In this way, the research start from the best potential type of vehicle, diesel Vans in UK.

## II. HYBRID PULS SYSTEM

The main objective of this research is modeling and validation a solution to retrofit the normal Diesel Van to mild-hybrid vehicle. Transfer the van into a vehicle which can do regenerate break and assist on start.

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

The system is mainly designed for big delivery fleet companies, so it should match the need of the market. It is quite different between a private car customer and a commercial fleet manager. The former would like to pay for new technology and comfort features that they can afford, while the later one often resistive to new technology and more interested in a reliable, robust vehicle with the lowest cost during the ownership. In this way, the hybrid plus system should be with an affordable price, provides acceptable vehicle performance, supports versatility of the vehicle, has low impacts on the environment, consumes drastically less fuel, provides some additional value to the customer without a big cost. The lowest cost and best robust are considered mainly throughout the design. The system contains four main parts, A Supercapacitor, A CVT, A PMDC Motor and controller units. The system works as follows in Figure 3.

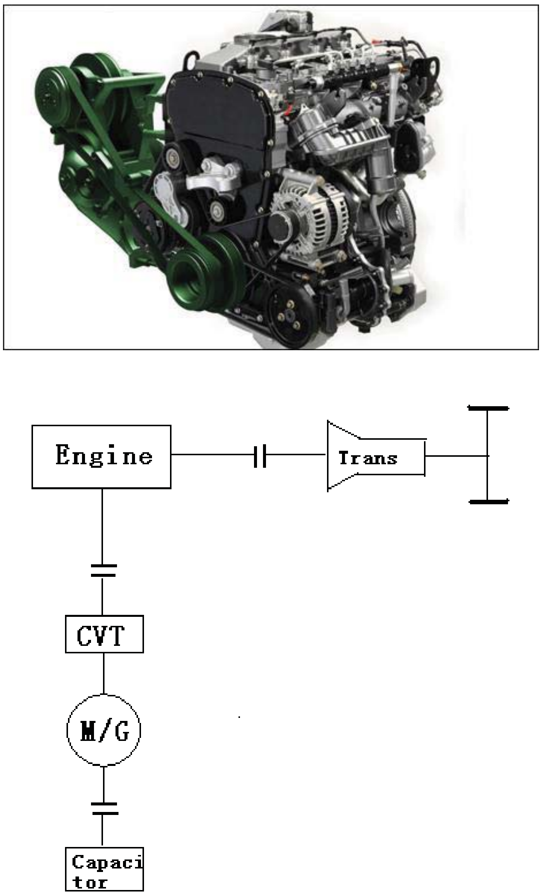

Figure.3 Hybrid plus system components

The retrofit kit will be installed in a VAN with a limit space allowed, so the size of the motor is limited. With a CVT installed between the motor and engine, the torque applied on the engine crankshaft will be increased, which means more assist and regenerate power will be provided. Normally the acceleration or brake process all finish within 3 seconds, to achieve the best assist or regenerate performance, a supercapacitor is used in this design mainly because of its quick charge/discharge performance is better than a lithium ion battery in this application

When the Engine is speed up from a very low speed, the CVT turns to a ratio which allows the motor speed same as engine speed at first. At this moment, the CVT out put the max torque and help engine accelerates. And then the engine speed is accelerating, the CVT need continuously change ratio allow the motor work at the slowest allowed speed which give a max torque on engine at every motor's speed. When the engine speed is equals to the max speed of the motor with the CVT max ratio. The clutch will off and the whole acceleration finished. This is how this system works on acceleration assist.

On the regenerate brake, it works just on the same theory. When the engine brake from a high speed to a low speed, the CVT turns to a ratio which allows the motor rotate at its max speed which will force it works as a generator. The motor generator will charge the Supercapacitor. With the engine slow down, the CVT should continuously change ratio allows the motor generator works at its max speed at every engine speed. When engine speed is decelerate to the min speed which can drive the motor as a generator, the clutch will off and the regenerate brake finish.

## III. VEHICLE POWERTRAIN MODELING

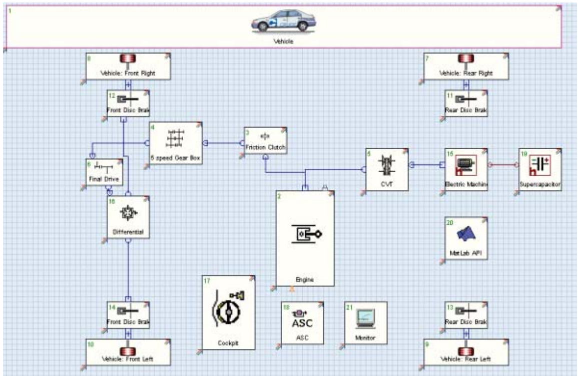

Figure.4 Hybrid plus system simulation layout

The system is basic on a typical Manual front wheel drive power-train, the system combines a CVT, a PMDC motor and a super-capacitor. With these units the system is retrofitted into a mild-hybrid vehicle. The simulation used Simulink/MATLAB run with other simulation software together build a co-simulation system.

## IV. MODELING AND SIMULATION RESULT OF THE VEHICLE

The basic theory of all hybrid vehicles is to regenerate the “free energy” from vehicle braking and use this energy to help a vehicle accelerate when it need more power. In this system the vehicle has four different states: assist mode, regenerate mode, curise mode and idle mode. The controller read CAN signal identify the vehicle mode and give the right command to motor and CVT.

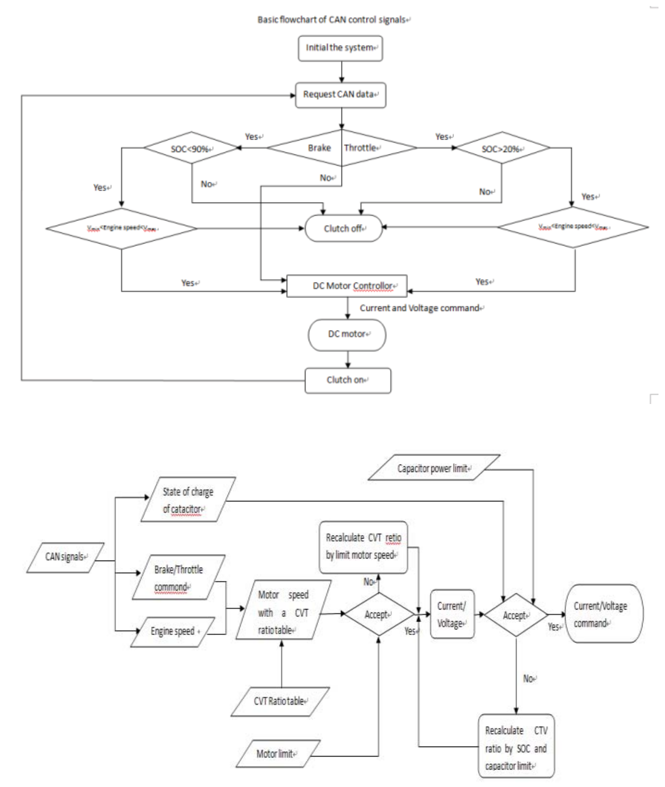

Figure.5 Hybrid plus system controller calculation piority chart

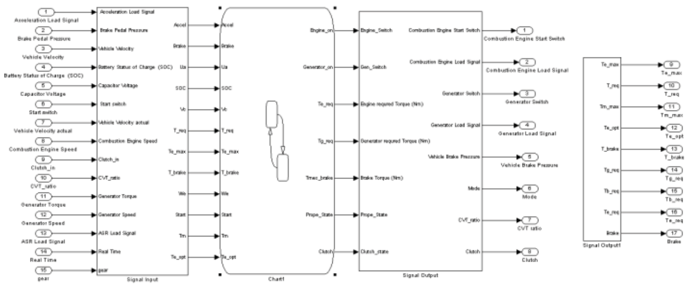

Figure.6 Hybrid plus system controller block in Matlab/SImulink

The simulation system is based on Simulink/MATLAB, the main inputs and outputs are shows in the following tables. There are three main calculation block in the model. The main part of the model is a stateflow chart. The main function of this chart is used the signals to identify the system states and gives out different commands to CVT and motor.

| | Name of inputs | unit |
|---|---|---|
| 1 | Acceleration Load Signal | % |
| 2 | Brake Pedal Pressure | bar |
| 3 | Vehicle Velocity Require | km/h |
| 4 | Battery Status of Charge (SOC) | % |
| 5 | Capacitor Voltage | V |
| 6 | Start switch | - |
| 7 | Vehicle Velocity actual | km/h |
| 8 | Combustion Engine Speed | 1/min |

Figure.7 Figure.3 Hybrid plus system controller all modes in Stateflow

In the stop mode, the Acceleration signal is 0, Brake signal is 0, torque required is 0 and vehicle speed is 0, an engine off signal will be given.

In the start mode, the engine is on, clutch signal is on and car is about to move.

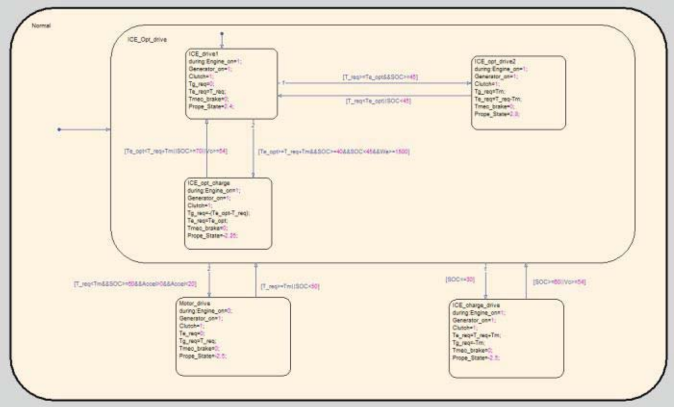

Figure.8 Hybrid plus system normal drive mode in  Stateflow

In the normal drive mode there are 3 different drive sub-modes. The motor drives only state, combine drive state and engine drive only state. When the vehicle get a start signal, the motor will spin up first drives the engine crankshaft and helps the engine to start. This state mode will be less than 1 second and then both of the engine and motor will working together or engine only. This depends on the SOC (state of charge) of the supercapacitor. When the SOC is lower than the minimum limit, the motor will work only as a generator to charge the battery.

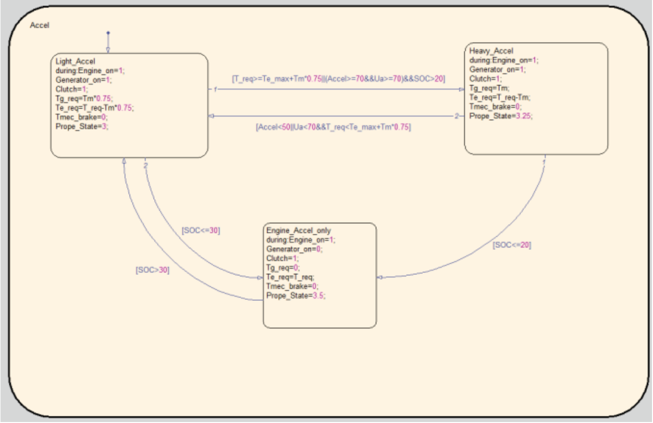

Figure.9 Hybrid plus system acceleration mode in  Stateflow

In the acceleration mode, there are 3 states. Engine accelerates only, light accelerate demand and heavy accelerate demand. When the SOC is lower than the minimum limit, the motor will stop working. In the heavy acceleration state, the motor will work in full load, in light acceleration mode the motor will work with a calculated load signal from the controller.

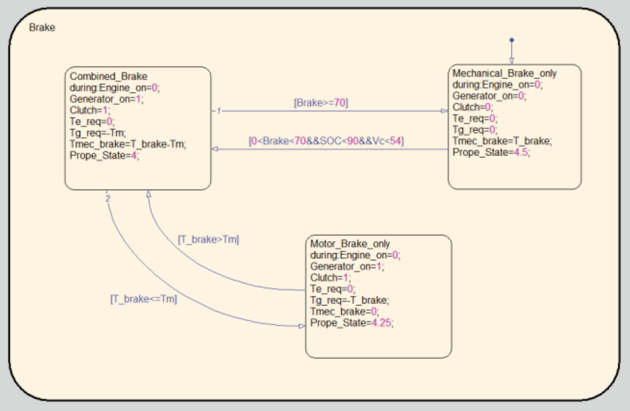

Figure.10 Hybrid plus system brake mode in Stateflow

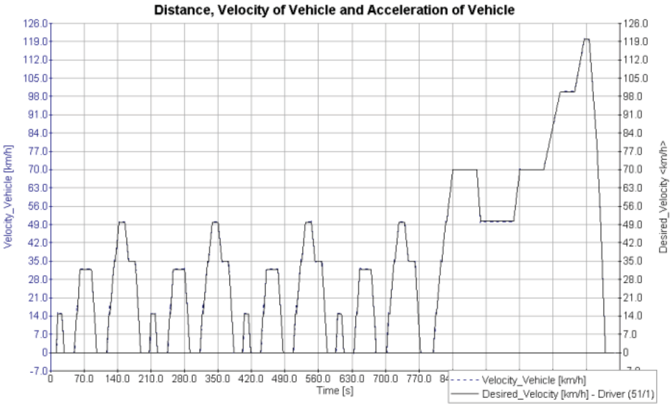
In the brake mode, there are 3 modes. Motor brake only, combined brake and mechanical brake only. This is depends on the brake signal from the CAN bus.

The vehicle been tested with several drive cycles. One simulation running under NEDC-manual (New European Driving Cycle), the simulation result shows as follows, the vehicle follows the drive cycle quite good. It follows other ones quite good as well.



## V. SUMMARY AND CONCLUSIONS

The focus on this study is the feasibility analysis and evaluation of the retrofit set, and the improvement of the fuel economy of the Van after the kit installed. This study utilized a combination of simulation and some on-road test. This paper presents the results of modeling and simulation of the mild hybrid vehicle after the kit installed.

In the NECD drive cycle the test results show that the hybrid plug in system will increase about 3% fuel consumption.

But in the door-door start stop Urban Delivery Drive Circle (UDDC) the conventional ICE vehicle test results are

| | | |
|---|---|---|
| *Overall Fuel Consumption:* | *0.6229* | *[kg]* |
| *Idle Fuel Consumption:* | *0.0310* | *[kg]* |
| *Acceleration Fuel Consumption:* | *0.2858* | *[kg]* |
| *Constant Drive Fuel Consumption:* | *0.2457* | *[kg]* |
| *Deceleration Fuel Consumption:* | *0.0603* | *[kg]* |
| *Fuel Consumption:* | *7.56* | *[l/100km]* |
| *CO2 Emission:* | *178.23* | *[g/km]* |

The Hybrid Plus system one is

| | | |
|---|---|---|
| *Overall Fuel Consumption:* | *0.5016* | *[kg]* |
| *Idle Fuel Consumption:* | *0.0009* | *[kg]* |
| *Acceleration Fuel Consumption:* | *0.3093* | *[kg]* |
| *Constant Drive Fuel Consumption:* | *0.1846* | *[kg]* |
| *Deceleration Fuel Consumption:* | *0.0068* | *[kg]* |
| *Fuel Consumption:* | *6.09* | *[l/100km]* |
| *CO2 Emission:* | *143.59* | *[g/km]* |

The fuel consumption has reduced 19.4% and CO2 emission has reduced 19.4% as well. Based on the result, this system has a great potential on energy saving and reduce CO2 emission in urban delivery vans. This retrofit gear could also be applied on the HGVs, with a proper size of motor and capacitor. The system still could be improved with the engine start/stop function while idling.

***Abstract*—This paper focuses on the development of a multivariable predictive controller for vibration suppression of a flexible manipulator using piezoelectric actuator. To the best of the authors knowledge, the predictive controller for active vibration suppression has been rarely studied, so making it a prime area research to explore. A two-step procedure performed to develop the detailed model of the whole structure. First a dynamic model of the structure without piezoelectric film actuator is developed using the combined Lagrange-Assume modes method. Second the influence of the actuator is incorporated by calculating generalized applied force on the substructure.**

***Keywords-Active Vibration Control; Flexible Structures; Model Predictive Control***

## I. INTRODUCTION

Design of flexible smart structures for vibration suppression and noise control represents a major challenge in the past two decades. Such structures are used in a variety of applications including robots, industrial machine design and tooling, aircraft systems, civil engineering structures and the space stations.

The flexible structures are generally lighter in weight, designed to use less material in order to be more transportable. They need less power for motion and therefore can be driven by smaller actuators resulting in less cost. Flexible structures are characterized by a significant number of closely spaced, lightly damped low frequency modes.

We focus on the algorithms which were recently developed and applied on motion control and active vibration damping of flexible structures. Lee and Moon [1] used two separate feedback loops for position and damping. They concluded that the controller is simple but robust, since it cancels out nonlinear and uncertain dynamics by acceleration feedback, and adds more damping by base motion feedback. Knotnic [2] used the linear quadratic regulator (LQR) and the acceleration feedback control method for vibration suppression. Chevallereau and Aoustin [3] applied nonlinear control laws for vibration control. Banks [4] used a linear quadratic Gaussian (LQG) compensator control with proper orthogonal decomposition to control a cantilever beam with a piezoelectric patch. Chen [5] applied the LQR algorithm and studied the optimum layout of the piezoelectric materials based on control performance specifications and a cost function. Robust control approaches such as $H_\infty$ control design, robust pole assignment and D-stability constraints have often been applied to the problem of controlling large flexible space structures [6].

The strategies mentioned above all provide reasonable suppression of structural vibration. However, the feedback loop controller is difficult to apply to MIMO systems. Also, LQR and LQG controllers need a very accurate plant model for good control while the $H_\infty$ controller can't easily handle multivariable constraints in the manipulated variables.

## II. MODELING

### *A. Modeling of bending vibration*

In this section the vibration of a flexible beam in the direction perpendicular to its length is considered. Such vibration is often called transverse vibration or flexural vibrations. Fig.1 illustrates a cantilevered beam with the transverse vibration [7].

From mechanics of materials, the beam sustains a bending moment M(x,t), which is related to the beam deflection by:

$$M(x,t) = EI_{cs} w_{xx}(x,t) \tag{1}$$

A model of bending vibration may be derived from examining the force diagram of an infinitesimal element of the beam as indicated in Fig. 1.

Figure 1. Simple beam in transverse vibration and a free body diagram of a small element as it is deformed by a distributed force

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

Assuming the deformation to be small enough such that the shear deformation is much smaller than w(x,t) so that the sides of the element dx do not bend, a summation of forces in the y direction yields:

$$\left(\mathrm{V(x,t)}+\frac{\partial \mathrm{V(x,t)}}{\partial \mathrm{x}}\mathrm{dx}\right)-\mathrm{V(x,t)}+\mathrm{f(x,t)dx} = \rho \mathrm{A}\frac{\partial^2 \mathrm{w(x,t)}}{\partial \mathrm{t}^2}\mathrm{dx} \qquad (2)$$

Here V(x,t) is the shear force at the left end of the element dx, V(x,t)+V(x,t)dx is the shear force at the right end of the element dx, f(x,t) is the total external force applied to the element per unit length, and the term on the right side of the equality is the inertial force of the element.

Next the moments acting on the element dx about the z axis through point Q are summed. This yield:

$$\left(\mathrm{M(x,t)}+\frac{\partial \mathrm{M(x,t)}}{\partial \mathrm{x}}\mathrm{dx}\right)-\mathrm{M(x,t)}+ \left(\mathrm{V(x,t)}+\frac{\partial \mathrm{V(x,t)}}{\partial \mathrm{x}}\mathrm{dx}\right)\mathrm{dx}+\left(\mathrm{f(x,t)dx}\right)\mathrm{dx}=0 \qquad (3)$$

It is assumed that the rotary inertia of the element dx is negligible. Simplifying this expression yields ((dx)$^2$ is assumed to be almost zero):

$$\mathrm{V(x,t)}=-\frac{\partial \mathrm{M(x,t)}}{\partial \mathrm{x}} \qquad (4)$$

Substitution of this expression for the shear force into (2) yields:

$$-\frac{\partial^2}{\partial \mathrm{x}^2}\left(\mathrm{M(x,t)}\right)\mathrm{dx}+\mathrm{f(x,t)dx}=\rho \mathrm{Adx}\frac{\partial^2 \mathrm{w(x,t)}}{\partial \mathrm{t}^2} \qquad (5)$$

Further substitution of (1) into (5) and dividing by dx yields:

$$\rho \mathrm{Adx}\frac{\partial^2 \mathrm{w(x,t)}}{\partial \mathrm{t}^2}+\frac{\partial^2}{\partial \mathrm{x}^2}\left[\mathrm{EI_{cs}}\frac{\partial^2 \mathrm{w(x,t)}}{\partial \mathrm{x}^2}\right]=\mathrm{f(x,t)} \qquad (6)$$

If no external force is applied so that f(x,t)=0 and (6) simplifies so that free vibration is governed by:

$$\frac{\partial^2 \mathrm{w(x,t)}}{\partial \mathrm{t}^2}+\mathrm{c}^2\frac{\partial^4 \mathrm{w(x,t)}}{\partial \mathrm{x}^4}=0 \quad \mathrm{c}=\sqrt{\frac{\mathrm{EI_{cs}}}{\rho \mathrm{A}}} \qquad (7)$$

Equation (7) is based on the classical undamped Euler-Bernoulli beam theory.

To solve (7), w(x,t) can take the following expanded separated form with the chosen deflection mode shapes $\varphi_i(x)$ and the modal amplitudes $q_i(t)$:

$$w(x,t)=\sum_{i=1}^{\infty} q_i(t).\varphi_i(x) \qquad (8)$$

By substituting (8) into the equation of motion (7) and after rearrangement yields:

$$\mathrm{c}^2\frac{\varphi_\mathrm{i}''''(\mathrm{x})}{\varphi_\mathrm{i}(\mathrm{x})}=-\frac{\ddot{\mathrm{q}}_\mathrm{i}(\mathrm{t})}{\mathrm{q}_\mathrm{i}(\mathrm{t})}=\omega_\mathrm{i}^2, \qquad \mathrm{c}=\sqrt{\frac{\mathrm{EI_{cs}}}{\rho \mathrm{A}}} \qquad (9)$$

where the partial derivatives have been replaced with total derivatives. (Note: $\varphi''''=d^4\varphi/dx^4, \ddot{q}=d^2q/dt^2$ ). $\omega_i$ is the natural frequency of vibration of mode i.

The spatial equation comes from rearranging (9), which yields:

$$\varphi_\mathrm{i}''''(\mathrm{x})-\frac{\omega_\mathrm{i}^2}{\mathrm{c}^2}\varphi_\mathrm{i}(\mathrm{x})=0, \qquad \mathrm{c}=\sqrt{\frac{\mathrm{EI_{cs}}}{\rho \mathrm{A}}} \qquad (10)$$

By defining:

$$\lambda_\mathrm{i}^4=\frac{\omega_\mathrm{i}^2}{\mathrm{c}^2}=\frac{\rho \mathrm{A}\omega_\mathrm{i}^2}{\mathrm{EI_{cs}}} \qquad (11)$$

And considering the boundary conditions for this problem correspond to those of a clamped-free beam [8]:

$$\varphi_\mathrm{i}(0)=0, \qquad \frac{\mathrm{d}\varphi_\mathrm{i}}{\mathrm{dx}}(0)$$
$$\frac{\mathrm{d}^2\varphi_\mathrm{i}}{\mathrm{dx}^2}(\mathrm{L})=0, \qquad \frac{\mathrm{d}^3\varphi_\mathrm{i}}{\mathrm{dx}^3}(\mathrm{L})=0 \qquad (12)$$

General solution of (10) can be obtained as:

$$\varphi_\mathrm{i}(\mathrm{x})=\cosh(\lambda_\mathrm{i}\mathrm{x})-\cos(\lambda_\mathrm{i}\mathrm{x})-\sigma_\mathrm{i}(\sinh(\lambda_\mathrm{i}\mathrm{x})-\sin(\lambda_\mathrm{i}\mathrm{x}))$$
$$\sigma_\mathrm{i}=\frac{\sinh(\lambda_\mathrm{i}\mathrm{L})-\sin(\lambda_\mathrm{i}\mathrm{L})}{\cosh(\lambda_\mathrm{i}\mathrm{L})+\cos(\lambda_\mathrm{i}\mathrm{L})} \qquad (13)$$

The quantities $\lambda_i L$ are the real roots of the equation:

$$1+\cos(\lambda_i L)\cosh(\lambda_i L)=0 \qquad (14)$$

These quantities determine the natural frequencies of the beam as follows:

$$\omega_i = \sqrt{\frac{EI_{cs}}{\rho A}}.\lambda_i^{\,2} \tag{15}$$

Table (I) shows the calculated $\lambda_i$ and $\omega_i$ for the first four modes of vibration. The temporal equation comes from rearranging (9), which yields:

$$\ddot{q}_i(t) + \omega_i^2 q_i(t) = 0 \tag{16}$$

A simple procedure for including damping is to add it to the temporal equation after separation of variables. So the modal damping can be added to (16) as follows:

$$\ddot{q}_i(t) + 2\xi_i\omega_i\dot{q}_i(t) + \omega_i^2 q_i(t) = 0 \tag{17}$$

Where $\xi_i$ is the ith modal damping ratio. The damping ratios $\xi_i$ are chosen based on experience or on experimental measurements. Empirical results in [8] show that the damping factor of the first mode is 0.01. The higher order modes were assumed to have the same damping factor. The solution, for an under damped mode becomes:

$$\begin{aligned} q_i(t) &= A_i e^{-\xi_i\omega_i t}\sin(\omega_{di}t + \Phi_i) \\ A_i &= \left[\frac{(\dot{q}_i(0) + \xi_i\omega_i q_i(0))^2 + (q_i(0)\omega_{di})^2}{\omega_{di}^2}\right]^{1/2} \\ \Phi_i &= \tan^{-1}\frac{q_i(0)\omega_{di}}{\dot{q}_i(0) + \xi_i\omega_i q_i(0)} \end{aligned} \tag{18}$$

Where $A_i$ and $\Phi_i$ are constants to be determined by the initial condition. The robot link transverse displacement, approximately obtained, as a solution of the damped Euler-Bernoulli beam theory is finally expressed by [7]:

$$\begin{aligned} w(x,t) = \sum_{i=1}^{\infty} A_i e^{-\zeta_i\omega_i t}\sin(\omega_{di}t - \Phi_i) \times \\ \{\cosh(\lambda_i x) - \cos(\lambda_i x) - \sigma_i(\sinh(\lambda_i x) - \sin(\lambda_i x))\} \end{aligned} \tag{19}$$

## B. Robot Dynamic Model

In order to obtain a set of ODE of motion to describe the dynamics of the flexible link manipulator, N differential equations must be satisfied [8]:

TABLE I. CALCULATED $\lambda_i$ AND $\omega_i$ FOR FIRST FOUR MODES

| Modes | $\lambda_i$ | $\omega_i$ (rad/s) |
|---|---|---|
| First mode | 1.8751 | 9.7474 |
| Second mode | 4.6940 | 61.0838 |
| Third mode | 7.8547 | 171.0406 |
| Fourth mode | 10.9955 | 335.1738 |

$$\frac{d}{dt}\left(\frac{\partial L}{\partial \dot{q}_i}\right) - \frac{\partial L}{\partial q_i} = Q_i \ , \ i = 1,\ldots,N+1 \tag{20}$$

Where L is the so called Lagrangian which is given by:

$$L = T - U \tag{21}$$

T represents the kinetic energy of the system and U its potential energy that can be found in [8]. The schematic of the system is shown in Fig. 2.

The joint angle $\theta$ and modal coordinates $q_i$ can form a new vector $\tilde{q}$ of the system's generalized coordinates as:

$$\tilde{q}_{(N+1)\times 1} = [\theta\, q_1\, q_2 \cdots q_N]^T \tag{22}$$

Substituting the expressions for kinetic and potential energy into (20) and performing the required operations, one obtains the following matrix equation, which is a set of N+1 ode that model the dynamic behavior of the system:

$$M\ddot{\tilde{q}}(t) + H\dot{\tilde{q}}(t) + K\tilde{q}(t) = fv_m \tag{23}$$

$v_m$ is the voltage applied to the motor. The mathematical derivation of the mass (M), damping (H) and stiffness (K) matrices also the expressions for energies of one link manipulator can be found in Appendix (B).The parameter $f$ in (23) is defined as:

$$f_{(N+1)\times 1} = [k_u\, 0\, 0 \cdots 0]^T \tag{24}$$

where $k_u$ is the torque constant and $v_m$ is the voltage applied to the motor. The model in (23) does not include the effects of the piezoelectric films, which will be derived in the following section.

## C. Analysis of Beam-Piezoelectric Interaction

Piezoelectric film could be used as an actuator or a sensor by applying a voltage or measuring the open circuit voltage, respectively. If the piezoelectric film is used as a sensor, the open circuit voltage of the sensor is given by [9] as:

$$V_{oc}(t) = \sum_{i=1}^{n} Q_i^{V_{oc}} q_i(t) \tag{25}$$

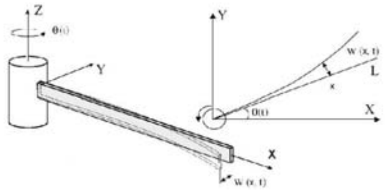

Figure 2. Schematic of the system

Where the ith modal coefficient is:

$$Q_i^{V_{oc}} = \frac{d_{31}E_cW_ct_b}{2C_c} \times \int_{a-m}^{a+m} \Xi_c(x)\frac{d^2\varphi_i(x)}{dx^2}dx \qquad (26)$$

The physical characteristics of the beam and piezoelectric films and motor for simulations are given in Appendix A. The variable $d_{31}$ is the transverse piezoelectric charge to stress ratio, $E_c$ is the Young's modulus of the film, $C_c$ is the capacitance of the piezoelectric film, $\Xi_c(x)$ is the shape function of the film, $W_c$ is the maximum width of the piezoelectric film, $t_b$ is the thickness of the beam. If the piezoelectric film is used as an actuator, its effect on the dynamic model is through the passive stiffness (negligible in this work) and the force produced by the actuator. The generalized force associated with ith mode is [9]:

$$F_i = f_i v_p \qquad (27)$$

$v_p$ is the voltage applied to the actuator. The coefficient of the generalized force is defined as:

$$f_i = -\operatorname{sgn}(z_c)\frac{d_{31}E_cW_ct_b}{2}\left(\int_{r_s^n}^{r_e^n}\Xi_c(x)\frac{d^2\varphi_i(x)}{dx^2}dx\right) \qquad (28)$$

Introducing the effect of piezoelectric films, the new system dynamic model can be described as:

$$M\ddot{\tilde{q}}(t) + H\dot{\tilde{q}}(t) + K\tilde{q}(t) = f_S v_m \qquad (29)$$

Where the new modal force coefficient matrix $f_S$, since one film were used as actuator in this work, becomes:

$$f_S = \begin{bmatrix} k_u & 0 & 0 & \dots & 0 \\ 0 & f_1 & f_2 & \dots & f_N \end{bmatrix}^T \qquad (30)$$

For modeling and control purposes it is convenient to write the model of the system in state-space form as follows:

$$\begin{aligned} \dot{x} &= Ax + Bu \\ y &= Cx \end{aligned} \qquad (31)$$

Where the matrices $A$ and $B$ are defined in terms of the stiffness, mass and damping matrices K, M and H, respectively, and the force vector $f_S$:

$$A = \begin{bmatrix} [0]_{(N+1)\times(N+1)} & I_{(N+1)\times(N+1)} \\ -[M^{-1}K]_{(N+1)\times(N+1)} & -[M^{-1}H]_{(N+1)\times(N+1)} \end{bmatrix}$$
$$B = \begin{Bmatrix} 0_{N\times1} \\ \{M^{-1}f_S\}_{N\times1} \end{Bmatrix}_{2N\times1} \qquad (32)$$

Where the state vector x includes the system's coordinates $\tilde{q}$ and $\dot{\tilde{q}}$ as:

$$x = [\tilde{q} \quad \dot{\tilde{q}}]^T_{2(N+1)\times1} \qquad (33)$$

The observation matrix C, which relates the state space to the output space, has to be obtained based on the available sensor. It includes the potentiometer encoder gain and the coefficients of the open circuit voltage for sensor that is expressed as:

$$C = \begin{bmatrix} \begin{bmatrix} k_\theta & 0 & 0 & \dots & 0 \\ 0 & Q_1^{V_{oc1}} & Q_2^{V_{oc1}} & \dots & Q_N^{V_{oc1}} \end{bmatrix} & [0] \end{bmatrix}_{2\times2(N+1)} \qquad (34)$$

Where its second row is obtained by evaluating (26) with the parameters of the sensor patch [8].

## III. Controller formulation

Model-based predictive control (MPC) is based on the principle of minimizing an objective function J that contains a vector of future errors e over a prediction horizon p, resulting in changes on m control actions every sampling instant. The error vector e is evaluated as the difference between a prediction of each output variable of the process and a set point trajectory r. If the controller focuses exclusively on set point tracking, it might choose to make large manipulated-variable adjustments. These could be impossible to achieve. They could also accelerate equipment wear or lead to control system instability [10]. Thus, the Model Predictive Controller also monitors a weighted sum of controller adjustments, calculated according to the following equation:

$$J = \begin{bmatrix} \Delta\underline{u}(0) \\ \dots \\ \Delta\underline{u}(p-1) \end{bmatrix}^T W_{\Delta u}^2 \begin{bmatrix} \Delta\underline{u}(0) \\ \dots \\ \Delta\underline{u}(p-1) \end{bmatrix} + \left(\begin{bmatrix} \hat{\underline{y}}(1) \\ \dots \\ \hat{\underline{y}}(p) \end{bmatrix} - \begin{bmatrix} \underline{r}(1) \\ \dots \\ \underline{r}(p) \end{bmatrix}\right)^T W_y^2 \left(\begin{bmatrix} \hat{\underline{y}}(1) \\ \dots \\ \hat{\underline{y}}(p) \end{bmatrix} - \begin{bmatrix} \underline{r}(1) \\ \dots \\ \underline{r}(p) \end{bmatrix}\right) \qquad (35)$$

In this work, there are two inputs to the system, one to the motor $v_m$ and one to the actuator $v_p$, and two outputs from the system, one is the motor or joint angular position which is measured by a high precision potentiometer that provides an analog voltage signal $v_\theta$, the second is the beam vibration which is measured by a piezoelectric sensor that provides an analog voltage output $v_{oc}$. So in (35), $\underline{u} = [v_m, v_p]^T$, $\underline{y} = [v_\theta, v_{oc}]^T$, $W_{\Delta u}$ and $W_y$ are weighting matrices as follows:

$$\begin{aligned} W_{\Delta u} &= \operatorname{diag}(w_{0,1}^{\Delta u}, w_{0,2}^{\Delta u}, \dots, w_{p-1,1}^{\Delta u}, w_{p-1,2}^{\Delta u}) \\ W_y &= \operatorname{diag}(w_{1,1}^{y}, w_{1,2}^{y}, \dots, w_{p,1}^{y}, w_{p,2}^{y}) \end{aligned} \qquad (36)$$

In this study, $W_y$ has unit diagonal terms so that all future errors are equally weighted while the diagonal terms in $W_{\Delta u}$ are set to the move suppression. The general MPC architecture can be illustrated in Fig. 3. The future inputs $\{\Delta \underline{u}(k \mid k), \ldots, \Delta \underline{u}(m-1+k \mid k)\}$ (optimal sequence) are calculated by minimizing the cost function subject to the following constraints on inputs to the motor and actuator: $-50 \le v_m \le 50, -200 \le v_p \le 200$.

## IV. Simulation Results

### A. Open loop

The open loop response simulation due to a step input on the motor is shown in Fig. 4. The open loop response simulation due to a step input to the piezoelectric actuator is shown in Fig 5. It is clearly seen from the open loop test that the piezoelectric actuator has very little effect on the motor's joint angle and the sensor signal is oscillating with the beam's natural frequency.

### B. Close loop

In the previous section we developed a model for the system to be controlled. In this section for simulation purposes we utilize a model as process for generating the data (see Fig. 3), considering four modes of vibration. Moreover the controller needs an approximate linear model to predict the future behaviors of the plant. We utilize a model as model predictor in Fig. 3 by considering only the first mode of vibration.

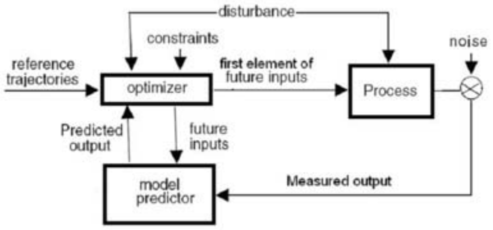

Figure 3. General MPC architecture

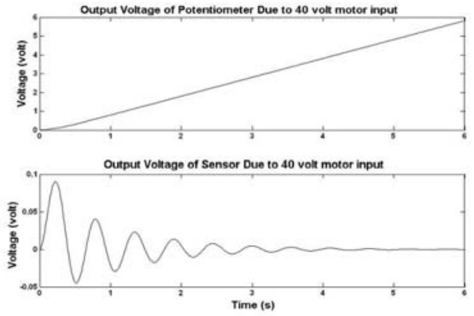

Figure 4. open loop test due to 40V motor input

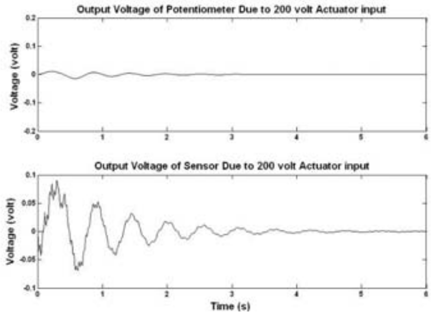

Figure 5. open loop test due to 200V actuator input

The value of prediction horizon p and control horizon m is based on the number of discrete sampling intervals required to reach within 95% of the plant output steady state. For many models, there is not much change beyond m=3~5, but *p* must be chosen as large as possible so that the value of p-m be greater than the settling time [11]. The motor is rotated and controlled to an angular set point using a multivariable predictive controller. During rotation, the beam’s vibration is suppressed until angular rotation of the motor has been completed. Fig. 6 and Fig. 7 illustrate simulation results comparison between predictive control and conventional PI control when positioning the manipulator to 57 degree (assumed prediction horizon for both output is p=70 and the control move horizon for both inputs is m=5). It can be seen the vibration is suppressed by motor and piezoelectric actuator effectively. Predictive controller signal to motor and actuator are shown in Fig. 8.

## V. CONCLUSIONS

As stated in the introduction, the aim of this paper is to present a vibration control design methodology based on predictive control strategy. This methodology is illustrated by the design of a controller for a flexible cantilever beam. The advantage of this methodology over existing methodologies is that adjustments can be made on the prediction of beam vibration that takes into account the effects due to nonlinearities in the system. This study successfully demonstrates that predictive control can be applied to suppress vibration on a flexible beam, making it an excellent candidate for future research on topics such as intelligent control using an array of sensors and actuators, as well as controller tuning specifically for other applications such as a multi-jointed flexible structures.

## APPENDIX A

This appendix contains the parameter values for the beam, motor and piezoelectric films.

TABLE II. BEAM PROPERTIES

| Material | Aluminum |
|---|---|
| Density $\rho$ (Kg/m$^3$) | 2700 |
| Young's modulus E (N/m$^2$) | $6.9\times10^{10}$ |
| Length×Width×Thickness (m) | 1×0.035×0.0019 |

# Real time Virtual Simulation of an Underactuated Pendulum-Driven Capsule System

Keattikorn Samarnggoon and Hongnian Yu

*Abstract*— **In this paper, a real time virtual simulation framework which is the foundation for studying human adaptive mechatronics (HAM) is proposed. This framework allows researchers to interact and experiment with the system in real time. Thus, motion control patterns can be identified and learned with, for example, a heuristic strategy. The prototype is developed with an underactuated pendulum-driven capsule robot model. Motion control patterns are identified and presented. The experimentation results demonstrate the proposed concept.**

***Keywords-human adaptive mechatronics, pendulum capsule robot, underactuated systems, virtual environment, real time system (key words)***

## I. INTRODUCTION

Human adaptive mechatronics (HAM) is defined as an intelligence human machine system in which the system can be self-adapted intelligently based on the current user competency level to obtain optimum performance [1–5]. To achieve the HAM requirements, there must be several mechanisms working together. The main components of a HAM system are human operators, the intelligent discrimination of operator actions, competency evaluation metrics, human machine interaction mechanisms, and the machine system.

The work presented in this paper is a part of HAM research which covers a real time virtual system for understand the functions of human operators in HAM which has many invaluable advantages. This kind of virtual simulation systems running in real time allows researchers to experiment with dynamic of the modelled system in an immediate and interactive manner. Robotic researchers usually design mechanical systems by modelling mathematical relation of system parts but there exists troublesome to find control patterns for human operating a robot. This issue can be overcome by the help of real time virtual simulation systems. Motion control patterns could be identified by trial and error (heuristic) experimentation strategies using this virtual system. Moreover, apart from the robot mechanical simulation itself, dynamics of the environment can also be integrated into the simulation, for examples, different frictions of ground areas, dynamic of fluid while controlling robot movements, and capsule bots moving on a simulated deformable surface in medical application robotics.

Virtual training is also capable with this real time simulation based on the human-in-the-loop concept of mechanical systems. Training scenarios can be implemented with little effort or at no cost. Measurement of performance improvements can also be done from the feedback within the environments. This allows users to practice as much as they want. As a result, the user learning curve could be improved drastically. Regarding training environment with virtual real time simulation, it is a novel concept called human adaptive mechatronics that could further help optimise the learning curve of a user while training by its assisting behaviours.

The main contributions of the paper are

- Proposing a real time virtual human and machine interactions framework. The proposed framework will be a basis for development and realisation of the HAM concept.
- Developing a human heuristic learning strategy for learning motion control patterns.
- Conducting the experimental tests to demonstrate the framework and the HAM concepts.

## II. RELATED WORKS

Human is considered the main component of the HAM systems because the aim of this system is a combination of an automatic control and adaptive manual control system which is operated by humans. Normally, humans are complex and unpredictable, but if they are involved in a goal oriented task, it is possible to recognise their intentions. Human has been long studied in many related fields e.g., neurophysiological, neuroscience, cognitive science, and psychophysical. In neuroscience study, Haynes and colleague successfully read human covert intention by decoding brain images from various sections simultaneously [6], [7]. The pattern recognition technique is used in decoding those human intentions by discriminate patterns from spatial information from various brain activity areas. This method of using spatial brain information is claimed to be more accurate than analysing only specific area of the human brain. The reason is that when human performing an activity, several of brain areas are working together according to its functions. Additionally, human intentions are influenced from personal experiences. This is indicated by Blakemore and Decety analysis of the evidences of brain activity [8]. The evidences show that when human perceive biological motions there exists brain activity that try to simulate these motions internally. As a consequence, this internal simulation would reflect as intentions in future actions. This basically works in the same way as training activity to improve personal experience.

Human has good abilities to learn, predict, and process information. However, these capabilities are depended on individual. A task that is performed by different persons might return different results because of individual ability. Individual ability is usually denoted by word ‘skill’ and the outcome from using skill to perform an action is called ‘performance’. Learning capability is another magnificence aspect of human being in which humans have learnt to improve their skills and as an overall result i.e., overall

This work has been supported by the European Erasmus-Mundus Sustainable eTourism project 2010-2359, the EPSRC UK-Japan Network on Human Adaptive Mechatronics Project (EP/E025250/1) and EU Erasmus Mundus Project-ELINK (EM ECW-ref.149674-EM-1- 2008-1-UK-ERAMUNDUS).

performance improvement. The most important part that ruled all of these capabilities is the thinking inside the human brain. Consequently, as mentioned earlier, internal thinking would reflect out as the intentions to do a specified task. This intended output actions could be identified by pattern recognition techniques. The intention recognition is also considered as part of the HAM system.

For the intelligent machine to serve or adapt to human appropriately, it needs to know human intentions by estimating from various kinds of related information. Fortunately, sensor technologies have advanced significantly along with the matured field of pattern recognition. These two combinations are essential for online human intention recognition. Observations and measurements from sensors are the inputs to pattern recognition algorithms to identify or estimate human intention at time. There exist numbers of information to be monitored and measured which is depended on the type of tasks. For examples, patterns of force signals exert on an arm gripper are recognised to discriminate human operator actions when performs industrial weight loading operation using Hidden Markov Models [9], motion and velocity pattern profiles are the information used to classify human actions in telemanipulation tasks [10]. The identified actions are useful for switching among virtual fixture models which help in different mode of operations. Once the machine has ability to identify human intention in which step the human operator is performing. It is functionality of the next component of the HAM system to evaluate how well the performing competency.

The aim of competency evaluation is to measure how well the operator is performing a step of the task so that the next component of the HAM system can make adaptations for assisting the operator. A generic performance evaluation framework, human performance index (HPI), is proposed in [11]. The framework consists of two layers of evaluation. The first layer is the collection of performance variables that evaluate raw competency of actions. The second layer is the weighted conditional integral of those variables in the first layer for specific area of measurement e.g. speed, and accuracy. This layer is called performance criterions. Final performance conclusion, HPI, is then weighted and accumulated from the second layer values. On the other hand, this HPI measurement concept can be viewed as grading evaluation in education such as school. Evaluations such as paper works, examinations, and attendance are scored. These scores are weighted with different percentage values according to its importance. The subject's grade is calculated from these values. Grading point average (GPA) is finally calculated from weighted credits of each subject. Therefore, the HPI is viewed as the GPA while performance criterions are viewed as subjects, and raw evaluations are viewed as those scorings. In addition, this HPI framework could be used in two modes, open form and closed form. The open form is located at the second layer in which these performance criterions can be used in any applicable future closed form. The closed form is located at the final accumulation evaluations, HPI or GPA. Performance criterions such as speed and accuracy are the example of competency measurement metric. This metric is a basis for the next step of the HAM system, adaptive tuning.

Intelligent adaptation of the HAM system is tuned based on current operator competency. There are two types of adaptation i.e., passive and active adaptation. Tuning parameters inside the machine without interfering the operator is a passive adaptation [12]. An active adaptation works in the opposite way. It actively assists the operator by, as an example, pushing small amount of force to the controller grip to help achieving the aimed intention easily [13–15].

The basis system model for this paper is an underactuated modelling approach and a 6-step motion control strategy to develop a desired driving profile studied in [16].

Underactuated mechanical systems are a system that has less control inputs than degrees of freedom of the system to be controlled. This system may also occur in a full actuated system because it losses some freedom of control due to some reasons such as accident or system failure.

## III. PROPOSED REAL TIME VIRTUAL SIMULATION SYSTEM

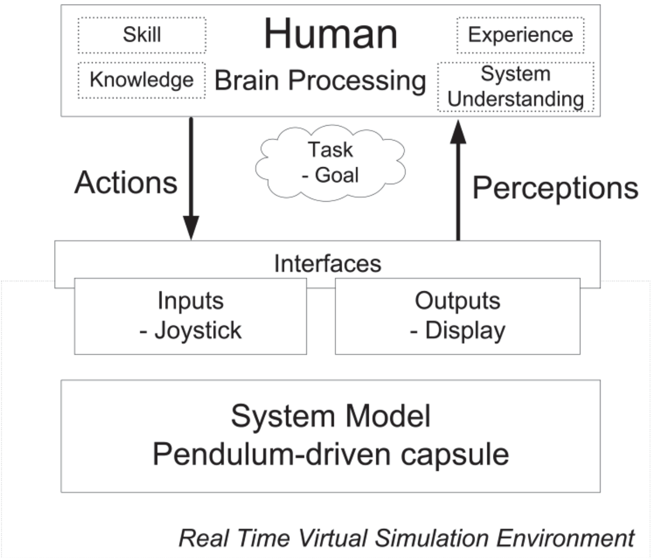

**Figure 1. Diagram of the proposed real time virtual simulation based on HAM.**

In this paper, the framework for the human machine controlling system in real time virtual simulation environment is proposed. Fig.1 shows a diagram and components of the system. The human operator interacts with a real time virtual simulation via the provided interfaces while perceiving information from the controlling system through a display monitor. It is the human operator's brain that processes information and orders the muscles to take actions to control an interface to manipulate the machine for accomplishing the desired task. Information is retrieved through various perception channels, e.g., eyes looking at meaningful data on the display screen, ears hearing the alert sound signal, and feeling of touching control interfaces. The human operator then observes, interprets, and processes this information and reacts with appropriate actions with the aimed goal in mind. Overall, these activities can be viewed as a human-in-the-loop control scheme and they are working together to be a system. Lacks of one of these components could cause the system failure.

The human block in the proposed framework diagram (Fig.1) acts as a controller that controls the underlying virtual simulation system. Loop of brain processing, perceptions, and actions that related to the human block is performed simultaneously. To control the system, the human operator first needs to know the goal of the controlling task. Then, the control strategy is planned to reach the goal. For example, the heuristic strategy is one of many strategy selections. Based on the planned strategy, series of actions are performed repeatedly. Outcome of each action may not be as planned but it can be adapted according to the situation because of adaptability of human. This process can be viewed as a learning process to control the system. It is individual skills that affect all blocks in the human related loop i.e., skill for perceptions, skill for information processing, and skill for conducting actions. These inputs (perceptions), outputs (actions), and internal flows (brain activities) work as a control system that interacts with the underlying virtual simulation environment.

There is a ‘task’ block located in conjunction between a human controller and the system (Fig.1). Task understanding is needed to be given first so that the human operator is able to plan actions ahead in mind. For example, the given task as controlling a robot to the right, an operator might think ahead about how to control to reach the given goal. Thus, it is very important to describe the task goal to the human operator.

The proposed real time virtual simulation environment needs software components to compose the system. These components are responsible to simulate the dynamical system, in this case the pendulum-driven capsule robot, to interface with the input system, to render the outputs to the display interface, and in the future functionalities; to recognise human intention and to calculate assisted tuning parameters and forces. The blocks component of this simulation environment from the software architecture point of view is shown in Fig.2.

Software architecture design for this proposed system in Fig.2 is designed centred on the following system functional requirements: 1) simulating dynamics in real time, 2) allowing the user to interact with the simulated dynamic via some controlling interfaces, 3) displaying adequate information for the user to perceive, 4) recognising and adapting the system behaviour based on the current user’s competency, and 5) logging and saving experiment data for future analysis. It starts with initial conditions and enters the main simulation loop with the aimed sampling time step. The simulation loop continues running until the software is terminated. Inside of the simulation loop, there are particular components executing to serve the whole functionalities of this virtual system. The ordinary differential equation solver, ODE Solver block, is used for solving ordinary differential equations with the implemented method and algorithm. The equations are based on the mathematical model of the mechanical system. The input system is responsible to handle an interface between the human operator and the virtual system. The input values from the device are transformed into the model’s input at every single step of simulation loops. The display output is drawn by the underlying graphic rendering system to visualize the simulating environment. Additional features such as the log system and the real time oscilloscope alike, the graphing system are essential for analysing immediate simulating values as well as logged values for later analysis. Realisation of HAM cannot be achieved without the following components; adaptation computation based on human intention and its corresponding competency, adaptation computation which is divided into passive and active tuning (Shaded blocks in Fig.2).

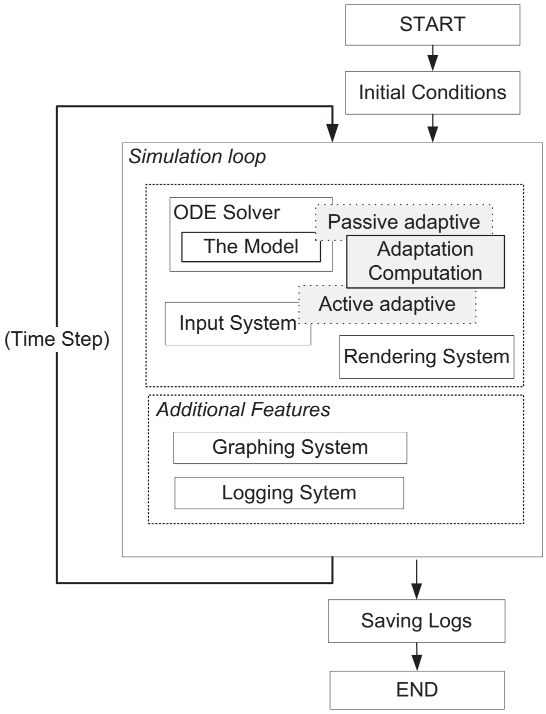

**Figure 2. The software architecture.**

## IV. MODEL OF THE DYNAMICAL SYSTEM

The schematic diagram of the underactuated pendulum-driven capsule system [16] shown in Fig.3 is adopted as a machine to the proposed virtual simulation system. M is mass of a capsule body. The mass m is on the top of the weightless link L. The link can rotate 360 degrees around the centre. One dimensional movement is defined by a position denoted by x and friction f is modelled to point in an opposite direction of the body movement base on the Coulomb’s friction model. The system is driven only by the force from the movement of the ball which is exerted by input torque τ and its moving momentum that causes forces.

The movement is possible because of both pendulum force and surface friction force.

From Fig.3, the ball position is defined in terms of cart position x at the centre as shown in equation (1). Then, the ball position equation is differentiated to get velocity and acceleration as in equations (2) and (3) respectively.

$$ball\ position = (x - Lsin\theta)\hat{\imath} + (Lcos\theta)\hat{\jmath} \quad (1)$$

$$ball\ velocity = \left(\dot{x} - L\dot{\theta}cos\theta\right)\hat{\imath} - (L\dot{\theta}sin\theta)\hat{\jmath} \quad (2)$$

$$ball\ acceleration = (\ddot{x} - L\ddot{\theta}cos\theta + L\dot{\theta}^2 sin\theta)\hat{\imath} - (L\ddot{\theta}sin\theta + L\dot{\theta}^2 cos\theta)\hat{\jmath} \quad (3)$$

Equation (3) and Newton's law of motion give forces from motion of pendulum ball in both x and y directions as follows.

$$F_{bx} = -m\ddot{x}_b \text{ , and } F_{by} - mg = m\ddot{y}_b$$

$$F_b = \begin{bmatrix} F_{bx} \\ F_{by} \end{bmatrix} = \begin{bmatrix} -m\ddot{x} + mL\ddot{\theta}cos\theta - mL\dot{\theta}^2 sin\theta \\ mg - mL\ddot{\theta}sin\theta - mL\dot{\theta}^2 cos\theta \end{bmatrix}$$

Also, the input torque to the joint is calculated as follows.

$$\tau = (-mLcos\theta)\ddot{x} + (mL^2)\ddot{\theta} - mgLsin\theta$$

$$F_{bx} - f = M\ddot{x}\ ; \quad \text{where } \ f = \mu N sgn(\dot{x})$$

$$N = Mg + F_{by}$$

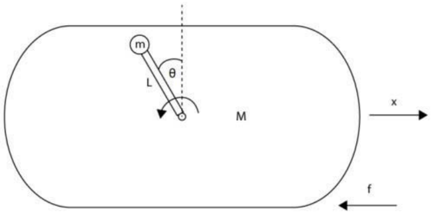

**Figure 3. Pendulum-driven capsule system.**

From above equations, we have

$$\ddot{x} = \frac{f\sigma_1 + \ddot{\theta}Lmcos\theta - \dot{\theta}Lmsin\theta}{M + m} \quad (4)$$

where $\sigma_1 = -g(M + m) + \dot{\theta}^2 Lmcos\theta + \ddot{\theta}Lmsin\theta$

$$\ddot{\theta} = \frac{Lmcos\theta\ddot{x} + \tau + gLmsin\theta}{L^2 m} \quad (5)$$

Equations (4) and (5) are the system equations with the single control input torque τ.

## V. IMPLEMENTATION OF REAL TIME SIMULATION

To conduct real time simulation, the forth order Runge Kutta numerical approximation method of ODEs [17] is used. From the system model (4) and (5), we have

$$\dot{v} = \frac{(2M + 2m)(\sigma_2 + \mu S\sigma_3) - \omega^2 Lmsin\theta}{(M + m)(2M + m - mcos2\theta - \mu Smsin2\theta)} \quad (6)$$

$$where\ \sigma_2 = \frac{cos\theta(\tau + gLmsin\theta)}{L}$$

$$and\ \sigma_3 = \frac{gLmsin^2\theta + \tau sin\theta}{L} - g(M + m) + \omega^2 Lmcos\theta$$

$$\dot{\omega} = \frac{(2M + 2m)(\tau + gLmsin\theta - \sigma_4)}{L^2 m(2M + m - mcos2\theta - \mu Smsin2\theta)} \quad (7)$$

$$where\ \sigma_4 = \frac{Lmcos\theta(\mu S(Mg + mg - \omega^2 Lmcos\theta) + \omega^2 Lmsin\theta)}{M + m}$$

$$\dot{x} = v \quad (8)$$

$$\dot{\theta} = \omega \quad (9)$$

where $S = sgn(\dot{x})$

Equations (6), (7), (8), and (9) are then solved by the forth order Runge Kutta numerical approximation algorithm.

An implementation of this real time virtual simulation system is developed using the industry leading application programming interface named Microsoft XNA and C# programming language. Sampling time is chosen at 10ms although it might change depending on the system performance but the system implementation is coded to compensate the issue by using elapsed time of each loop as a time step. The system parameters are as follows; M=0.5kg, m=0.05kg, L=0.3m, g=9.81m/s$^2$, μ=0.01 N*m/s.

The proposed real time virtual simulation system is controlled by the gaming joystick. The only system input is the amount of torque applied to the joint. The amount of torque can be varied by pushing an analogue stick in which its value is range between -1.0 and 1.0 N. In this case, the mapping is straightforward i.e. [-1.0, 1.0], value from an analogue stick is mapped to the input torque, τ, to drive the underactuated pendulum-driven capsule robot. However, it is noticed that the aimed system time step is 10ms. Therefore, the torque pushed by the joystick in real time is applied to the system at every time step of the system loop.

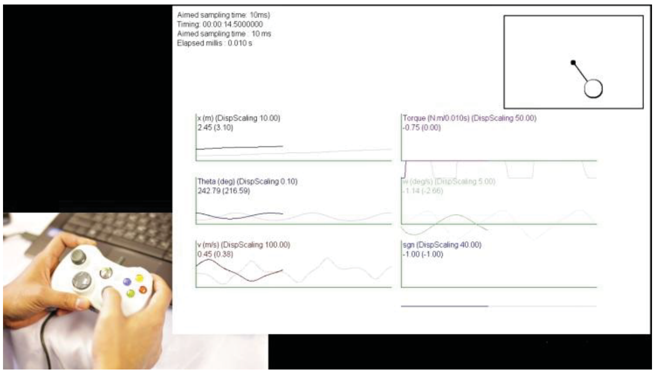
The screenshot of the simulation display is shown in Fig.4 when the system is simulated. The capsule body and its inner swinging shaft with the attached pendulum ball are displayed for the user to observe the capsule robot. Also, additional features for output information data are shown as online oscilloscope like a graphing system for both user observation and validation purposes.

Observations and manual controls are an inevitable couple in the human-in-the-loop control system. The proposed online simulation system displays necessary information on the monitor for observation while the user control amount of input torque via a joystick is shown in Fig.4. The user has an assigned task in mind while observing the pendulum movement on the screen and react to the dynamic behaviour of the system in real time to achieve desire control motions. In this case motion is in one dimensional movement i.e. moving to the left or vice versa.

Both input and output raw data during runtime experimentation of controlling are logged and saved for further analysis. Angle θ, angular velocity ω, capsule position x, capsule velocity v, and input torque τ are those variables that have been recorded. Also, an extra variable such as sign ($sgn\dot{x}$) of the friction term is logged for more clarification and validation of the implemented friction model.

## VI. Learning of Motion Control Patterns

One of the useful functionality of the real-time simulation system is apparent for heuristic strategy experimentation. In the following section, searches and results of motion control patterns for the pendulum-driven capsule system are presented. Control characteristics were experimented by the heuristic strategy. Ability to control this dynamical system is depended on the user's skill and understanding of the system. However, once understood, control characteristics can be identified and used as a pattern of control strategy.



Aimed sampling time: 10ms)
Timing: 00:00:14.5000000
Aimed sampling time : 10 ms
Elapsed millis : 0.010 s

x (m) (DispScaling 10.00)
2.45 (3.10)

-0.75 (0.00)

Theta (deg) (DispScaling 0.10)
242.79 (216.59)

w (deg/s) (DispScaling 5.00)
-1.14 (-2.66)

v (m/s) (DispScaling 100.00)
0.45 (0.38)

sgn (DispScaling 40.00)
-1.00 (-1.00)

**Figure 4. User using the joystick to control virtual simulation system.**

The system initial values θ, ω, x, v, and τ are 180 degrees, 0 rad/s, 0 m, 0 m/s, and 0 N.m/s respectively. At the beginning the system stays still with the pendulum shaft and the ball lying straight down. When a small torque is applied, the pendulum begins to swing and the capsule start to move to the left and to the right repeatedly according to forces from the ball and the surface friction model as shown in Fig.5. The capsule is unintentionally displaced to the right by small torque after it finally comes to the steady state.

After several tries to control movement of the pendulum-driven capsule, the control strategy is developed. The system begins at the steady state and is intentionally controlled using the identified control patterns to move a capsule to the left and then to the right (Appendix 1). The identified control patterns to move a capsule by an input torque is summarised by the following strategies.

Step 1) Generate a torque by pushing the joystick to allow the pendulum to swing freely around, and then release the joystick (Fig.6).

Step 2) If one wants to move the capsule to the left, while the pendulum is freely swinging to the left side, the human operator needs to push the torque backward suddenly only in an appropriate short period of time. Moving to the right is done in the opposite way (Fig.7).

More precisely, to move to the left, the user needs to push the torque in the middle of rising or falling of angular velocity. In other words, one needs to push the torque at the edge of sine curves. These torque control strategies allow the user to control the pendulum driven capsule in the desired directions.

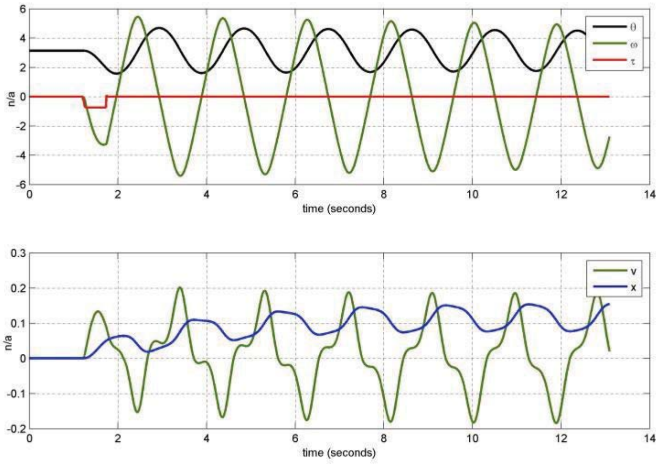

**Figure 5. Single pushed torque.**

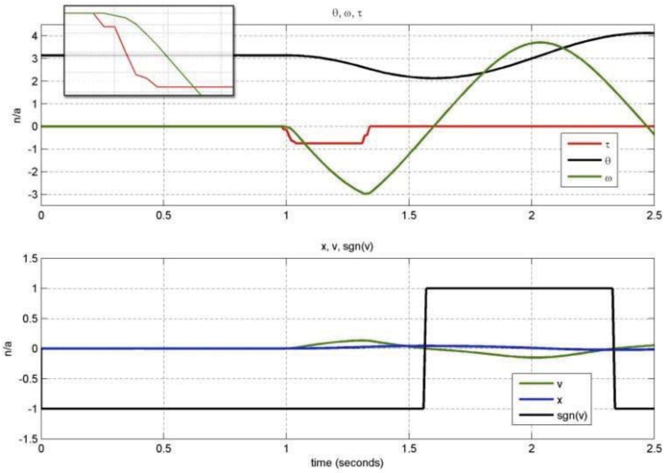

**Figure 6. Control characteristics for step 1.**

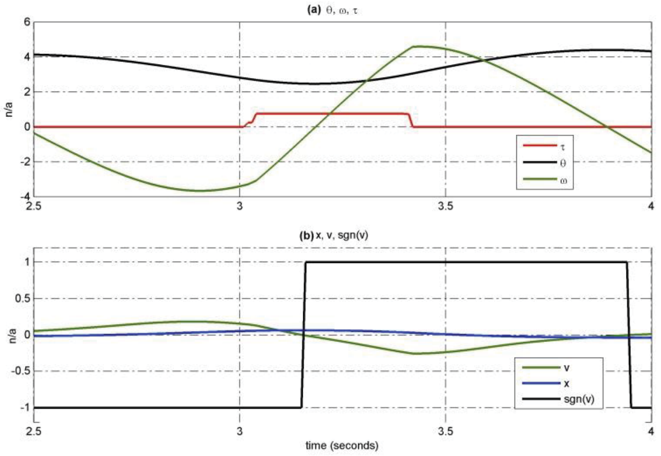

**Figure 7. Control characteristics for step 2.**

## VII. CONCLUSIONS AND FUTURE WORK

A framework of the human-in-the-loop control scheme using real time virtual simulation has been proposed. The software architecture and implementation of the underactuated pendulum-driven capsule robot system have been developed. Usefulness of real time simulation is apparent because of an interactivity nature of this type of systems. The system dynamic model can be realised experimentally. As a result, systematic motion control patterns can be identified. The system also exposes an important of human controlling ability. Different user controlling skills appear to be an important factor in the human-in-the-loop system control. The human controlling skill is depended on user's perceptions, brain processing of particular circumstances, and control actions. Overall performance of the system is another aspect compared to user skills that control the system.

The identified patterns of motion control for the joint torque seem similar to a walking cycle of human. The inverted bottom half circle of leg movements is shown in Fig.8. For example, given that desired movement is to move to the right, at first push the pendulum to swing freely from A to B and vice versa. At the moment that the pendulum ball nearly reaches point B, the torque should add in the opposite way. This will make the capsule move to the right because of both pushed torque and friction. This is working in the same way as human walking habits.

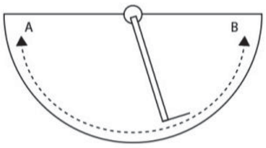

**Figure 8. Human walk cycle.**

In future works, closed loop control of an underactuated pendulum-driven capsule robot and a more complex model of double underactuated pendulum-driven robot [18] will be implemented as well as realization of an assisting control system based on human adaptive mechatronics. Also, the important adaptive mechanisms that would affect and optimise the learning curve of training will be experimented.

*Abstract*— **A Current-to-Pressure (I/P) converter is a device which converts a current input, typically between 4mA and 20mA, to a proportional pressure output. Such devices are often used in valve positioners and regulators to provide accurate and flexible control. This paper describes a physics based mathematical model of an I/P converter implemented using Matlab which is capable of simulating response under dynamic conditions. Detailed physical conditions such as thermal conduction and convection (and their effects on components), compressible orifice flow and inertial movement of components have been incorporated into the model using an explicit time-stepping lumped-parameter scheme. Parameters were obtained for the model using a series of novel experimental procedures. Experimental tests were carried out on a set of I/P converters over a range of operating temperatures and input current sequences. It is shown that the correlation between the simulated results (based on only measured physical characteristics of components) and the experimental test results is quantitatively accurate. It is further shown that the simulation allows the effects of significant design changes to be predicted, and that comparison between experimental and simulated results reveals areas where complex flow behaviour modifies pressure output significantly.**

***Keywords: Current-to-Pressure converter, Time-stepping, compressible flow***

## I. INTRODUCTION

Current-to-pressure converters are used to control the pressure of many applications in a wide range of industries because of their capacity for precise control and their dynamic behaviour. The dynamic modelling of a voice-coil I/P converter relies on the information obtained from actual testing done on existing devices and eventually can be used to validate the simulation model for various parameters which the system might endure during its operation.

The mathematical model has been developed based on governing equations which are determined by the flow, mechanical and electromagnetic behaviours of the system. The following sequential steps were used for the model: calculation of mass flow rate through each compartment, determination of the pressure in each compartment by considering thermal effects and finally the determination of the dynamics of mechanical elements. By means of various tests on specific components, key parameters were found which could be fed to the mathematical model and by making sensible approximation of non-critical parameters (for which information proved difficult to obtain), a working simulation was developed on Matlab to predict the dynamic behaviour of the I/P converter. The simulation is based on an explicit time-stepping lumped-parameter scheme.

There is a limited number of reported researches on the modelling and simulation of current-to-pressure converters; however the following references have proved valuable. There are different methodologies for developing and simulating pneumatic actuators which are controlled by proportional valves [1][3]. Simulation based on polytropic and bondgraph modelling are two different methods which can allow analysis of the dynamics of pneumatic actuators. The polytropic method does not take into consideration the effect of thermal heat transfer [2]. Validation of a simulation of a developed model is important. By means of experiments, it is possible to investigate how accurate the dynamics of a theoretical model is compared with pneumatic actuators [4].

A non-linear mathematical modelling which considers the 1) mass flow rate through restrictions, 2) pressure and temperature evolution in each compartment and 3) dynamics of the mechanical elements has been used in this paper [5]. Effects of non-linear flow through valves, and compressibility, are critical elements for accurate modelling [6]. To validate the results of simulation, testing was carried out on an actual I/P converter and the results were compared for quantitative analysis.

## II. MATHEMATICAL MODEL

An analysis of subsystems at a fundamental level was applied to derive the mathematical model; fluid, thermal and electro-mechanical interactions were incorporated as differential equations of motion. Considering the flow through the compartments of the I/P convertor, there are three points in the system which actively restrict the mass flow rate as illustrated in Fig.1; modelling must include the effects of compressibility as the pressures involved can exceed 5 bar.

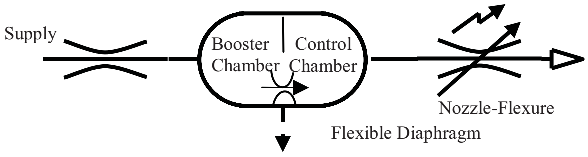

Figure 1: Simplified Schematic of I/P converter

Norgren Ltd., (Watson Smith) – A subsidiary of IMI plc.

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

The governing equation for mass flow rate through a restrictor for a compressible fluid is given by (1).

$$\dot{m} = \frac{C_d P_{01}}{\sqrt{RT_{01}}} A_t \left(\frac{P_t}{P_{01}}\right)^{1/\gamma} \sqrt{\frac{2\gamma}{\gamma-1}\left(1-\left(\frac{P_t}{P_{01}}\right)^{\frac{\gamma-1}{\gamma}}\right)} \qquad (1)$$

for a Critical Pressure ratio >0.528, and

$$\dot{m} = \frac{C_d P_{01}}{\sqrt{RT_{01}}} A_t \, \gamma^{\frac{1}{2}} \left(\frac{2}{\gamma+1}\right)^{(\gamma+1)/2(\gamma-1)} \qquad (2)$$

for a Critical Pressure ratio ≤0.528,

where $\dot{m}$ is the mass flow rate, $C_d$is the discharge coefficient, $P_{01}$is the upstream pressure, $T_{01}$is the upstream temperature and $A_t$ is the cross sectional area of the throat.

The density, pressure and temperature in each compartment are linked by the ideal gas law:

$$P = \rho RT \qquad (3)$$

Where P is the Pressure, $\rho$ is the density and T is temperature.

The characteristic of the pressure, volume and density in each volume varies as a function of time, thus giving the following expression for the differential pressure:

$$\frac{dP}{dt} = \frac{d\rho}{dt} RT + \rho R \frac{dT}{dt} \qquad (4)$$

Heat transfer will have an effect on the overall system, especially considering the operating range of the I/P converter varies between -40°C and +85°C.

Heat transfer through conduction is modelled by considering the overall heat transfer coefficients, the contact area between pairs of components, and the temperature differences. This allows a calculation of heat flow rate between any given pair of components (the word ‘components’ is here used to include the external air or the flowing pressurized gas). Reasonable assumptions have been made for the heat transfer coefficients based on the types of material. Direct application of Fourier’s law of heat conduction by considering thermal conductivity proved quite difficult since many of the components within the I/P converter have an uneven shape and a varied surface finish. The rate of change of temperature from heat transfer follows from Newton’s Law:

$$\frac{dT_i}{dt} = \frac{1}{m_i C_i} \sum_j h_{ij} A_{ij} \Delta T_{ij} \qquad (5)$$

Where $m_i$ is the mass of individual component $i$, $C_i$ is the specific heat capacity of the component (or air), $h_{ij}$ is the overall heat transfer coefficient between adjacent components (or fluids) $i$ and $j$, $A_{ij}$ is the area of component $i$ in contact with $j$ and $\Delta T_{ij}$ is the temperature difference between the components.

Hence the temperature of each component, $i$, evolves in time according to

$$T_i(t+\Delta t) = T_i(t) + \frac{dT_i}{dt} \times \Delta t, \qquad (6)$$

where $\Delta t$ is the time step used in the simulation. Each volume contains mechanical elements which regulate the flow. A poppet valve controls the flow going into the booster region from a high pressure air supply and its distance of travel determines the throat area and thus the flow rate. The distance ($x$) it moves is dependent upon the balancing force created by the control volume pressure and the booster volume pressure. The mass of the poppet valve is assumed to be negligible and considering the elastic component controlling the movement, the following equation was derived:

$$\mathrm{x} = \mathrm{b}(\mathrm{P_c} - \mathrm{P_b}) + \mathrm{x_o} \qquad (7)$$

Where $x_o$ is the initial clearance of the ball valve and *b* is the opening per Pascal difference in the control and booster pressure, measured using a force gauge.

A voice coil is used to regulate the flow from the control volume which eventually controls the control pressure ($P_c$). An electromagnetic force, $F_e$ which is created by the voice coil is used to push a flexure towards a nozzle and by varying the input signal the amount of force can be controlled.

The electromagnetic force is given by:

$$F_e = d.I, \qquad (8)$$

Where *d* is the force per unit current of the solenoid (measured experimentally) and *I* is the input current.

The flexure behaviour is quite similar to a spring and obeys Hooke’s law.

$$F_x = k.\Delta x_2 \qquad (9)$$

Where, k is the stiffness of the flexure element and $x_2$ is the distance travelled by the flexure.

By considering the system in balance condition, the opening of the flexure from the nozzle is a function of the force of the pressure pushing against the flexure through a nozzle, the electromagnetic force and the mechanical (spring) force resulting from the flexure.

Neglecting spring stiffness of the flexure and aerodynamic effects, the (idealized) steady-state pressure of the control volume is given by a force balance between the magnetic force of the voice-coil pulling the flexure towards a nozzle ($dI$) and the control volume's pressure within the nozzle that pushes against this force :

$$P_c \frac{\pi D^2}{4} = dI \,, \tag{10}$$

where $P_c$ is the control volume pressure and $D$ is the diameter of the nozzle.

## III. SIMULATION

The mathematical model was implemented in Matlab to allow the simulation of the response under dynamic conditions. This was achieved by using a forward-difference method to time-step the differential equations. Various physical parameters have to be defined in the simulation model for accurate response; these physical parameters were obtained by means of experiments on crucial components.

The Matlab model has been defined such that it will generate graphs of the booster pressure ($P_b$) and the control pressure ($P_c$) with respect to time and input current. The following step inputs current have been used:

From 0-1s: 0mA
From 1-2s: 1mA
From 2-3s: 2mA
From 3-4s: 4mA
From 4-5s: 10mA
From 5-6s: 20mA

### *A. Simulation Results*

The initial values of the temperatures of each compartment and component were set at 293K. The fluid supply temperature set at 283K. Initial values of the booster volume pressure and the control volume pressure were set at1bar (absolute) and the supply pressure at 6bar (absolute). Fig.1 shows the simulation result and Fig.3 shows the simulation results which takes into consideration the volumes of the connecting pipes to the pressure sensors.

## IV. EXPERIMENTAL SET-UP AND RESULTS

Dynamic test was carried out at Norgren Ltd. where the booster pressure and control pressure were recorded. As illustrated in Fig.2, the I/P converter and a volumetric load cell from which the flow was supplied, were mounted inside an environmental chamber to maintain uniform temperature during the test. The current signal was generated from a programmable D.C. current supply. The pressure data from the pressure transducers were captured and processed by an oscilloscope.

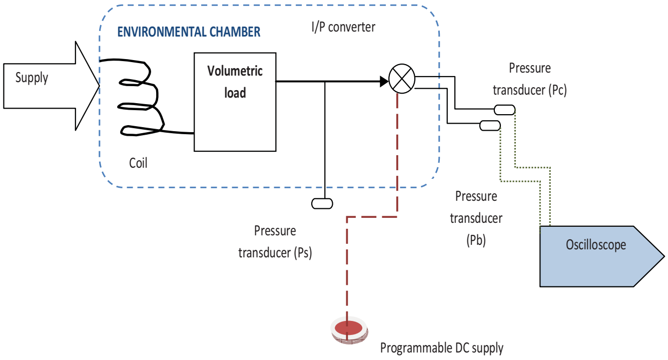

Figure 2: Experimental setup

Fig.4 shows the test results carried at a constant temperature of 293K.

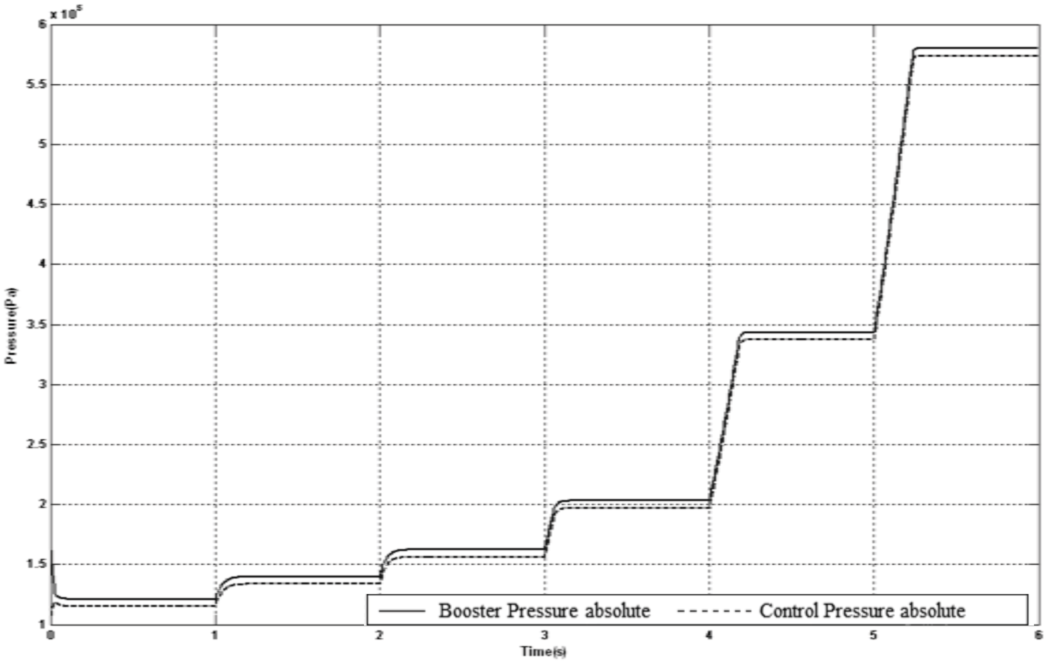

Figure 1:Simulation of output pressure as input current is increased in steps.

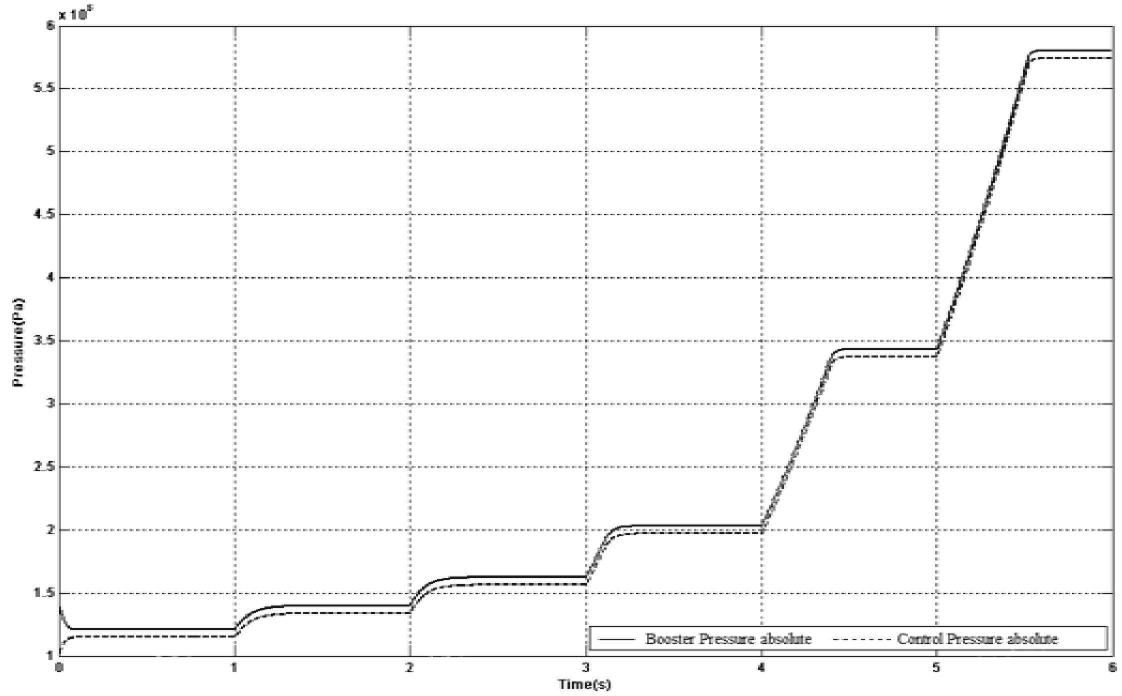

Figure 3: Simulation including volumes of connecting pipes

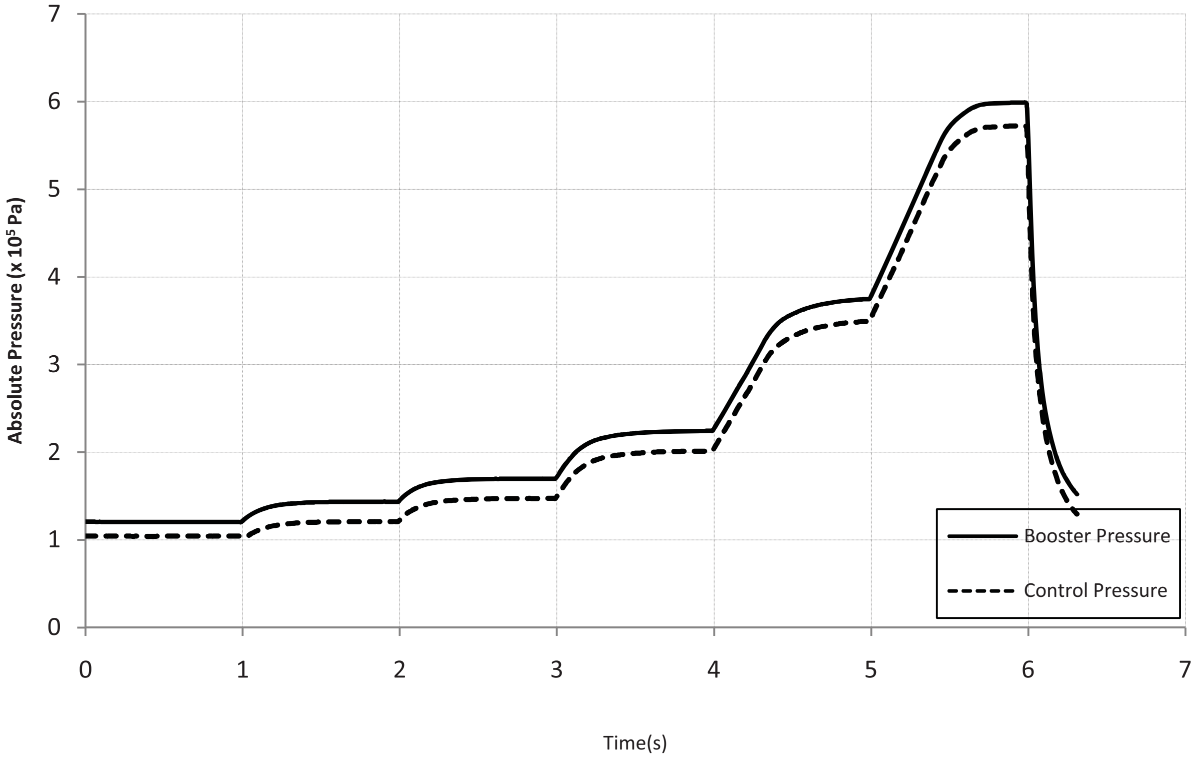

Figure 4: Test results for Pb and Pc

## V. Discussion

Table 1 and Table 2 show the test results versus the simulation results for the booster volume pressure and the control volume pressure respectively. From table 1 and table 2, it shown that the simulation results varies up to 14.3% for the booster volume pressures and up to 26.2% for the control volume pressures. Considering the normal range of input current which is *4-* to *20*-mA, the variation of the control volume pressures is within reasonable range.

TABLE 1: BOOSTER PRESSURE WITH PERCENTAGE VARIATION

| | **Booster Pressure (Bara)** | | |
|---|---|---|---|
| **I/mA** | ***Physical Test*** | ***Simulation*** | ***% variation*** |
| 0 | 1.2 | 1.372 | 14.3 |
| 1 | 1.43 | 1.581 | 10.5 |
| 2 | 1.7 | 1.818 | 7.1 |
| 4 | 2.23 | 2.148 | -3.6 |
| 10 | 3.71 | 3.527 | -4.9 |
| 20 | 5.98 | 5.879 | -1.7 |

TABLE 2: CONTROL PRESSURE WITH PERCENTAGE VARIATION

| | **Control Pressure (Bara)** | | |
|---|---|---|---|
| **I/mA** | ***Physical Test*** | ***Simulation*** | ***% variation*** |
| 0 | 1.04 | 1.312 | 26.2 |
| 1 | 1.21 | 1.521 | 25.7 |
| 2 | 1.47 | 1.756 | 19.5 |
| 4 | 2.01 | 2.087 | 3.8 |
| 10 | 3.49 | 3.465 | -0.7 |
| 20 | 5.71 | 5.812 | 1.8 |

It should be noted that from Fig. 1 and Fig. 4, that the response times for both booster volume pressures and the control volume pressures are quite different, this can be explained by the fact that the connecting pipes to the pressure sensors increase the volumes and eventually increases the response time. The additional volumes of the connecting pipes were included in the simulation run to give better accuracy of the results. This is shown in Fig. 3. It is important to highlight that the simulation will not give complete accuracy as there are assumptions and approximations made in the modelling, however comparison between simulation and experiment can lead to greater understanding of both.

## VI. CONCLUSION

This paper analyses how a mathematical model based on domains of fluid, mechanical and electromagnetic of a current-to-pressure can be developed in Matlab to simulate the dynamic response of the system. The simulation results show that the mathematical modelling of the system is effective over the operating range of input current. In addition, experiments were carried out in a controlled environment to validate the simulation model. Within acceptable levels of accuracy, the simulation has been shown to predict important behaviour of the pressures in the booster and control chambers with regards to changes made to the physical I/P converter.

## NOMENCLATURE

| Symbol | Description | Units |
|---|---|---|
| $A_i$ | Contact area | $m^2$ |
| $A_t$ | Cross sectional area of orifice | $m^2$ |
| b | Displacement per unit pressure | m/Pa |
| $C_d$ | Coefficient of discharge | |
| $C_i$ | Specific heat capacity | J/(kgK) |
| d | Electromagnetic force constant | N/A |
| $\gamma$ | Heat capacity ratio | |
| $h_i$ | Overall heat transfer coefficient | $W/(m^2 K)$ |
| I | Current | A |
| $\dot{m}$ | Mass flow rate | kg/s |
| $P_{01}$ | Upstream Pressure | Pa |
| $P_b$ | Booster volume pressure | Pa |
| $P_c$ | Control volume pressure | Pa |
| $P_t$ | Pressure at orifice | Pa |
| $\rho$ | Density | $kg/m^3$ |
| $T_{01}$ | Upstream temperature | K |
| $x_0$, x, $x_2$ | Displacement | m |

***Abstract*—Main bearing that plays the role of supporting and making the cutter to rotate and tunnel is the core part of TBM. Because of the harsh working conditions and complex changeful construction, the axial and radial load and environmental factors such as temperature of TBM main bearing are changing to make the fault of main bearing presenting randomness, and then the not easy identified fault may be produced. The traditional neural network model can not dynamic consider the cause of the reasons, parts and types, BP neural network fault diagnosis model based on fault reasons—signs matrix is presented in this paper. Firstly, the faults are screened through the fault reasons—symptom matrix, and the neural network structure is designed according to the screening result, then, the fault type is identified by way of model training. According to TBM main bearing fault symptoms data provided by a heavy enterprises practical engineering and MATLAB simulation validation, the feasibility and superiority of this model method are proved.**

***Keywords-TBM; BP neural network; fault diagnosis; signs matrix; MATLAB***

## I. INTRODUCTION

TBM is the main construction machinery of the underground tunneling construction, it can prevent soft foundation excavation face collapse and keep excavation face stable, at the same time, it can also finished the tunnel excavation and lining operations securely in machine[1-2]. At present, TBM is used widely in the large tunnel projects of city subway, river tunnel, and sea-crossing tunnel and so on. Because of the harsh working conditions and complex construction, the TBM fault rate is higher. Now, troubleshooting means still mainly rely on artificial maintenance, and timely fault repaired rate is low. The experiences show that a skilled technicians who to eliminate fault, need the time of total time of 70% to 90% to determine the fault reasons and parts, while only about 10%-30% for clearing the faults.

Main bearing that plays the role of supporting and making the cutter to rotate and tunnel is the core part of TBM[3]. In the Shiziyang tunnel engineering right line of China railway 12th bureau Guangshengang special passenger line, when the TBM was propelling, because of the bad lubrication and severe wear making the TBM appearing the abnormal vibration, the TBM was often at half stop condition, and the average working time was 2-5 hours. The construction progress was influenced seriously. Therefore, the significance is very great to ensure the security of TBM main bearing.

## II. ESTABLISHMENT OF THE FAILURE REASONS — SYMPTOM MATRIX

### A. *Main Bearing Fault Diagnosis Model Based on Boolean Function*

Assume that the fault symptoms of a common system are $S_1, S_2, \cdots, S_n$, and the reasons of the malfunction are $R_1, R_2, \cdots, R_m$. Fault diagnosis means that it infers one or a few possible failure causing reasons in the collection basing on a few signs in the collection of the observed fault symptoms. Therefore, we define a Boolean function $E(S_1, S_2, \cdots, S_n; R_1, R_2, \cdots, R_m)$, which is used to describe which combinations of fault symptoms appearing in which causes of the malfunctions; Define Boolean function $G(S_1, S_2, \cdots, S_n)$ to indicate the sign of a combination of the cause of the malfunction, namely the fault symptoms detected by the sensor.

Then define the Boolean function $C(R_1, R_2, \cdots, R_m)$, which is used to show that which combinations of the causes of the malfunctions can match with the existing sign combinations, namely the fault diagnosis which is looking for. The whole process of the fault diagnosis can be described the process of looking for the function $G(\bullet)$ in Formula (1):

$$C(\bullet) = G(\bullet) \bullet E(\bullet) \tag{1}$$

Failure causes and symptoms are binary Boolean relations, so Boolean Relation matrix is used to represent the function $E(\bullet)$ in the actual diagnosis, namely the failure reasons — symptom matrix.

Function $G(\bullet)$ is the fault symptoms collected through sensors and other detection means, which can be represented by Boolean vectors. So with the knowing of $G(\bullet)$ and $G(\bullet)$, we can get the diagnostic results $G(\bullet)$ through equation (1), $G(\bullet)$ is also a Boolean vector.

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

### *B. Establishment of Failure Reasons —Symptom Matrix*

The binary Boolean relation matrix between systems' failure causes and symptoms is used to describe Boolean function $E(S_1, S_2, \cdots, S_n; R_1, R_2, \cdots, R_m)$ in this paper.

An ordinary system, for example, the relationship matrix between failure causes and symptoms is:

$$\begin{bmatrix} I_{1,1} & I_{1,2} & \cdots & I_{1,j} & \cdots & I_{1,m} \\ I_{2,1} & I_{2,2} & \cdots & I_{2,j} & \cdots & I_{2,m} \\ \\ I_{i,1} & I_{i,2} & \cdots & I_{i,j} & \cdots & I_{i,m} \\ \\ I_{n,1} & I_{n,2} & \cdots & I_{n,j} & \cdots & I_{n,m} \end{bmatrix}$$

In the formula: $R_j$ is the fault type of number $j$; $S_i$ is the sign type of number $i$; $m$ is the type number of the possible cause of the malfunctions; $n$ is the type number of the detected signs.

$I_{i,j}$ is the possible state of sign $S_i$, when a fault $R_j$ occurs, and

$$I_{i,j} = \begin{cases} 1, & \left(S_i \textit{ may be caused by fault } R_j\right) \\ 0, & \left(S_i \textit{ may not be caused by fault } R_j\right) \end{cases}$$

At the same time, Let $s_j = \left(I_{1,j}, I_{2,j}, \cdots, I_{n,j}\right)$ is the sign vector produced by fault $R_j$; $r_i = \left(I_{i,1}, I_{i,2}, \cdots, I_{i,m}\right)$ is the fault vectors may exist when symptom $S_i$ occurs; $s' = \left(I_1', I_2', \cdots, I_n'\right)$ is the observation vector, If we can observe sign $S_i$, the value of $I_i'$ is 1, and 0 otherwise; $r' = (I_1, I_2, \cdots, I_m)$ is the result vector, when $I_j$ is 1, there may be a fault, on the contrary, there is no fault; $s_j$ $(j = 1, 2, \cdots, m)$ is the matrix's column vector, namely the vertical rules of a matrix. When $I_{i,j}$ is 1, it means the sign type $S_i$ may occur when the fault type $R_j$ occurs; And the sign type $S_i$ may not occur when $I_{i,j}$ is 0. $r_i$ $(i = 1, 2, \cdots, n)$ is the Matrix's row vector, namely the horizontal rules of a matrix. When $I_{i,j}$ is 1, it means the sign $S_i$ may be caused by failure $R_j$, otherwise, it isn't caused by failure $R_j$.

We collect the system's Fault signal (Fault symptoms), and then Make the assignment of each sign type whit 1 or 0, to determine the function $G(\bullet)$.

The results of the observation signs Depicted by $G(\bullet)$ is called the observation vector, which is represented by $s'$, and $s' = \left(I_1', I_2', \cdots, I_n'\right)$. If the sign $S_i$ can be observed, the value of $I_i'$ is 1 and 0, otherwise. Then we get an observation vector $s'$, namely we assign a value to the function $G(\bullet)$, we can get a result vector According to equation (1), which is represented by $r'$, $r' = (I_1, I_2, \cdots, I_m)$. When $I_j$ is 1, that may be a problem, and there is no fault on the contrary. This method is the theoretical model of the matrix screening method.

## III. BP NEURAL NETWORK MODEL OF THE MAIN BEARING

BP network is a multilayer feed forward neural network, and it is composed of input layer, hidden layer and output layer. Figure 1 shows the structure of the BP network, Neural network learning uses BP algorithm, The learning process are composed of prior to the calculation process and the error back-propagation process, In the prior to the calculation process, the input information calculates layer by layer from the input layer to the hidden layer, and transmit to the output layer, the state of each layer's neuron only affect the status of the next layer's neurons. If the output layer can not get the desired output, it transfers to the error back-propagation process, and the error signal returns along the original connection path, then makes the network system error minimization by modifying the value of every layer's neuron. Finally, the actual outputs of the network are approaching to their corresponding desired output.

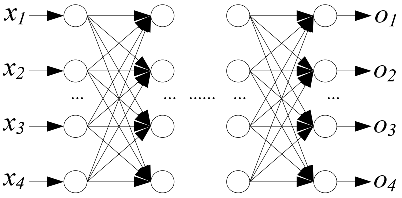

Figure 1. BP network model

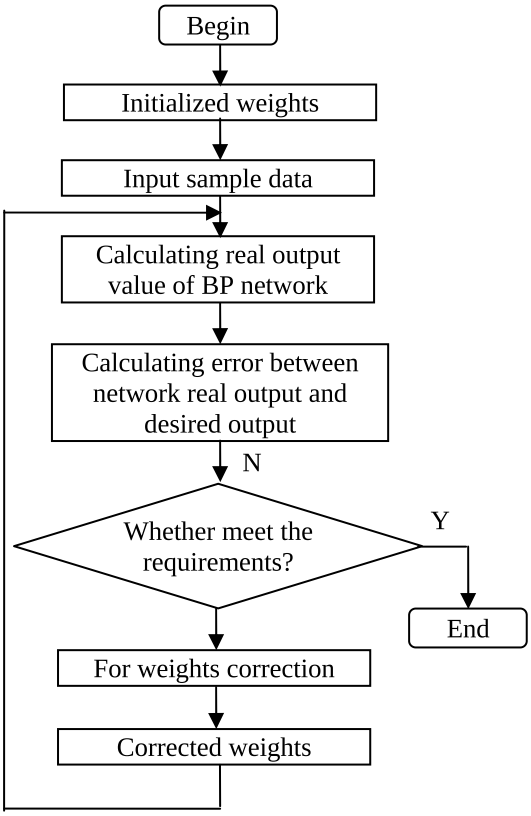
To make the algorithm implementation process clearly, we can use the flow chart 2 to represent. The specific steps are as follows:



Begin
Initialized weights
Input sample data
Calculating real output value of BP network
Calculating error between network real output and desired output
N
Whether meet the requirements?
Y
End
For weights correction
Corrected weights

Figure 2. Flow chart of BP algorithm

- Initialize the weights $W$ and the threshold $\theta$, namely assign the weights $W_{ij}$ Connecting input layer units and the hidden layer, the weights connecting the hidden layer and output layer, the threshold of hidden layer $\theta_j$ and the unit threshold of output layer $\theta_k$ with a smaller value between 0 and l.
- Provide a learning sample pair (Input and expected output values), give the input vector $X_i = (x_1, x_2, \dots x_n)$ and the expected output vector $\hat{Y}_i = (\hat{y}_1, \hat{y}_2, \dots, \hat{y}_m)$ , which corresponds with the input one, import value $x_i$ to input and output layer node, and calculate forward one by one:

$$x'_j = f(\sum_{i=0}^{n} w_{ij} x_i - \theta_j) \qquad (j = 1,2,\dots,n) \qquad (2)$$

$$y_k = f(\sum_{k=1}^{n} v_{jk} x'_j - \theta_k) \qquad (j = 1,2,\dots,n) \qquad (3)$$

- Calculate the error { $\delta_k$ } between the output value { $y_k$ } of the output node and the expected value { $\hat{y}_k$ }.

$$\delta_k = y_k(1-y_k)(\hat{y}_k - y_k)$$

- Allocate error to the hidden layer nodes Reversely, namely use the connect right{ $V_{jk}$ }、the generalization error of the output layer{ $\delta_k$ }、output of the hidden layer { $x'_j$ }to calculate the error{ $\delta_J$ } of hidden layer's every unit:

$$\delta_j = x'_j(1-x'_j)\sum_{k=1}^{n} v_{jk}\delta_k \qquad (4)$$

- Use the generalization error { $\delta_k$ } of the output layer unit and the output { $x'_j$ } of hidden layer's each unit to correct the output layer's weights { $V_{jk}$ } and thresholds { $\theta_k$ }:

The weights correction of output layer and hidden layer:

$$v_{jk}(t+1) = v_{jk}(t) + \eta\delta_k x'_j \qquad (5)$$

The threshold correction of output layer:

$$\theta_k(t+1) = \theta_k(t) + \eta\delta_k \qquad (6)$$

- Use the generalization error { $\delta_j$ } of hidden layer and input { $x_i$ } of input layer's each unit to correct the connection weight { $W_{ij}$ } and threshold { $\theta_j$ }:

Correction of connection weights between the input layer and hidden layer:

$$w_{ij}(t+1) = w_{ij}(t) + \eta\delta_j x_i \qquad (7)$$

The threshold correction of the hidden layer:

$$\theta_j(t+1) = \theta_j + \eta\delta_j \qquad (8)$$

- Repeat steps two select different training samples, implement the above iterative process constantly, until meet the requirements, makes the error is small enough or zero, stop learning.

## IV. Realization of the Fault Diagnosis for Main Bearing

There are three steps in the process of TBM fault diagnosis. Firstly, collect different vibration signal by the data acquisition card. Then, eliminate the noise of vibration signal by wavelet, and pick up the Eigen value. Finally, determine the fault type and remove the faults by fault diagnosis.

Applying TRFDS based on BP neural network to diagnose faults includes the following steps:

*1) Using vibration data about main bearing from TBM produced by one Heavy equipment company in Shenyang, we can establish the faults cause—symptoms matrix.* Due to the limited space, it can only take the 6*6 sub matrix. The values of fault symptoms function $G(\bullet)$ by the data collecting are $s' = (1 \;\; 0 \;\; 1 \;\; 0 \;\; 0 \;\; 0)$. Then by formula (1):

$$\begin{aligned} r' &= C(\bullet) = G(\bullet) \bullet E(\bullet) = \\ &(1 \;\; 0 \;\; 1 \;\; 0 \;\; 0 \;\; 0)\begin{bmatrix} 1 & 1 & 1 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 1 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 & 1 \end{bmatrix} \\ &= (1 \;\; 1 \;\; 1 \;\; 0 \;\; 1 \;\; 1) \end{aligned}$$

Then we can know that, $r' = (1 \;\; 1 \;\; 1 \;\; 0 \;\; 1 \;\; 1)$ shows when the value of the function $G(\bullet)$ is $s' = (1 \;\; 0 \;\; 1 \;\; 0 \;\; 0 \;\; 0)$, the possible fault types are in the table 1.

*2) To design neural network structure.* According to the faults cause—symptoms matrix, we can determine the node number of input and output layer in neural network. If the vibration signal was divided into N layers, the input layer node number is N; if there are M kinds of equipment fault, the output layer node number is M; the hidden layer node number is chosen by experience. And the transfer function is single polarity S function. According to successful experience of neural networks in fault diagnosis, we can determine the following two preliminary conclusions:

*a) Most problems of the fault pattern recognition could be resolved by the three-layer network.*

*b) There is the approximate relationship between the neurons number of hidden layer and the input layer in three-layer network* $N_2 = 2N_1 + 1$.

*3) Training the neural network.* The extracted eigenvector is input neural network as training samples, and it assume that there are $M$ kinds of equipment fault, then the output of the network is $\hat{Y}_i = (\hat{y}_1, \hat{y}_2, \dots, \hat{y}_m)$ , if the equipment is in $j$ state, the output of the network is $\hat{y}_j = 1$ , and the rest is 0, finally the output of network is $(0, 0, 0, ..., 1, ..., 0)$ . Using sample data to train the network until the simulation error is less than the target error, and save the network weights and bias after training.

TABLE I. THE VIBRATE FAULTS CAUSE—SYMPTOMS MATRIX OF MAIN BEARING OF TBM

| Fault symptoms | Fault causes | | | | | |
|---|---|---|---|---|---|---|
| | Unbalance | Touch grinding | Not centring | Rotor damaged | Surge | Bearing pedestal loosened |
| Vibration value whether stable | 1 | 1 | 1 | 0 | 1 | 1 |
| Vibration value whether mutations | 0 | 0 | 0 | 0 | 0 | 1 |
| Axial vibration whether obvious | 0 | 0 | 0 | 0 | 1 | 0 |
| cutter pressure fluctuations | 1 | 0 | 0 | 1 | 1 | 0 |
| Vibration value with the oil temperature changes | 0 | 1 | 0 | 0 | 0 | 0 |
| Vibration value with engine speed change | 0 | 0 | 0 | 1 | 1 | 1 |

*4) Identifying the fault type.* The eigenvector of vibration signals are put into neural network and trained BP neural network is used to solve the problems, then to identify the fault type according to the output of network.

The six typical faults, including unbalance, touch grinding, rotor damaged, surge, bearing pedestal loosened, are the neural network output; six spectrum peak energy value of frequency spectrum from vibration signal spectrums are used as characteristic variable to form the training samples. Shown as table 2 and table 3.

TABLE II. MAPPING TABLE OF OUTPUT NODES AND FAULT TYPES

| Output nodes | 1 | 2 | 3 | 4 | 5 | 6 |
|---|---|---|---|---|---|---|
| Fault types | unbalance | touch grinding | not centring | rotor damaged | surge | bearing pedestal loosened |

TABLE III. MAPPING TABLE OF INPUT NODES AND FREQUENCY RANGE

| Input nodes | 1 | 2 | 3 | 4 | 5 | 6 |
|---|---|---|---|---|---|---|
| Frequency range | 0-0.5f | 0.5-0.99f | 1f | 2f | 3-5f | High frequency range |

To avoid network saturation, the value of spectrum peak energy value cannot be used as input vector directly, so the data must be normalized before network training. Each input is normalized as following:

$$\overline{E}=\frac{E}{\sum_{i=1}^{n}\left|E_i\right|} \qquad i=1,2,...,6$$

In this way, the input values of network are all among [0, 1].

The membership degree vector of faults is obtained by membership function through measured data. For example, like the fuzzy relation of the ‘large vibration’ and ‘fault severity’, according to the experience, the fault is obvious when vibration is small. So it is appropriate to use Half Causy distribute function in fault diagnosis, the mathematic representation is:

$$\mu(x)=\begin{cases} 0 & (0\le x\le a) \\ \dfrac{k(x-a)^2}{1+k(x-a)^2} & (a\le x\le\infty) \end{cases} \tag{9}$$

In the problems we researched, $a=0$ , that is effective for positive region. The formula (9) can be simplified as follows:

$$\mu(x)=\frac{kx^2}{1+kx^2}=\frac{x^2}{1/k+x^2}$$

In the formula, the influence of $k$ to $\mu(x)$ can be obtained by formula (10): when $k$ is the maximum, that is $k=1$ , the influence of $k$ to $\mu(x)$ is very small; but $k$ is too small, the influence of $k$ to $\mu(x)$ is still very small. They all do not reflect the membership degree, so $k$ depends on the value of $x$ .

$$k=\frac{1}{\left(\sum_{i=1}^{n}\frac{x_i}{n}\right)} \tag{10}$$

In the formula, $n$ is the number of not equal to 0.

TABLE IV. TRAINING SAMPLE AND TARGET OUTPUT

| Input sample | | | | | | Expected output | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| 0.00 | 0.90 | 0.05 | 0.05 | 0.00 | 0.00 | 1 | 0 | 0 | 0 | 0 | 0 |
| 0.10 | 0.10 | 0.10 | 0.20 | 0.10 | 0.30 | 0 | 1 | 0 | 0 | 0 | 0 |
| 0.00 | 0.10 | 0.70 | 0.10 | 0.10 | 0.00 | 0 | 0 | 1 | 0 | 0 | 0 |
| 0.60 | 0.06 | 0.16 | 0.18 | 0.00 | 0.00 | 0 | 0 | 0 | 1 | 0 | 0 |
| 0.20 | 0.10 | 0.60 | 0.05 | 0.05 | 0.00 | 0 | 0 | 0 | 0 | 1 | 0 |
| 0.90 | 0.00 | 0.00 | 0.00 | 0.10 | 0.00 | 0 | 0 | 0 | 0 | 0 | 1 |

It chose the three layer network, 6 input units, 13 middle layers, and 6 output units. Besides, the error coefficient is set as 0.0001. Simulation result of the MATLAB is displayed as the figure 3; the actual output is displayed as table 5.

After the wavelet neural network has finished the study for the input and output sample, we can use it to the fault diagnosis on the bearings. Assume that a new vibration signal $[0.00, 0.15, 0.65, 0.10, 0.10, 0.00]$ which is put into neural network as Eigenvectors, then we can get the results [-0.0315, 0.1574, 0.6221, 0.0329, 0.2245, -0.0626] by nonlinear mapping in neural network. From the output results, it is obvious that the maximum is 0.6221 , which correspond the third fault type. So the fault signal is in line with the type of not centring fault.

TABLE V. ACTUAL OUTPUT OF TRAINING SAMPLE

## V. CONCLUSIONS

Real-time fault diagnosis of TBM main bearing can improve the efficiency of the project construction, and ensure the construction period. This paper put forward BP neural network fault diagnosis model based on the fault reasons—symptom matrix. Through practical engineering data validation and MATLAB simulation, it confirmed that this fault diagnosis model of TBM main bearing is more feasible and advantaged than the common BP neural network model.

1) The fault reason of TBM main bearing is dynamic changing, so the scope of the fault types can be further narrowing through the fault reasons—symptom matrix screening, and make the BP neural network to lock the fault type rapidly in the training process. Then the problem that the traditional algorithm can't dynamic diagnosis main bearing fault is solved.

2) The training process of neural networks can be real-time tested by MATLAB simulation, to ensure that the training results are accurate feasible.

3) The algorithm has shorten the fault diagnosis time and improved the working efficiency of TBM.

*Abstract*. **Condition monitoring of a gearbox is a very important activity because of the importance of gearboxes in power transmission in many industrial processes. Thus there has always been a constant pressure to improve measuring techniques and analytical tools for early detection of faults in gearboxes. This study forces on developing gearbox monitoring methods based on operating parameters which are available in machine control processes rather than using additional measurements such as vibration and acoustics used in many studies. To utilise these parameters for gearbox monitoring, this paper examines a model based approach in which a data model has been developed using a General Regression Neural Network (GRNN) to captures the nonlinear connections between the electrical current of driving motor and control parameters such as load settings and temperatures based on a two stage helical gearbox power transmission system. Using the model a direct comparison can be made between the measured and predicted values to find abnormal gearbox conditions of different gear tooth breakages based on a threshold setup in developing the model.**

## I. INTRODUCTION

Condition monitoring (CM) is a technique for acquiring different datasets and analyzing them to assess the health and condition of equipment. Thus potential problems can be detected and diagnosed at an early stage in their development, providing the opportunity to take suitable recovery measures before they become so severe as to cause machine breakdown. To obtain accurate results CM collects large amounts of data with wide diversity including operating parameters, high density dynamic signals and special event datasets to produce historical trends which are presented to engineers and stored in databases. This gives rise to the problem that the volume of data is very large and the relationship between measurements is very complicated. Consequently, the CM data is not always understood properly [1] and the extraction of useful and meaningful information from the data is extremely challenging. In addition, because machine and sensor technologies are growing in complexity, combined with the recent progress in information technology (IT), data acquisition systems (DQS) can produce an overwhelming amount of data which is continuously increasing and contains features representing hundreds of attributes.

Among the different methods for condition monitoring of rotating machinery, artificial neural networks (ANN), in the recent decades have become an outstanding method exploiting their non-linear pattern classification properties, offering advantages for automatic detection and identification of gearbox failure conditions, whereas they do not require an in-depth knowledge of the behaviour of the system.

Vibration signals which have been widely used in the condition monitoring and fault diagnosis systems of rotating machinery [2-4] can be exploited as the detection medium in this case due to straightforwardness of menstruation and the rich contents of the signal incorporating system-critical information. However for fault detection and identification matters, the frequency ranges of the vibration signals are often wide; and according to the Shannon's sampling theorem, a high sampling rate is required, and consequently, large-sized samples are needed for the bearing fault detection purposes. Therefore due to existence of superfluous data and their large dimensionality, there is a requirement to pre-processing to extract an appropriate and economised feature vector which is essentially used to train a well-educated ANN.

In the literature, there are many signal processing tools for data analysis and diagnostic feature development. These include time domain averaging, power spectrum, cepestrum, demodulation, adaptive noise cancellation, time-series analysis, high-order statistics, time–frequency distribution, wavelet, etc., [5-7] and show good results in detecting gearbox faults. However, these techniques often need an additional vibration measurement system, which leads to high cost of the monitoring system.

This paper examines the performance of a model based condition monitoring approach by using just operating parameters for fault detection in a two stage gearbox. It has the potential to achieve cost effective monitoring system because the operating parameters are available in many systems. A model for current prediction is developed using a GRNN, which captures the complicated connections between measured variables and allows a direct comparison between the measured and predicted values to achieve gearbox fault detection.

## II. MODEL-BASED CONDITION MONITORING

The aim of model-based fault detection and diagnosis is to create a model based on known and accepted mathematical and scientific principles verified and fine-tuned by past experience to generate accurate predictions of faults and defects likely to occur in target systems. Such models may be quantitative, qualitative or a combined system model. The model-based method is often referred to as an analytical method and has the enormous advantage that it is much less costly than constructing a real-life system for testing (possibly to destruction). Typically, the model of the target system is a continuous-variable dynamic system, with input(s) *u(k)* and output(s) *y(k)* in the presence of an unknown fault [8].

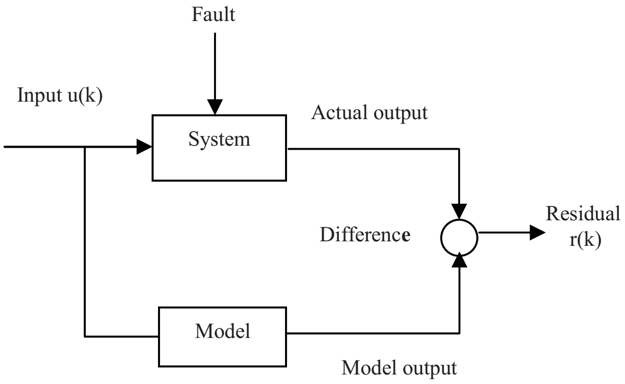

Figure 1: Model based fault detection

The model based fault detection method can easily find the fault in a system as shown in Figure 1. Residual *r(k)* in the figure is the difference between the outputs of the model and the actual system. The aim of the model is to generate a residual which can be used to indicate whether a fault is present and to identify that fault. However, the model can also be used "in reverse" information representing the behaviour of the system can be input to the model which produces an output that predicts what change in system components and/or features have taken place to produce that behaviour. The model can then predict likely causes of the change and even suggest other symptoms to search for to aid diagnosis.

A frequency division duplex (FDD) system includes three stages (procedures) with different functions: system modelling, residual generation and fault diagnosis. Firstly, a precise mathematical model is required to accurately predict system performance as model-based methods require such a model of the supervised process [11]. For most systems, such models are often very difficult to obtain. The robustness of the FDD system is often achieved by designing algorithms where the effects of model uncertainties and un-modelled dynamic disturbances on residuals are minimised and sensitivity to faults is maximised [9, 10]. Secondly, a set of residuals is generated to represent the deviation between actual and nominal features. Finally, the residuals are evaluated to relate to certain faults and to locate the fault if it is present. The model implementation and residual generation compose the model-based fault detection system.

## III. GENERAL REGRESSION NEURAL NETWORKS

Artificial intelligence and neural nets are widely used for fault detection and diagnostic. General Regression Neural Networks (GRNN) is one of the type neural networks that can be used for fault detection and diagnostic. (GRNN) works as a multi-layer feed-forward network. It is the most common network today [12]. Due to their powerful nonlinear function approximation and adaptive learning capabilities, neural networks have drawn great attention in the arena of fault diagnosis [13]. GRNN is based on localized basis function NN which uses the probability density functions. The term general regressions imply that the regression surface is not restricted to be linear. In many previous applications of the GRNN, the sigma (sigma) which is referred to as the smoothing factor in the GRNN algorithm is usually fixed and thus not applicable in a dynamic environment [14].

The main task for regression is getting relations between input variables X and output variables Y based on data including representative set of elements for analysed field. If **X** is vector containing known inputs, it is possible to define the following scalar function

$$D_i^{\,2} = (\boldsymbol{X} - X_i)^T (\boldsymbol{X} - X_i) \qquad (1)$$

This parameter provides the information about difference between two vectors. The estimate of output vector **Y** can be calculated by using this factor by:

$$\hat{Y}(\boldsymbol{X}) = \frac{\sum_{i=1}^{n} Y_i \exp\left(-\frac{D_i^{\,2}}{2\sigma^2}\right)}{\sum_{i=1}^{n} \exp\left(-\frac{D_i^{\,2}}{2\sigma^2}\right)} \qquad (2)$$

The major algorithm of the GRNN model is expressed by Equations (1) and (2). The estimate $\hat{Y}(X)$ is a weighted average of all the observed samples, $Y_i$, where each sample is weighted in an exponential manner according to the Euclidean distance, $D_i$, from each $X_i$. This appropriate weighting is explained by the inversely proportional relationship between the expression $\exp\left(-\frac{D_i^{\,2}}{2\sigma^2}\right)$ and $D_i$. That is, as $D_i$ increases, $\exp\left(-\frac{D_i^{\,2}}{2\sigma^2}\right)$ decreases and vice-versa. An optimal value for the smoothing parameter, $\sigma$- is the width of sample probability for each sample $X_i$, $Y_i$. Larger values of $\sigma$ improve smoothness of the regression surface. It must be greater than 0 and can usually range from .01 to 1 with good results [15].

## IV. GEAR FAULT SIMULATION

A tooth breakage is one of common faults in gearbox. Different levels of breakages on the pinion gear are examined in this part of research. Three levels of fault severity: 25%, 50% and 75% of a tooth are removed from three pinion gears respectively. Figure 2 illustrates the details of the faults for Gear 07 with 25% tooth breakage and Gear 08 with 50% tooth breakage. Although the defects look very large they not influence the transmission significantly because of high overlap ratio of the gear set.

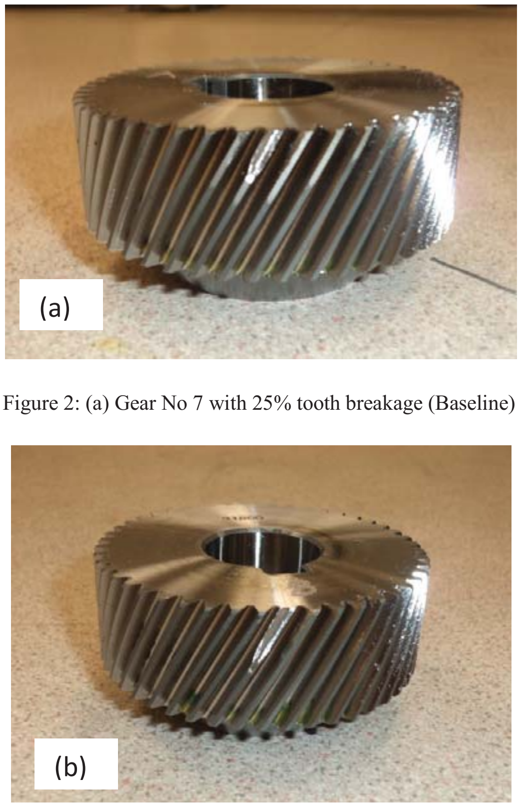

Figure 2: (a) Gear No 7 with 25% tooth breakage (Baseline)

(b) Gear No 8 with 50% tooth breakage

## V. GRNN MODEL DEVELOPMENT

GRNN was proposed by Donald Specht [14]. It uses non-iterative process and hence fast learning capability. In addition, it requires only a few training samples and very flexible to add new information with very small amount work of retraining. For these benefits, many condition monitoring applications applied GRNN to classify different fault cases. For example, GRNN is used to diagnosis different engine faults based on features extracted wavelet packet transform analyses of acoustic signals, showing GRNN is effective to classify the faults induced to the test engine[16]. In addition GRNN detectors of rotor faults of induction motor load, showing good results for rotor fault classification [17].

### *A. Data characteristics*

The data were collected for the three gear sets: Gear07, Gear08 and Gear09 using a same gearbox case. Gear07, Gear08 and Gear09 were induced with 25%, 50% and 75% tooth breakage respectively. As there was not a healthy gear for more tests, Gear07 with the smallest gear fault are taken as the baseline for model development.

To evaluate the neural network, only three variables: AC current, load set points and gearbox temperate are explored for full understanding of the principle behind. Figure 3 shows eight data sets collected from eight independent tests respectively based on Gear07. It can be seen that each data set shows a gradual increase in the current with increase in load and temperature of the gearbox. The rate of current increase with load settings is very high and in a nonlinear behavior, which indicate a complicated correlation between the current and load setting and it is not easy to model it with a simple method.

In addition, the temperature also shows considerable influences on the current. As can be seen in Figure 3, a slight inverse influence on the current can be observed. However, the decrease rate becomes smaller at higher temperature, which again indicates a more complicated model is required to describe the connections between electrical current, load settings and temperature influences.

Figure 4 shows more details of the temperature influence. It can be seen that the current decreases with the increase in temperature at each load setting. It may be due to that the damping effect of lubrication decreases with temperature. Nevertheless, the correlation also shows a nonlinear way.

As this temperature influence is very clear, it will certainly impact the model development. Fault detection must include this influence for obtaining more accurate results.

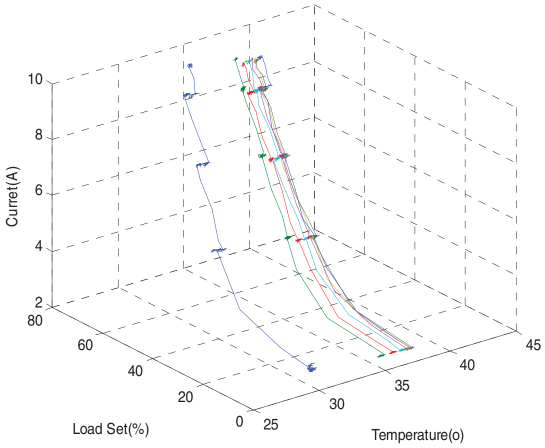

Figure 3: Data characteristics of current with temperature and load of gear in Gear07

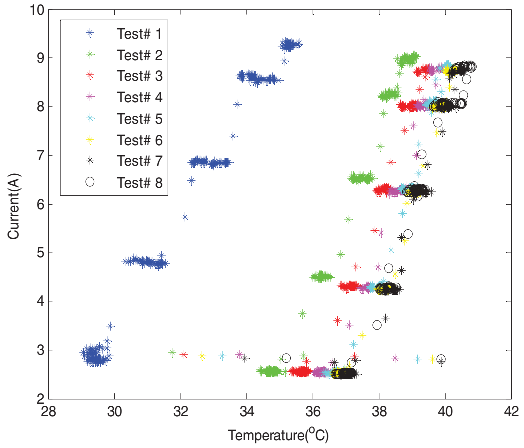

Figure 4: Data characteristics of current with temperature of gear in Gear07

### *B. Model development*

To capture the relations between the three measurements and hence to perform the model based detection discussed in Section II, a GRNN model is developed using MATLAB software based on the baseline datasets from Gear07. The model has two inputs: temperature and load set points and one output: AC current.

To train the GRNN model, the datasets from Gera07 is used as the baseline for model development. In total there are 2088 data samples from 8 tests of different runs. The 2088 data points are divided into two equal subsets of 1044 points: one for GRNN model training and the other for model verification.

After several tuning cycles, it is found that when GRNN spread parameter is 0.06, the network produces a balanced prediction in generalisation and accuracy for the first subset of data. As shown in Figure 5, the measured values are all on the model surface where the training data set is distributed. On the other hand, the model produces very small output for these which are not in the training set, which means that if there is deviation of the inputs the output will be small and the difference between measured output and predicted output will be large.

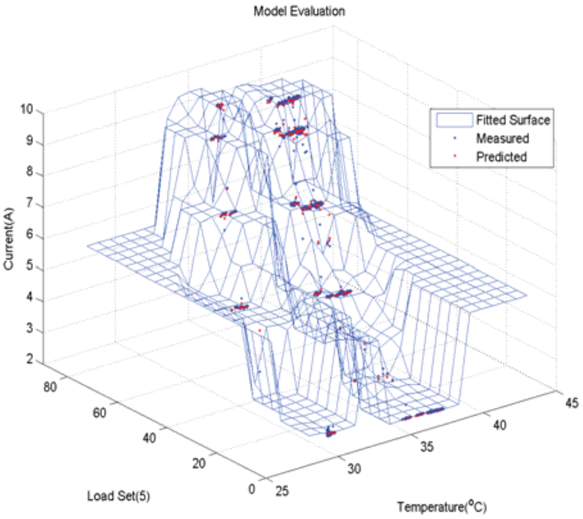

Figure 5: GRNN model inspection in the input space

### C. *Model evaluation and detection threshold*

To confirm the model performance, the 2nd dataset is employed as the input and output of the model developed from the 1st set. To measure the quality of the model in fitting to the second data and to detect abnormalities from new datasets, a threshold is developed based on the 1st dataset by comparison between the actual current and the predicted current. In particular, a threshold $D_{th}$ is defined as 3 times of the root mean squared value between the real measurement and the model prediction:

$$D_{th} = 3\sqrt{\frac{1}{N}\sum_{i=1}^{N}(I_{mi} - I_{pi})^2} \quad (1)$$

Where:
N = The number of sample.
$I_{mi}$= The actual value determined from measurements.
$I_{pi}$ = the predicted value using the GRNN.

Figure 6 shows model verification results which are calculated using the model using the 2nd part of data from Gear07. It can be seen that most of the errors are within the threshold and means that the model is fit the data very well.

On the other hand there are several data points exceeding the threshold. These data points are regarded as the outliers arisen from the load transient periods when the temperature measurements have delayed responses to current increases.

In general the model is sufficiently accurate for implementing fault detection for new data sets from other 2 gear sets.

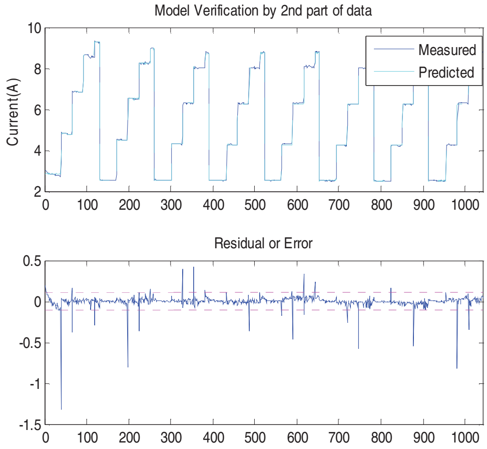

Figure 6: Model verification by 2nd part of data from Gear07

## VI. Detection results and discussions

### A. *Fault Detection on Gear08*

Figure 7(a) illustrates measured and predicted current for Gear 08 with 50% tooth breakage. It can be seen that the predicted current is very close to the measured one. However, many measurements have observed to have large difference from the predicted one.

To examine the difference only the residual data is predicted in Figure 7(b) and the details of the data points exceeding the threshold can be seen more clearly. Compared with Figure 6, many successive data points exceed the thresholds and indicate there is a fault in Gear08.

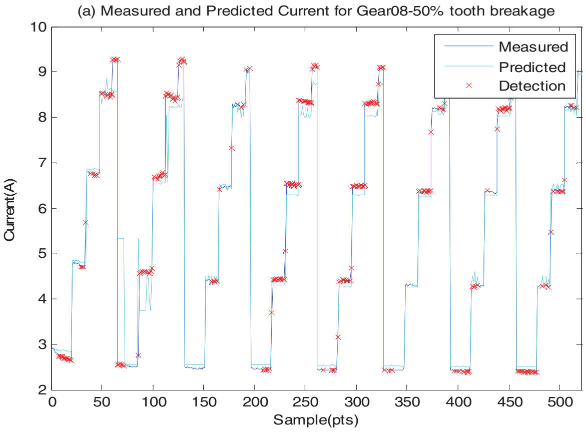

Figure 7:( a) Measured and predicted current for Gear08 under 50% tooth breakage

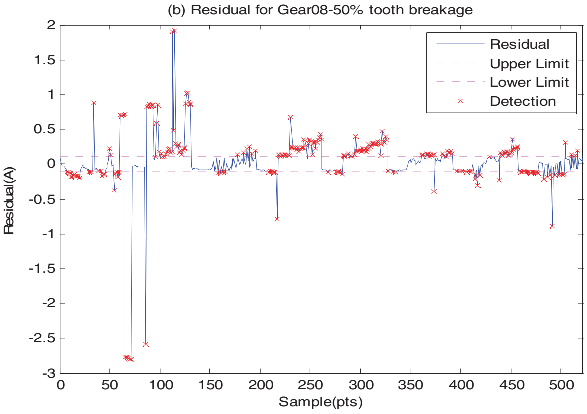

(b) Residual for Gear08 under 50% tooth breakage

### B. *Fault Detection on Gear09*

Figure 8(a) illustrates measured and predicted current for Gear09 on which 75% tooth breakage was induced. It can be seen clearly that the predicted currents have large difference from the measured one. To examine the difference only the residual data is predicted in Figure 8(b) and the details of the data points exceeding the threshold can be seen more clearly. Compared with Figure 6, many successive data points exceed the thresholds, which indicate that there is a fault in Gear09.

Compared with Figure 7(b), the overall amplitudes of the errors are much higher and shows that this gear have a much severer fault than Gear08.

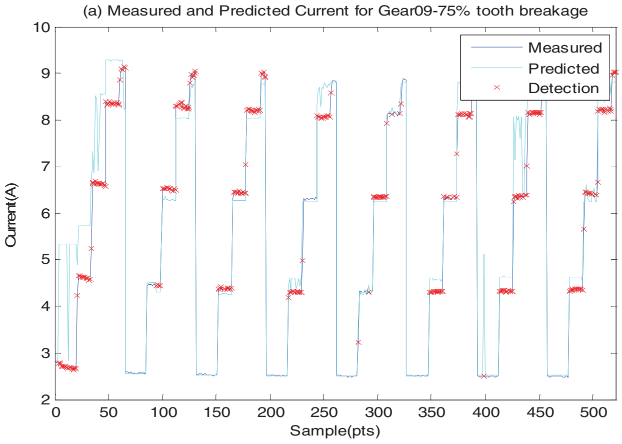

Figure 8: (a) Measured and predicted current for Gear09 under 75% tooth breakage

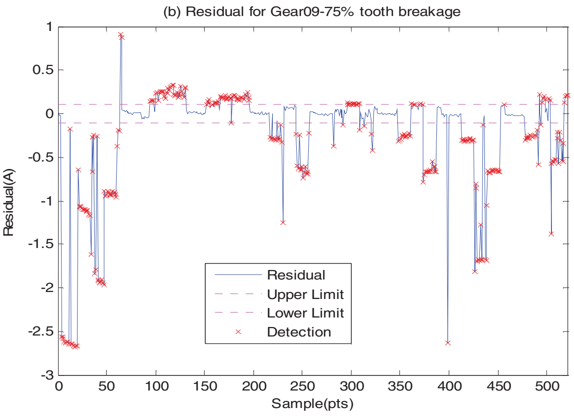

(b) Residual for Gear09 under75% tooth breakage

## VII. Conclusion

A GRNN model based approach is presented in this paper to detect and diagnose different faults in a gearbox using motor operating dataset. The model developed using a baseline data captures the nonlinear connections between AC current, load setting and gearbox temperature. Test results show that the GRNN model based method is accurate estimators of the complex gearbox process and allows the generation of differences from baseline and between different gear faults. Therefore, it demonstrates the effectiveness of the proposed method for detecting and diagnosing tooth faults in a two stage gearbox just using motor operating parameters.

***Abstract*—This paper concerns data driven fault detection of vertical rail vehicle suspension systems issue. The underlying vehicle system are equipped with only accelerator sensors in the four corners of the carbody, the front and trail bogie, respectively. The faults considered are the vertical damper fault and vertical spring fault. Both PCA-based and CVA-based fault detection methods are studied in this paper. When there is a detectable fault, the detector sends an alarm signal if the residual evaluation is larger than a predefined threshold. By using the professional multi-body simulation tool, SIMPACK, the effectiveness of the proposed approach is demonstrated by simulation results for several fault scenarios.**

## I. Introduction

Suspension systems for rail vehicles are to support the carbody and bogie, to isolate the forces generated by the track unevenness at the wheels, and to control the attitude of the carbody with respect to the track surface for providing ride comfort. The railway vehicle suspension system is very important parts of railway vehicle and the reliability of the suspension system is directly related to the vehicle safety.

On line fault detection and condition monitoring for the suspension system of rail vehicles offer a number of benefits to railway systems/operations. Detection of component faults at their early stages will prevent further deterioration in vehicle performance and enhance vehicle safety. Timely repair or replacement of the faulty components will lead to increased operational reliability and availability. The need for scheduled maintenance and associated costs can be significantly reduced, because maintenance in the future may be carried out on demand. So it is necessary to timely detect the fault of vehicles suspension after it occurs. Some studies on the condition monitoring of railway vehicle and suspension systems are reported in [1],[2],[3], [6], [9], [8]and the references therein.

The fault detection issue of the rail vehicle suspension systems are paid some attentions in the recent years. In [10][11], the authors derived a fault detection approach for the rail vehicle suspension systems based on Kalman filter. The fault isolation is handled by using the similarity measurements. The interaction multi-model (IMM) approach and parameter estimation reported in [4],[6] are convinced to be appropriate alternatives. However, when IMM method is applied, the models needed is increasing very dramatically when more components in the primary suspension and secondary suspension are considered. Parameter estimation method [6] applies the particles filter for the parameter estimation. The parameter changes are identified online to indicate the health condition of the components. Nevertheless, the computation burden of this approach cannot afforded by the current available monitoring unit. It is true that there is great potential for the improvement in the performance of condition monitoring if the a priori knowledge or information captured by the models is fully used. However, in many cases, the parameters of the vehicle suspension system are not available. In the mean time, due to nonlinearities of the components and the complexities of the suspension systems, a precise model cannot be obtained. Due to these limitations of the model based fault detection approaches, there is increasing interest in using the multivariate statistical approaches to monitoring system health conditions[7][12][5]. As the knowledge of the authors, there is no any report which solves the fault detection problem based on data driven methods.

In this paper, we consider data driven fault detection of rail vehicle systems problem. The underlying vehicle are only equipped with accelerator sensors in the corners of the carbody, the front and trail bogie, which provide the measured signals for the condition monitoring for the vehicle suspension system. The Dynamical Principle Component Analysis (DPCA) and Canonical Variate Analysis (CVA) based approaches are applied for the fault detection problem, respectively. The considered faults are the vertical damper faults and the vertical spring faults of both primary and secondary suspensions. A subway vehicle model is used for the Matlab-Simpack hybrid simulation study in this paper.

This paper is organized in the following. The railway vehicle system, its dynamics and the sensor configuration for the data collection are introduced in Section 2. In the third section, the DPCA and CVA fault detection methods are briefly reviewed. The SIMPACK-Matlab co-simulation results are provided in Section 4. Finally, conclusions are given in Section 5.

## II. THE VERTICAL RAIL VEHICLE SUSPENSION SYSTEMS

### A. The Vehicle Suspension System

A subway vehicle model is used for the study in this paper. To describe the dynamic behaviour more accuracy, three degree-of-freedom (bounce, pitch and roll) is considered for both carbody and bogies. The vertical suspension system of this subway vehicle is depicted in Fig. 1. The equations describing the dynamic behaviour of the railway vehicle are developed from the application of Newton's laws of motion to the individual masses. The dynamical equations of the suspension system for a vehicle moving on a straight track are derived in the following.

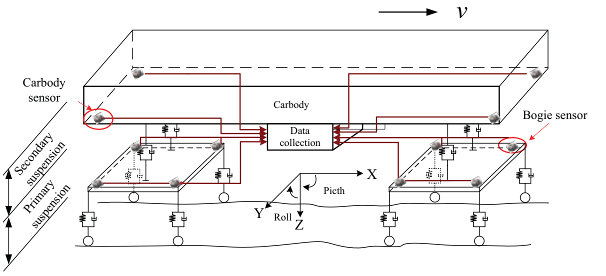

Fig. 1. The vertical suspension system of the rail vehicle

For the carbody, the three DOF equations are described as:

$$M\ddot{z} + 4C_{2z}\dot{z} - 2C_{2z}\dot{z}_{FB} - 2C_{2z}\dot{z}_{RB} + 4K_{2z}z$$
$$-2K_{2z}z_{FB} - 2K_{2z}z_{RB} = 0 \tag{1}$$

$$J_{\phi}\ddot{\phi} + 4C_{2z}l^2\dot{\phi} - 2C_{2z}l\dot{z}_{FB} + 2C_{2z}l\dot{z}_{RB} +$$
$$4K_{2z}l^2\phi - 2K_{2z}lz_{FB} + 2K_{2z}lz_{RB} = 0 \tag{2}$$

$$J_{\theta}\ddot{\theta} + 4C_{2z}b^2\dot{\theta} - 2C_{2z}b^2\dot{\theta}_{FB} - 2C_{2z}b^2\theta_{RB}$$
$$+(4K_{2z}b^2 + 2K_{\theta})\theta - (2K_{2z}b^2 + K_{\theta})\theta_{FB}$$
$$-(2K_{2z}b^2 + K_{\theta})\theta_{RB} = 0 \tag{3}$$

Where $z, z_{FB}$ and $z_{RB}$ are the vertical displacement of the carbody, the leading bogie and the trailing bogie, respectively. $\phi$ represents the pitch angle of the center of gravity(c.g.) while $\theta$ is the roll angle of the c.g. for the masses. Their subscripts have the same meaning with the subscripts of $z$. Please refer to Table I for the parameters.

For the leading bogie, the three DOF equations are described as:

$$M_B\ddot{z}_{FB} - 2C_{2z}\dot{z} - 2C_{2z}l\dot{\phi} + (4C_{1z} + 2C_{2z})\dot{z}_{FB}$$
$$-C_{1z}\dot{z}_{W1R} - C_{1z}\dot{z}_{W1L} - C_{1z}\dot{z}_{W2R} - C_{1z}\dot{z}_{W2L} -$$
$$2K_{2z}z - 2K_{2z}l\phi + (4K_{1z} + 2K_{2z})z_{FB} - K_{1z}z_{W1R}$$
$$-K_{1z}z_{W1L} - K_{1z}z_{W2R} - K_{1z}z_{W2L} = 0 \tag{4}$$

TABLE I
VEHICLE PARAMETERS

| | Description | Unit |
|---|---|---|
| $M$ | Carbody mass | $kg$ |
| $M_B$ | Bogie mass | $kg$ |
| $J_{\phi}$ | Carbody pitch inertia | $kgm^2$ |
| $J_{\theta}$ | Carbody roll inertia | $kgm^2$ |
| $J_{B\phi}$ | Bogie pitch inertia | $kgm^2$ |
| $J_{B\theta}$ | Bogie roll inertia | $kgm^2$ |
| $l_b$ | Half of the distance between two wheelsets in a bogie | $m$ |
| $w_b$ | Half of the distance between two air spring in lateral | $m$ |
| $l_c$ | Half of the carbody length | $m$ |
| $w_c$ | Half of the carbody width | $m$ |
| $K_{2z}$ | Spring constants of air spring | $kN/m$ |
| $K_{1z}$ | Spring constants of primary spring | $kN/m$ |
| $C_{2z}$ | Damping constants of secondary damper | $kNs/m$ |
| $C_{1z}$ | Damping constants of primary damper | $kNs/m$ |
| $K_{\theta}$ | Spring constants of the anti-roll spring | $kN/m$ |

$$J_{B\phi}\ddot{\phi}_{FB} + 4C_{1z}l_1^2\dot{\phi}_{FB} - C_{1z}l_1\dot{z}_{W1R} - C_{1z}l_1\dot{z}_{W1L} +$$
$$C_{1z}l_1\dot{z}_{W2R} + C_{1z}l_1\dot{z}_{W2L} + 4K_{1z}l_1^2\phi_{FB} - K_{1z}l_1z_{W1R}$$
$$-K_{1z}l_1z_{W1L} + K_{1z}l_1z_{W2R} + K_{1z}l_1z_{W2L} = 0 \tag{5}$$

$$J_{B\theta}\ddot{\theta}_{FB} - 2C_{2z}b^2\dot{\theta} + (2C_{2z}b^2 + 4C_{1z}b_1^2)\dot{\theta}_{FB} +$$
$$C_{1z}b_1\dot{z}_{W1R} - C_{1z}b_1\dot{z}_{W1L} + C_{1z}b_1\dot{z}_{W2R} - C_{1z}b_1\dot{z}_{W2L}$$
$$-(2K_{2z}b^2 + K_{\theta})\theta + (2K_{2z}b^2 + 4K_{1z}b_1^2 + K_{\theta})\theta_{FB} +$$
$$K_{1z}b_1z_{W1R} - K_{1z}b_1z_{W1L} + K_{1z}b_1z_{W2R} - K_{1z}b_1z_{W2L}$$
$$= 0 \tag{6}$$

Where $z_{W1R}$ represents the vertical displacement of the right wheel in the leading wheelset under the leading bogie while $z_{W2L}$ means the vertical displacement of the left wheel in the trailing wheelset under the leading bogie. The meanings of other symbols can be easy understood in this logic. In consideration of the fact that the wheelsets are rolling against the track, the vertical displacement of the wheel can be seen as the the unevenness of the track. In a similar way, the model of the trailing bogie can be derived.

The state-space form of the vehicle dynamical model can be derived as:

$$\dot{x} = Ax + B_d d \tag{7}$$
$$y = Cx + D_d d \tag{8}$$

where

$$x = \begin{bmatrix} \dot{z} & \dot{\phi} & \dot{\theta} & z & \phi & \theta & \dot{z}_{FB} & \dot{\phi}_{FB} & \dot{\theta}_{FB} & z_{FB} \\ \phi_{FB} & \theta_{FB} & \dot{z}_{RB} & \dot{\phi}_{RB} & \dot{\theta}_{RB} & z_{RB} & \phi_{RB} \\ \theta_{RB} \end{bmatrix}^T$$

$$d = \begin{bmatrix} \dot{z}_{W1R} & \dot{z}_{W1L} & \dot{z}_{W2R} & \dot{z}_{W2L} & z_{W1R} & z_{W1L} \\ z_{W2R} & z_{W2L} & \dot{z}_{W3R} & \dot{z}_{W3L} & \dot{z}_{W4R} \\ \dot{z}_{W4L} & z_{W3R} & z_{W3L} & z_{W4R} & z_{W4L} \end{bmatrix}^T$$

$$y = \begin{bmatrix} z & \phi & \theta & z_{FB} & \phi_{FB} & \theta_{FB} & z_{RB} & \phi_{RB} \\ \theta_{RB} \end{bmatrix}^T$$

Matrixes $A, B_d, C$ and $D_d$ can be derived from the above differential equations, $d$ is the vertical track velocity and displacement due to track vertical irregularities.

### *B. The Model Based on Acceleration Measurements*

The developed model (7) and (8) represent the dynamical property of the vehicle suspension system. In this model, the vertical displacement, pitch angle displacement and roll angle displacement of the cardody and the bogie are needed to be measured for the fault detection purpose. However, displacement sensor and angle sensors have the problems such as reliability, maintenance and installation. Compare to these sensors, accelerator sensors have the advantages of cheap and reliable. It does not need to be maintained for a long time period. Due to all the reasons stated above, only accelerator sensors are adopted for obtaining the measurement signals. The sensor configuration is designed as shown in Fig. 1. In the following, the new output equation will be derived.

Carbody sensors are equipped in the four corners on the floorboard, and the bogie sensors are equipped in the four corners on the upside of the bogie. By applying double integral to the acceleration signals, displacement signals are acquired. That is

$$z = \int\int a dt dt \tag{9}$$

where $a$ is the acceleration value and $z$ is the displacement. However, these displacement signals obtained is different from the outputs in our model, for example, the angle displacements. So, the model outputs needed to be modified.

As depicted in Fig. 2, we set four index points on the rectangle to discuss the relationship between the vertical displacements at the four corners with the angle displacement. These four index points are the center of the rectangle, the middle pint of the front edge, the middle pint of the right edge and the front corner on the right. The vertical displacement of the four index points are $z, z_F, z_R$ and $z_{FR}$, respectively. Then one obtains

$$z + z_{FR} = z_F + z_R \tag{10}$$

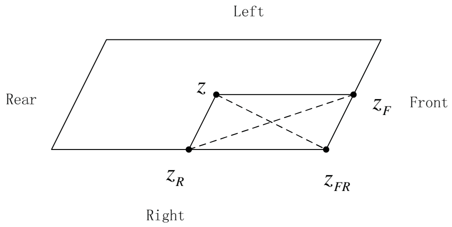

Fig. 2. Relationship among the displacement of the four index points

Consider the pitch motion, we have the equation

$$z_F = z + l\sin(\phi) \approx z + l\phi \tag{11}$$

for a small pitch angle.

Consider the roll motion, we have a similar equation:

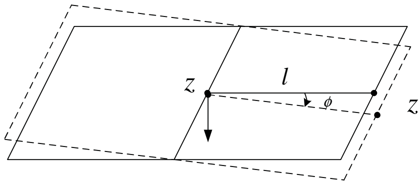

Fig. 3. The pitch motion

$$z_R \approx z - w\theta \tag{12}$$

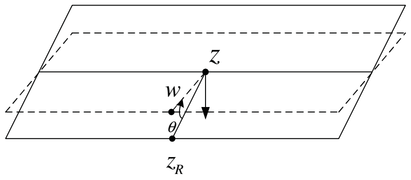

Fig. 4. The roll motion

Combing with (10),(11),(12) together, we have the following transformation relationship:

$$z_{FR} \approx z + l\phi - w\theta \tag{13}$$

In the same procedure, one obtains:

$$z_{FL} \approx z + l\phi + w\theta \tag{14}$$

$$z_{RR} \approx z - l\phi - w\theta \tag{15}$$

$$z_{RL} \approx z - l\phi + w\theta \tag{16}$$

Then the new state space is transformed into

$$\dot{x} = Ax + B_d d \tag{17}$$

$$y_{cor} = TCx + TD_d d \tag{18}$$

where the transformation matrix

$$T = \begin{bmatrix} 1 & l_c & -w_c & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & l_c & w_c & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & -l_c & -w_c & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & -l_c & w_c & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & l_b & -w_b & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & l_b & w_b & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & -l_b & -w_b & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & -l_b & w_b & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & l_b & -w_b \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & l_b & w_b \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & -l_b & -w_b \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & -l_b & w_b \end{bmatrix}$$

where

$$y_{cor} = \begin{bmatrix} z_{FR} & z_{FL} & z_{RR} & z_{RL} & z_{FB\_FR} z_{FB\_FL} \\ z_{FB\_RR} & z_{FB\_RL} & z_{RB\_FR} & z_{RB\_FL} \\ z_{RB\_RR} & z_{RB\_RL} \end{bmatrix}^T$$

$z_{FR}$ and $z_{FL}$ represent the vertical displacement of the front corners on the right and left, respectively. $z_{FB_{FR}}$ represent the vertical displacement of the front corner on the right of the leading bogie.

*Remark 2.1:* Data is the very critical for the data driven fault detection methods. The data should contain rich information of the system dynamics and the fault information when a fault occurs in the system. In this paper, only acceleration sensors are used for the vehicle suspension fault detection systems. From the above observation, the dynamics of rail vehicle suspension systems are contained in the displacements of the the carbody, the front and rail bogies, which can be obtained by the acceleration sensors. The sensor configuration presented before can provided enough information for the fault detection.

## III. DPCA AND CVA FAULT DETECTION PRINCIPLE

Thanks to its simplicity and efficiency in processing huge amount of process data, PCA is recognized as a powerful tool of statistical process monitoring and widely used in the process industry for purpose of fault detection and diagnosis[12][7]. In the meantime, it is noticed that the CVA based condition monitoring methods are outperformed PCA based approaches [5]. In this paper, both methods are studied for the considered vehicle suspension fault detection systems. The main steps for these two methods are briefly reviewed in this section.

### *A. A Brief Description of PCA*

The standard PCA-based fault detection consists of three steps and can be formulated as follows:

- Data collection and pre-processing: Consider a data matrix $X \in \mathbf{R}^{N \times m}$ consisting of $N$ samples and $m$ sensors collected from process. Matrix $X$ is then scaled to zero mean, and often to unit variance. Let the scaled data be

$$\mathbf{Y} = \left[ \begin{array}{c} y_1^T \\ \vdots \\ y_N^T \end{array} \right] \in \mathbf{R}^{N \times m} \tag{19}$$

with $y_i \in R^m$, $i = 1, \cdots, N$ , denoting the ith scaled vector.

- Decomposition of covariance matrix: The covariance matrix is formed as

$$\sum\nolimits_0 \approx \frac{1}{N}\mathbf{Y}^T\mathbf{Y}.$$

By means of SVD or EVD (eigen value decomposition), the covariance matrix is decomposed as follows:

$$\frac{1}{N-1}\mathbf{Y}^T\mathbf{Y} = \mathbf{P}\Lambda\mathbf{P}^T, \Lambda = \left[ \begin{array}{cc} \Lambda_{pc} & 0 \\ 0 & \Lambda_{res} \end{array} \right] \tag{20}$$

with $\sigma_i^2$ , $i = 1, \cdots, m$, is the $i^{th}$ singular value of the covariance matrix and

$$\begin{array}{l} \Lambda_{pc} = diag(\sigma_1^2, \cdots, \sigma_l^2), \Lambda_{res} = diag(\sigma_{l+1}^2, \cdots, \sigma_m^2) \\ \sigma_1^2 \geq \cdots \geq \sigma_l^2 \gg \sigma_{l+1}^2 \geq \cdots \geq \sigma_m^2, \mathbf{P}\mathbf{P}^T = \mathbf{I}_{m \times m} \\ \left[ \begin{array}{c} \mathbf{P}_{pc}^T \\ \mathbf{P}_{res}^T \end{array} \right] \left[ \begin{array}{cc} \mathbf{P}_{pc} & \mathbf{P}_{res} \end{array} \right] = \left[ \begin{array}{cc} \mathbf{I}_{l \times l} & 0 \\ 0 & \mathbf{I}_{(m-l)\times(m-l)} \end{array} \right] \end{array}$$

- On-line fault detection: When a new scaled measurement $x \in \mathbf{R}^m$ is available, the SPE and Hotelling's $T^2$ indices can be computed as

$$\mathbf{T}^2 = y^T\mathbf{P}_{pc}\Lambda_{pc}^{-1}\mathbf{P}_{pc}^T y \tag{21}$$

$$SPE = y^T\mathbf{P}_{res}\mathbf{P}_{res}^T y \tag{22}$$

The fault detection logic is $SPE \leq J_{th,SPE}$ and $T^2 \leq J_{th,T^2} \Rightarrow$ fault-free. Otherwise $\Rightarrow$ faulty.

where $J_{th,T^2}$ and $J_{th,SPE}$ are the thresholds for SPE and $T^2$ respectively.

The PCA methods can be extended to take into account the serial correlations, by augmenting each observation vector with the previous $l$ observations and stacking the data matrix in the following manner,

$$\mathbf{Y}(l) = \left[ \begin{array}{cccc} y_t^T & y_{t-1}^T & \cdots & y_{t-l}^T \\ y_{t-1}^T & y_{t-2}^T & \cdots & y_{t-l-1}^T \\ \cdots & \cdots & \ddots & \vdots \\ y_{t+l-n}^T & y_{t+l-n-1}^T & \cdots & y_{t-n}^T \end{array} \right] \tag{23}$$

where $y_t^T$ is the $m$-dimensional observation vector in the training set at time instance $t$. By performing PCA on the data matrix in Eq. 23, a multivariate autoregressive (AR) (ARX model if the process inputs are included) is extracted directly from the data. This approach of applying PCA to Eq. 23 is referred to here as dynamic PCA (DPCA).

### *B. CVA for Dynamic Processes*

The stacked past and future vectors, **p** and **f**, are represented as follows:

$$\begin{array}{rcl} \mathbf{p}_{t-1}^{t-l} & = & [\mathbf{y}_{t-1}^T \cdots \mathbf{y}_{t-l}^T]^T \qquad (24) \\ \mathbf{f}_t^{t+l+1} & = & [\mathbf{y}_t^T \cdots \mathbf{y}_{t+l-1}^T]^T \qquad (25) \end{array}$$

where **y** denotes output vectors, subscript t is the present time index for **y**, and $l$ is the number of the lag or the lead. In CVA, the stacked future and past vectors are normalized using

$$\mathbf{d}_{f,t} = \sum\nolimits_{ff}^{-1/2} \mathbf{f}_t^{t+l+1}, \mathbf{d}_{p,t-1} = \sum\nolimits_{pp}^{-1/2} \mathbf{p}_{t-1}^{t-l} \tag{26}$$

where $\sum_{ff} = E(\mathbf{f}_t^{t+l+1}\mathbf{f}_t^{t+l+1^T})$ and $\sum_{pp} = E(\mathbf{p}_{t-1}^{t-l}\mathbf{p}_{t-1}^{t-l^T})$ ( $E(\cdot)$ denotes the expectation operator). The normalized vectors $\mathbf{d}_{f,t}$ and $\mathbf{d}_{p,t-1}$ are defined as the scaled stacked future and past vectors at time $t$, respectively. The conditional expectation of the scaled future vector takes the form:

$$\hat{E}(\mathbf{d}_{f,t}|\mathbf{d}_{p,t-1}) = \sum\nolimits_{ff}^{-1/2}\sum\nolimits_{fp}\sum\nolimits_{pp}^{-1/2}\mathbf{d}_{p,t-1} \tag{27}$$

where $\hat{E}(\alpha|\beta)$ denotes the expectation of $\alpha$ under condition $\beta$. The physical mean of $\sum_{fp}$, defined as $E(\mathbf{f}_t^{t+l+1}\mathbf{p}_{t-1}^{t-l^T})$, is the well-known Hankel matrix. Thus, $\sum_{ff}^{-1/2}\sum_{fp}\sum_{pp}^{-1/2}$ indicates the scaled Hankel matrix. The scaled Hankel matrix can be factorized using singular value decomposition (SVD),

$$\begin{array}{rcl} \widehat{\mathbf{d}}_{f,t} & = & \sum\nolimits_{ff}^{-1/2}\sum\nolimits_{fp}\sum\nolimits_{pp}^{-1/2}\mathbf{d}_{p,t-1} \\ & = & \mathbf{USV}^T\mathbf{d}_{p,t-1} \approx \mathbf{U}_k\mathbf{S}_k\mathbf{V}_k^T\mathbf{d}_{p,t-1} \qquad (28) \end{array}$$

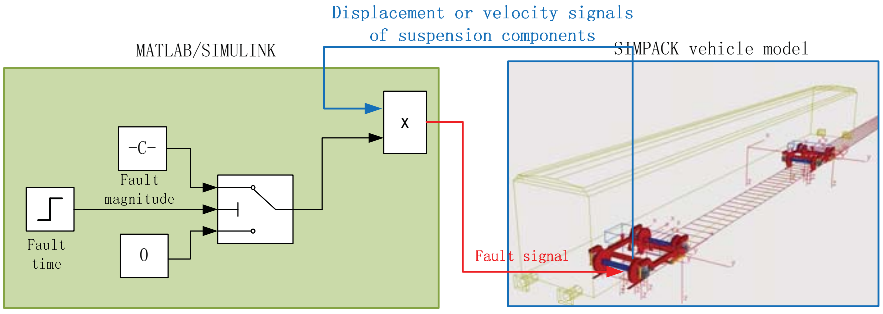

Fig. 5. Co-simulation between SIMPACK and MATLAB/SIMULINK

where $\widehat{\mathbf{d}}_{f,t}$ denotes $\hat{E}(\mathbf{d}_{f,t}|\mathbf{d}_{p,t-1})$ and $k$ represents the state order. $\mathbf{U}_k$ and $\mathbf{V}_k$ consist of the first $k$ column vectors of $U$ and $V$, respectively, and the diagonal matrix $\mathbf{S}_k$ is the $k \times k$ principal submatrix of $\mathbf{S}$. Then, the past and future CVs at time $t$ are given by

$$\begin{aligned} \mathbf{z}_t &= \mathbf{U}_k^T \mathbf{d}_{f,t} = \mathbf{U}_k^T \sum_{ff}^{-1/2} \mathbf{f}_t^{t+l+1} = \mathbf{L}_k \mathbf{f}_t^{t+l+1} \\ \mathbf{m}_t &= \mathbf{V}_k^T \mathbf{d}_{p,t-1} = \mathbf{V}_k^T \sum_{pp}^{-1/2} \mathbf{p}_{t-1}^{t-l} = \mathbf{J}_k \mathbf{p}_{t-1}^{t-l} \end{aligned} \tag{29}$$

respectively, and these CVs satisfy

$$\mathbf{z}_k = \mathbf{S}_k \mathbf{m}_t \tag{30}$$

Similar to the $T^2$ and SPE indices, the following indices are used in this paper:

$$T_s^2 = \mathbf{y}^T \mathbf{J}_k \mathbf{J}_k^T \mathbf{y} \tag{31}$$

$$SPE_s = r_t^T r_t \tag{32}$$

where $r_t = (I - \mathbf{J}_k \mathbf{J}_k)\mathbf{y}$

## IV. SIMULATION

### A. Co-simulation to Generate the Suspension Faults

In this section, SIMPACK vehicle model is used to generate the acceleration signals and different faults in both primary and secondary suspension are simulated. Here we discuss how to simulate the suspension faults in SIMPACK. The interface between MATLAB/SIMULINK and SIMPACK make it possible to simulate suspension fault with different fault magnitudes at any time during the operation.

As we all known, the damper will generate a force, whose value equals the damper coefficient times piston's velocity, to reject the moving of the piston. And we generate the damper fault signal in the way it works. As shown in Fig. 5, for example, sensors are equipped at the position of a secondary damper to measure it's moving velocity. Suggest that the damper lose half of its value at the 15th second. Then a external force is exerted on the piston to reduce the performance of the damper as shown in Fig. 5. The direction of the external force is opposite to the force generated by the damper, and the value of force equals the fault magnitude times piston's velocity. In a similar way, spring fault can be simulated.

TABLE II
FAULT SCENARIOS

| scenario | fault | fault pattern | faulty time (s) |
|---|---|---|---|
| fault 0 | no fault | | |
| fault 1 | $C_2$ | failure | 15 |
| fault 2 | $K_1$ | lost 90% | 20 |
| fault 3 | $K_2$ | lost 25% | 30 |
| fault 4 | $K_2$ | lost 90% | 30 |

### B. Fault Detection Results

The simulation results for the railway vehicle suspension fault detection are shown in this section. The track irregularities used in the simulations are the German 6th grade track spectrum. The faults considered in the simulation study are listed in Table II.

The no fault data are used for training the models. For the DPCA approach, the time lags is selected as 20. 120 principle components are selected to be retained in the model. For the CVA approach, the measured data is compressed by PCA method and only 6 variables are kept in the new data. This avoids the problem that $\Sigma_{ff}^{-1/2}$ and $\Sigma_{pp}^{-1/2}$ are not real. The time lags and leads in the CVA approach are selected as 20. In the CVA model, 18 states are selected.

The fault detection results are shown in Fig. 6-9. In all the figures, the red solid line indicates the no fault case. The blue dashed line represents the case of $C_2$ failure. The $K_1$ lost 90% of its value is indicated by the green dash-dotted line. For the fourth scenario, $K_1$ lost 25% of its value, is represented by the black dotted line. Finally, the $K_1$ lost 90% of its value fault is represented by the cyan dots.

Fig. 6 shows the fault detection results of PCA approach using the $T^2$ index. Fault 1, 2 and 4 are detected successfully. The $T^2$ index of the weak fault 3 is not obvious. The SPE index of the PCA approach is shown in Fig. 7. The performance is similar to that of the $T^2$ index. Fig. 8 shows the results of the CVA approach by using $T_s^2$ index. It can be seen that the CVA approach is very sensitive to fault 2. The fault 1 is also detected successfully. The detection results of the fault 3 and 4 are not very satisfied. Similar performance is observed by using the $SPE_s$ index.

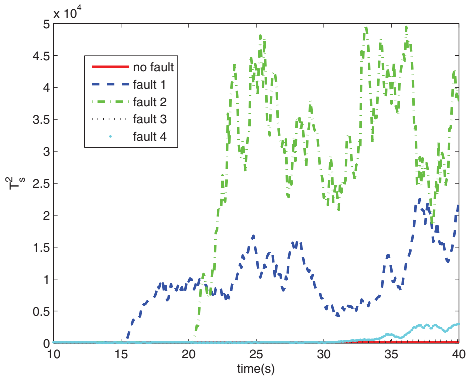

Fig. 8. Fault detection results based on CVA and $T_s^2$ index

## V. Conclusion

In this paper, the data driven fault detection problem for the railway vehicle suspension systems are studied. A new fault detection system is proposed where only the acceleration signals are used for the detection purpose. Both PCA and CVA based approaches are studied. For large magnitude faults, both approaches achieves very good detection performance. However, for weak faults, for instance, the $K_2$ lost of $25\%$ of its value, both methods do not detect the faults obviously. This means that both methods cannot detect early stage fault. New strategy for improving the sensitivity of the data driven fault detection methods are necessary. The final comment is that the components nonlinearities are not considered in the simulation study. They should be investigated in the future work.

*Abstract*— **A linear time invariant model-based robust fast adaptive fault estimator with unknown input decoupling is proposed to estimate aircraft elevator oscillatory faults. Since the robust fast adaptive fault estimator depends on system output error dynamics which are de-coupled from the unknown inputs (modeling uncertainty), the fault estimation signal generated by the designed fault estimator is robust to the estimated unknown inputs. To obtain a fast fault estimation speed, an adaptive fault estimator involves both proportional and integral components. A Lyapunov stability analysis of the robust fast adaptive fault estimator is given and the fault estimator dynamic response is achieved by pole assignment in subregions realized by LMIs. The proposed robust fast adaptive fault estimator is implemented on a high-fidelity nonlinear aircraft model to detect and estimate elevator actuator oscillatory faults.**

***Keywords- adaptive fault estimator; unknown input ; fault estiamation ; linear matrix inequalities; Oscillatory Fault Case.***

## I. INTRODUCTION

The traditional approach to detecting and isolating faults in a flight control system makes use of hardware redundancy by a replication of hardware [1] (sensors, actuators or even flight control comp3ters). However, there is a growing interest in methods which do not require additional hardware redundancy, for easing the development of the future more sustainable aircraft (Cleaner, Quieter, Smarter and More Affordable). Highlighting the link between aircraft sustainability and fault detection, it can be demonstrated that improving the diagnosis performance in flight control systems allows the designers to optimize the aircraft structural design (resulting in weight saving), which in turn helps improve aircraft performance and to decrease its environmental footprint. Concretely, if the minimum detectable fault amplitude and/or the detection time can be decreased, the aircraft structural design will be improved and the aircraft will be made lighter [2].

As an alternative to hardware redundancy the model-based approach, often referred to as Fault Detection and Diagnosis (FDD) or Fault Detection and Isolation (FDI) makes use of analytical redundancy by generating redundant estimates of measured signals [3]. Although fault information generation via model-based FDD method for actuators (or sensors) generally increases the flight control system computational load, they can increase aircraft sustainability by improving fault diagnosis performance which leads to the possibility of optimizing aircraft structural design. All of which can help to achieve the challenges related to the "greening" of the aircraft. Model-based FDD has often been considered for fault detection, fault location and even diagnosis of fault severity in aircraft flight control systems [4, 5].

Many approaches to robust model-based FDD have been proposed in the past decades [4-8]. The major challenge is that the fault information signal should be robust to unknown inputs (UIs), used to represent a structured form of modelling uncertainty. To achieve the FDD robustness, different methods have been studied, e.g. the use of optimization methods [4], the unknown input observer (UIO) [6], the sliding mode observer [7] and geometric design approaches [8].

The method proposed in this paper is applied to a non-linear simulation of a generic aircraft provided by AIRBUS for a benchmark study within the ADDSAFE FP7 project [9, 10]. The benchmark is considered highly representative of the flight physics and aircraft handling qualities. One of the often considered fault scenarios is the oscillatory fault case (OFC) {sometimes referred to as the "oscillatory failure case"} which can be caused, for example by electronic system component faults. The moving flight surface of an aircraft can sometimes experience oscillation which may be generated in the servo-loop control, i.e. between the flight control computer (FCC) and the actual control surface itself. The spurious sinusoidal signals can propagate through the FCC and hence the control surface, as shown in Fig.1 [11]. As the fault is a local phenomenon within a single actuator, it only has an impact on one control surface. This OFC scenario has been studied by [7, 11] to detect the OFC fault.

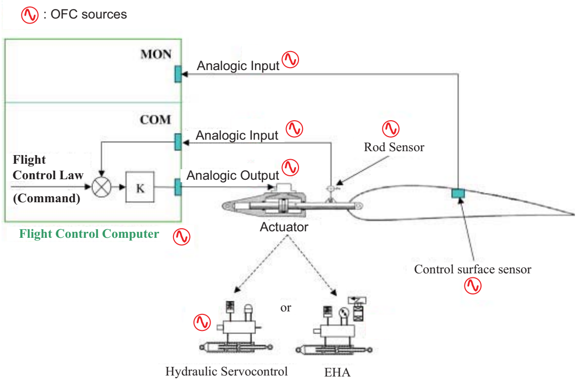

Figure 1. OFC source location in the control loop

A well-known method for estimating fault signals uses a combination of proportional and integral action within a full

order identity observer [12]. However, these authors did not consider the robustness of the fault estimation to modeling uncertainty. The current work provides an extension to the work of [12] by using a UIO to take into account the effects of so-called UI signals. The estimator design problem is divided into two stages of (i) UI distribution matrix estimation followed by (ii) the actual fault estimation, with inclusion of proportional (not only integral) action to enhance to the fault estimation speed. The proposed approach is termed a Robust Fast Adaptive Fault Estimator (RFAFE) based on a combination of the UIO proposed in [6] and the Fast Adaptive Fault Estimator of [12]. The RFAFE is applied to the problem of estimating the oscillatory fault signal acting on an elevator of the ADDSAFE benchmark system. The benefit of the proposed RFAFE is that by making the output error of the observer insensitive to modelling uncertainty the fault estimation robustness is improved.

The robustness of the fault estimation is defined to be the degree of comparison between the sensitivity of the estimation to the fault compared with the sensitivity to modeling uncertainty. The fault estimation must be accurate with relative insensitivity to modelling uncertainty.

The nonlinear aircraft model is not available for publication due to confidential issues. However, the results in this paper have been generated by applying the new RFAFE fault estimation strategy to the fully non-linear aircraft system dynamics via the ADDSAFE project. Following a procedure in [6] the structure of the modelling uncertainty inherent between the nonlinear and linear time invariant (LTI) aircraft models are considered as UI terms in the linear models used for the development of the fault estimator. In stage (i) of the RFAFE design, the influences of the UIs are estimated by estimating the "directions" (i.e. distributions) of these terms into the state space model as described in [3, 13]. In stage (ii) the fault estimator is then applied directly to the fault residual signal. This study focuses on the problem of detecting OFC fault activity in one elevator actuator (referred to as the "left" actuator).

The structure of the paper is as follows: In Section II, the proposed RFAFE design is formulated. In Section III, the LTI longitudinal aircraft model dynamics including elevator model dynamics are constructed. The RFAFE method is applied to the ADDSAFE benchmark system in Section IV to estimate various OFC faults. The conclusion is given in Section V.

## II. ROUBST ADAPTIVE FAULT ESTIMATION THEORY

### *A. Fast adaptive fault estimation with UI decoupling*

A LTI system considering actuator faults (all sensors are assumed to be fault-free) and with modeling uncertainty, represented by the UI term $Ed(t)$ is represented as:

$$\left.\begin{aligned} \dot{x}(t) &= A\,x(t) + Bu(t) + Ed(t) + F_a f_a\,(t) \\ y(t) &= C\,x(t) \end{aligned}\right\} \tag{1}$$

where $x \in \Re^n$ denotes the time-varying system state vector, $u \in \Re^r$ and $y \in \Re^m$ denote the input and measurement vectors, respectively and $d \in \Re^p$ is a vector of UIs. $f_a \in \Re^l$ represents a vector of time-varying actuator faults. $A, B, C$ are known system matrices with appropriate dimensions. The matrix $E \in \Re^{n\times q}$ represents the distribution matrix for the UIs. The columns of the matrix $F_a \in \Re^{n\times l}$ denote the independent fault directions. It is thus considered that both $E$ and $F_a$ act as system inputs.

Following [3], a functional observer is constructed as:

$$\left.\begin{aligned} \dot{z}(t) &= Nz(t) + TBu(t) + Ky(t) + TF_a\hat{f}_a(t) \\ \hat{x}(t) &= z(t) + Hy(t) \end{aligned}\right\} \tag{2}$$

where $\hat{x} \in \Re^n$ is the estimated state vector and $z \in \Re^n$ is the observer state vector, and $N$ , $T$, $K$ and $H$ are design matrices.

**Definition 1**: Observer (2) is defined as a *robust fast adaptive fault estimator (RFAFE)* for the system (1), if its state and fault estimation errors $e_x = x - \hat{x}$ and $e_f = f_a - \hat{f}_a$ approach zero asymptomatically, in the presence of the system UIs and faults.

Assuming that $E$ is known, the estimation error dynamics are governed by:

$$\begin{aligned} \dot{e}_x(t) = (A - HCA - K_1C)e_x(t) \\ +[N - (A - HCA - K_1C)]z(t) \\ +[K_2 - (A - HCA - K_1C)H]y(t) \\ +[T - (I - HC)]Bu(t) \\ +(HC - I)Ed(t) + TF_a e_f(t) \end{aligned} \tag{3}$$

where

$$K = K_1 + K_2 \tag{4}$$

If the following relations are satisfied:

$$(HC - I)E = 0 \tag{5}$$

$$T = I - HC \tag{6}$$

$$N = A - HCA - K_1C = A_1 - K_1C \tag{7}$$

$$K_2 = NH \tag{8}$$

The state estimation error is then refined as:

$$\dot{e}_x(t) = Ne_x(t) + TF_a e_f(t) \tag{9}$$

$$e_y(t) = ce_x(t) \tag{10}$$

$$r(t) = y(t) - C\hat{x}(t) = Ce_x(t) = e_y(t) \tag{11}$$

Furthermore, if all eigenvalues of $N$ are stable, $r(t)$ will approach zero asymptotically, i.e. $\hat{x} \rightarrow x$ and $\hat{f}_a \rightarrow f_a$ . The observer (2) is an UI decoupling *fast adaptive fault estimator* for the system (1) when conditions (5) – (8) are satisfied. Therefore, this RFAFE design involves the solution of (4) to (8) whilst placing all the eigenvalues of the system matrix $N$ to be stable. Meanwhile, $N$ , $T$ , $K$ and $H$ in (2) are designed to achieve the required fault estimation performance.

A particular solution to (5) can be calculated as follows:

$$H = E(CE)^{+} \tag{12}$$

where: $(CE)^{+} = [(CE)^{T}CE)]^{-1}(CE)^{T}$ denotes the Moore-Penrose pseudo-inverse.

**Theorem 1**. The necessary and sufficient conditions for the existence of RFAFE of system (1) are [3, 12]:

(i) $rank(CE) = rank(E)$
(ii) $rank(CF_a) = rank(F_a)$
(iii) $rank([E\ F_a] = q + l$
(iv) $(C, A_1)$ is a detectable pair

**Remark 1**: Condition (i) denotes that the maximum number of independent UIs cannot be larger than the maximum number of independent measurements, i.e. the necessary condition for UI decoupling in the state estimation error dynamics is $rank(E) \leq m$. If this condition is not satisfied, a rank approximation via a matrix $E^{*}$ can be derived using Singular Value Decomposition (SVD) [14]. The details in [3] are addressed in Section B.

**Remark 2**: (ii) expresses that the maximum number of independent faults cannot be larger than the maximum number of independent measurements, i.e. the necessary condition for fault estimation in the states error dynamics is $rank(F_a) \leq m$.

**Remark3**: (iii) means that the UIs and faults are separable.

**Remark 4**: (iv) is equivalent to the following two equations.

*(1)* $rank\begin{bmatrix} sI - A & E \\ C & 0 \end{bmatrix} = n + rank(E)$

*(2)* $rank\begin{bmatrix} sI - A & B \\ C & 0 \end{bmatrix} = n + rank(B)$

Lemma 1 is used to verify the RFAFE existence conditions:

**Lemma 1** [15]: Given a scalar $\theta > 0$ and a symmetric positive definite matrix $P$, the following inequality holds:

$$2x^{T}y \leq (1/\theta)(x^{T}Px) + \theta y^{T}P^{-1}y \quad x, y \in \Re^{n} \tag{13}$$

Assume that $\dot{f}_a \neq 0$, e.g. a sinusoidal perturbation (as required for the OFC fault case). The derivative of $e_f$ is represented as:

$$\dot{e}_f = \dot{f}_a - \dot{\hat{f}}_a \tag{14}$$

The system error dynamics can be guaranteed by Theorem 2.

**Theorem 2**: With the assumption of Theorem 1, given the scalar $\alpha, \theta > 0$, if there exist symmetric positive definite matrices $P \in \Re^{n\times n}$, $Q \in \Re^{n\times n}$, $G \in \Re^{l\times l}$, and matrices $Y \in \Re^{n\times m}$, $N \in \Re^{l\times m}$ such that the following conditions hold.

$$\begin{bmatrix} PN + N^{T}P & -(1/\alpha)(N^{T}PTF_a) \\ * & -2(1/\alpha)(TF_a)^{T}PTF_a + (1/\alpha\theta)G \end{bmatrix} < 0 \tag{15}$$

$$(TF_a)^{T}P = MC \tag{16}$$

$*$ denotes the elements of a symmetric matrix, the UI decoupling fast adaptive fault estimator can be defined as:

$$\dot{\hat{f}}(t) = \Gamma M(\dot{r}(t) + \alpha r(t)) \tag{17}$$

(17) can be realized when $r(t)$ and $e_f$ are uniformly bounded functions. $\Gamma \in \Re^{l\times l}$ is a symmetric positive definite learning rate matrix.

**Proof**: Consider the following Lyapunov function:

$$V(t) = e_x^{T}(t)Pe_x(t) + (1/\alpha)\, e_f^{T}(t)\Gamma^{-1}e_f(t) \tag{18}$$

Substituting (9) and (17) into (18), the derivative of $V(t)$ with respect to time is derived as:

$$\begin{aligned} \dot{V}(t) &= \dot{e}_x^{T}(t)Pe_x(t) + e_x^{T}(t)P\dot{e}_x^{T}(t) + 2(1/\alpha)\, e_f^{T}\Gamma^{-1}\dot{e}_f(t) \\ &= e_x^{T}(t)(PN + N^{T}P)e_x(t) + 2e_x^{T}(t)PTF_a e_f(t) \\ &\quad -2(1/\alpha)\, e_f^{T}(t)M(\dot{r}(t) + \sigma r(t)) \\ &\quad -2(1/\alpha)\, e_f^{T}(t)\Gamma^{-1}\dot{f}(t) \end{aligned} \tag{19}$$

Using (16), the term $-2(1/\alpha)\, e_f^{T}(t)M\big(\dot{r}(t) + \sigma r(t)\big)$ on the left hand side of (19) can be rewritten as:

$$\begin{aligned} &-2(1/\alpha)\, e_f^{T}(t)M\big(\dot{r}(t) + \sigma r(t)\big) \\ &\quad = -2(1/\alpha)\, e_f^{T}(t)(TF_a)^{T}P\big(\dot{e}_x(t) + \sigma e_x(t)\big) \end{aligned} \tag{20}$$

Substituting (9) and (20) into (19), $\dot{V}(t)$ can be formulated as:

$$\begin{aligned} \dot{V}(t) &= \dot{e}_x^{T}(t)(PN + N^{T}P)e_x(t) \\ &\quad -2(1/\alpha)\, e_f^{T}(t)(TF_a)^{T}PNe_x(t) \\ &\quad -2(1/\alpha)e_f^{T}(t)(TF_a)^{T}PTF_a e_f(t) \\ &\quad -2(1/\alpha)\, e_f^{T}(t)\Gamma^{-1}\dot{f}(t) \end{aligned} \tag{21}$$

By using Lemma 1, the following inequality can be obtained:

$$\begin{aligned} -2(1/\alpha)\, e_f^{T}(t)\Gamma^{-1}\dot{f}(t) &\leq (1/\alpha\theta)\, e_f^{T}(t)Ge_f(t) \\ &\quad +(\theta/\alpha)f_1^{2}\lambda_{max}(\Gamma^{-1}G^{-1}\Gamma^{-1}) \end{aligned} \tag{22}$$

Substituting (22) into (21), $\dot{V}(t)$ can be reformulated as:

$$\dot{V}(t) = \varphi^{T}(t)\, \Xi\, \varphi(t) + \delta \tag{23}$$

where

$$\varphi(t) = \begin{bmatrix} e_x(t) \\ e_f(t) \end{bmatrix}, \quad \delta = (\theta/\alpha)f_1^{2}\lambda_{max}(\Gamma^{-1}G^{-1}\Gamma^{-1}),$$

$$\Xi = \begin{bmatrix} PN + N^{T}P & -(1/\alpha)(N^{T}PTF_a) \\ * & -2(1/\alpha)(TF_a)^{T}PTF_a + (1/\alpha\theta)G \end{bmatrix}$$

$TF_a$ is full column rank, under the condition of $\Xi < 0$, and $\epsilon = \lambda_{min}(-\Xi)$, then:

$$\dot{V}(t) < -\epsilon\|\varphi(t)\|^2 + \delta \tag{24}$$

for

$$\delta < \epsilon\|\varphi(t)\|^2 \tag{25}$$

Then, it follows that:

$$\dot{V}(t) < 0 \tag{26}$$

In terms of Lyapunov stability theory, (26) indicates that $e_x(t)$ and $e_f(t)$ converge to a small set of $\delta$. This ends the proof.

If the fault signal is defined as:

$$f_a(t) = \begin{cases} 0 & t \in (0,\ t_f) \\ f_a(t) & t \in (t_f,\ \infty) \end{cases} \tag{27}$$

The fault estimation can be derived by (17) and given as:

$$\hat{f}(t) = \Gamma M(r(t) + \alpha \int_{tf}^{t} r(t)\, d\tau) \tag{28}$$

From (28), it can be seen that the fault estimation includes both proportional and integral parts. The proportional part enhances the fault estimator dynamic performance giving improved fault estimation speed.

**Remark 5**: Although inequality (15) can be solved easily via the Matlab LMI tool box, the simultaneous solution of (15) and (16) is difficult to achieve using functions in the LMI tool box. However, the problem can be solved by reformulating (16) into (29), which leads to the solution of optimization problem:

$$\begin{bmatrix} -\gamma I & (TF_a)^T P - MC \\ * & -\gamma I \end{bmatrix} < 0 \tag{29}$$

The RFAFE derivation is complete with proof of stability.

Apart from guaranteeing the observer stability, the observer dynamic response plays an important role in obtaining a qualified observer performance achieved by forcing the poles to lie within suitable complex plane subregions comprising either vertical strips, disks, conic sectors etc. (or their combinations) using LMIs optimization [16]. Here, disk and vertical strip LMI regions are employed as a further refinement to improve the fault estimator dynamics with LMIs defined as:

**Definition 2**: $N$ is defined as in (7). Let $\mathcal{D}$ be an LMI subregion with characteristic function in the left hand side of the complex plane as a disk of radius $r$ and centre $(-q, 0)$. Then there exists a symmetric matrix $P$ such that:

$$\begin{pmatrix} -rP & qP + N^T P \\ * & -rP \end{pmatrix} < 0 \qquad P > 0 \tag{30}$$

Then, $N$ is called $\mathcal{D}$–stable.

**Definition 3**: $N$ is defined as in (7). Let $\mathcal{D}$ be a subregion which presents a $\zeta$-stability region in the left-half plane. $\mathcal{D}$ is an LMI region with characteristic function, so that there exists a symmetric matrix $P$ such that:

$$N^T P + PN + 2\zeta P < 0 \qquad P > 0 \tag{31}$$

Then, $N$ is called $\mathcal{D}$ –stable. Fig. 2 shows the RFAFE poles assignment within an subregion $\mathcal{D}$ of an intersection between a specified disk and vertical strip by solving (30) & (31).

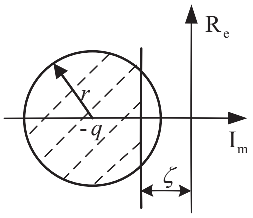

Figure 2. $\mathcal{D}$ subregion (hatched)

Consequently, a complete RFAFE with UI decoupling can be designed by solving (15), (29), (30), (31) and conditions (5)–(8) with the satisfaction of Theorem 2.

### *B. UI distribution matrix estimation*

An augmented state observer is utilized to estimate the UI distribution matrix $E$. Assume that $d_1(t) = Ed(t)$ is a slowly time-varying vector, then the system model can be formulated in augmented form as [3, 13]:

$$\begin{bmatrix} \dot{x}(t) \\ \dot{d}(t) \end{bmatrix} = \begin{bmatrix} A & I \\ 0 & 0 \end{bmatrix} \begin{bmatrix} x(t) \\ d_1(t) \end{bmatrix} + \begin{bmatrix} B \\ 0 \end{bmatrix} u(t)$$

$$y(t) = \begin{bmatrix} C_a & 0 \end{bmatrix} \begin{bmatrix} x(t) \\ d_1(t) \end{bmatrix} \tag{32}$$

If the system inputs and outputs $\{u(t), y(t)\}$ are available, an observer based on the model presented by (32) can be used to estimate the $d_1(t)$ directly. The distribution matrix $E$ is calculated as the ratio of the elements of $\hat{d}_1(t)$. The necessary condition for observability is given in Theorem 3:.

**Theorem 3** The system (32) is observable if and only if the following conditions are satisfied [6].

(i) $rank(C) = n$
(ii) $rank(C, A)$ is a observable pair

**Remark 6**: Normally, the condition (i) could limit the application of this estimation approach. For a modern aircraft the states are available for measurement and this is also the case in the simulated non-linear system, so that the above observability and rank conditions are satisfied. Furthermore, the $E$ estimation is a state space problem, and hence independent of any measurement restrictions.

For the RFEFA design, the necessary rank condition $rank(E) \leq m$ has been given in Theorem 1. If this condition is not satisfied, a sub-optimal matrix $E^*$can be computed as follows via an SVD expansion of $E$ [3, 14]:

$$E = S\Sigma T^T \tag{33}$$

where:

$$\Sigma = \begin{bmatrix} diag\{\sigma_{1,\cdots,}\sigma_k\} & 0 \\ 0 & 0 \end{bmatrix} \tag{34}$$

$S$ and $T$ are orthogonal matrices, $k$ is the rank, and $\sigma_{1,\dots,}\sigma_k$ are the singular values of $E$ , respectively. A low rank approximation for $E$ by minimizing $\|E - E^*\|_F^2$ is given by:

$$E^* = S\hat{\Sigma}T^T \tag{35}$$

where

$$\hat{\Sigma} = \begin{bmatrix} diag\{0,\cdots,0,\sigma_{k-q,\cdots,}\sigma_k\} & 0 \\ 0 & 0 \end{bmatrix} \tag{36}$$

$q = rank(E^*) \leq m$ to satisfy Theorem 1 (for $E^*$ instead of $E$).

## III. LTI LONGITUDINAL AIRCRAFT MODEL DYNAMICS

The proposed RFAFE is implemented on a global longitudinal LTI model derived from the ADDSAFE benchmark system. Two parts constitute the global aircraft LTI model: one is the aircraft body axis LTI model derived from an LPV realization of the benchmark system obtained by choosing the trimming parameters given in TABLE I. The other part comprises the locally linear aircraft actuator models representing the right and left elevators on the aircraft tail surface. The linearized aircraft actuator models are generated for the same trimming parameters as the aircraft body axis LTI model.

TABLE I. TRIMMING POINTS FOR LONGITUDINAL AIRCRAFT LTI MODEL

| Trimming parameter | value |
|---|---|
| MASS (Net mass in Kg) | 200000 |
| XG (Centre gravity of the aircraft in % / 100) | 0.30 |
| ZP (Altitude in feet) | 20000 |
| VC (Calibrate aircraft speed in kts) | 290 |

The LTI local elevator model is represented by a first order system dynamic. For the longitudinal motion, the left and right elevator dynamics combined together have the structure:

$$\left.\begin{aligned} \dot{x}_a(t) &= A_a\, x_a(t) + B_a u_c(t) \\ y_a(t) &= C_a\, x_a(t) + D_a u_c(t) \end{aligned}\right\} \tag{37}$$

where $x_a(t) \in \Re^{2\times1}$ is the augmented state vector for both the left and right elevators. $u_c(t) \in \Re^{2\times1}$ is the vector of elevator control inputs (the actuator input signals fed from the FCC), $y_a$ is the actuator output. $A_a$, $B_a$, $C_a$,$D_a$ are corresponding system matrices with proper dimensions.

The LTI state space representation of the aircraft body axis dynamics can be expressed as:

$$\left.\begin{aligned} \dot{x}_b(t) &= A_b\, x_b(t) + B_u u_b(t) \\ y_b(t) &= \ C_b x_b(t) + D_u u_b(t) \end{aligned}\right\} \tag{38}$$

where $x_b = [V_{tas}, \ \alpha, \ q, \theta]$ and $y_b = [V_{tas}, \ \alpha, \ q, \theta]$ are the aircraft body axis states and outputs, respectively. $u_b$ is equal to $y_a$. $V_{tas}$ is the true air speed in m s$^{-1}$, $\alpha$ is the angle of attack in deg, $q$ is the pitch rate in deg s$^{-1}$, $\theta$ is pitch angle in deg. $A_b$, $B_b$,$C_b$, $D_b$ are the corresponding system matrices.

The complete LTI longitudinal motion model is formulated as:

$$\begin{bmatrix} \dot{x}_b(t) \\ \dot{x}_a(t) \end{bmatrix} = \begin{bmatrix} A_b & B_u C_a \\ 0 & A_a \end{bmatrix} \begin{bmatrix} x_b(t) \\ x_a(t) \end{bmatrix} + \begin{bmatrix} B_u D_a \\ B_a \end{bmatrix} u_c(t)$$

$$\begin{bmatrix} y_b(t) \\ y_a(t) \end{bmatrix} = \begin{bmatrix} C_b & D_u C_a \\ 0 & C_a \end{bmatrix} \begin{bmatrix} x_b(t) \\ x_a(t) \end{bmatrix} + \begin{bmatrix} D_u D_a \\ D_a \end{bmatrix} u_c(t) \tag{39}$$

(39) can be rewritten as:

$$\left.\begin{aligned} \dot{x}(t) &= A\, x(t) + Bu(t) \\ y(t) &= C\, x(t) + Du(t) \end{aligned}\right\} \tag{40}$$

LTI system (40) with UIs and faults can be presented as:

$$\left.\begin{aligned} \dot{x}(t) &= A\, x(t) + Bu(t) + Ed(t) + F_a f_a\, (t) \\ y(t) &= C\, x(t) + Du(t) \end{aligned}\right\} \tag{41}$$

## IV. SIMULATION RESULTS

In this paper, the RFAFE design is implemented on a generic AIRBUS aircraft model to estimate the left elevator OFC fault. Two types of OFC are classified, the “liquid” and “solid” faults. The liquid fault is considered as an additive fault which adds to the control command inside the control loop. The solid fault is considered as a ‘disconnected’ fault which substitutes the control command completely inside the control loop. Both of these two OFC faults lead to the control surface performing with a spurious control command. In this project, the OFC faults are simulated as sinusoidal signals within a range of magnitudes and frequencies. The estimated OFC fault signals are normalized into the entire interval [0, 1] according to the elevator control surface deflection range of operation. In this simulation result section, the OFC signals 0.016 and 0.33 (in normalized units) are estimated to (a) demonstrate the effect that the OFC has on the elevator operation and (b) the effectiveness of the RFAFE design.

The first step of the RFAFE design is to estimate the UI distribution matrix as an off-line analysis. The modelling uncertainties between the nominal nonlinear aircraft model and the LTI aircraft longitudinal model are considered as UIs. The off-line design of the ASO for $E$ estimation is made by running the ADDSAFE benchmark model. Six single fault-free cases (cruise phase, triggering of angle of attack protection, nose-up (abrupt longitudinal maneuver), triggering of pitch protection, coordinated turn and a “yaw-angle-mode” which roughly corresponds to an enhanced auto-pilot hold mode) are used to implement the estimation of the matrix $E$. The lower rank technique via the SVD approach is applied to post-process the modelling uncertainty data, so that condition (i) in Theorem 1 is satisfied. The second step of the RFAFE design is to construct the UI decoupling fast adaptive estimator in terms of the matrix $E$ estimated in step 1. A set of conditions should be satisfied first and a group of LMIs should be solved as discussed in Section II. All the designs described in this paper use one aircraft longitudinal LTI model that corresponds to the operating point in TABLE I. The left elevator fault direction $F_a$ is the first column of $B = [B_G, B_D]$, i.e. $F_a = B_G$.

Figs. 3&4 show the left elevator control surface position in two fault cases compared with the fault-free case, respectively. The control surface deflection is apparent, i.e. the OFC fault leads to unwanted control surface oscillation.

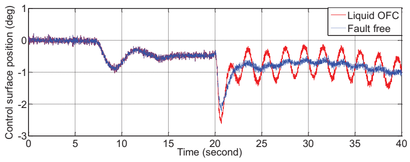

Figure 3. Left elevator control surface position (liquid OFC&fault-free cases)

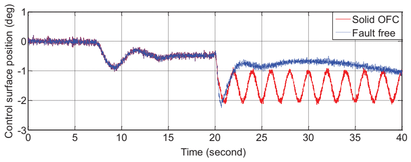

Figure 4. Left elevator control surface position (solid OFC & fault-free cases)

Fig. 3 corresponds to the liquid OFC. A sinusoidal signal is added to the normal control surface position. Fig. 4 shows the control surface movement trajectory is totally substituted by a sinusoidal signal for the solid OFC “disconnection” behaviour.

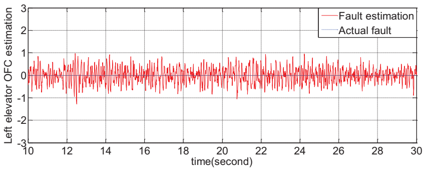

Figure 5. Left elevator fault estimation for the fault-free case

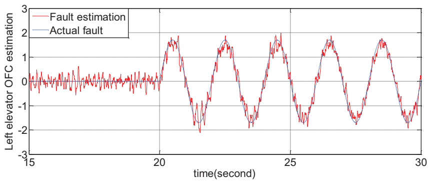

Figure 6. Left elevator fault estimation for the liquid OFC fault

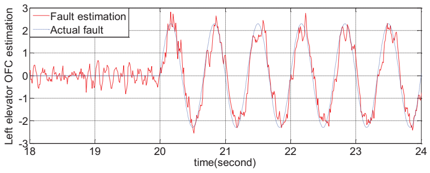

Figure 7. Left elevator fault estimation for solid OFC

Fig. 5 shows that in the fault-free case (left elevator) the estimates are in a noise level. In Figs. 6&7, the estimation of the so-called liquid OFC (0.016 OFC) and solid OFC (0.033 OFC) are shown, respectively. For each fault scenario, the faults occur at 20s and the fault estimation signals track the actual fault signals in magnitude and frequency.

The RFAFE design learning rate should be tuned to a suitable value to achieve accurate and fast fault estimation. It can also be seen that the fault estimation signal is not significantly affected by the modelling uncertainties, but is influenced by high frequency sensor noise. Hence, the fault estimation signal obtained is considered robust to modelling uncertainties.

## V. CONCLUSION

In this paper, the RFAFE approach to fast fault estimation has been applied to an aircraft actuator OFC problem, taking into account modeling uncertainties through UI estimation. The UIs reflect the modelling mismatch between the linear and non-linear aircraft systems. The UI estimation considering a range of flight conditions provides a structured approach to robustness which leads to a robust fault estimation. The UI estimation with UI decoupling is utilized in the RFAFE design. The results show that the fault estimation signals track the actual fault signals accurately under both liquid and solid OFC faults in different magnitudes and frequencies, demonstrating the effectiveness and efficiency of the RFAFE method.

# A variable structure observer for unknown input estimation in sampled systems

L. Orihuela, S. K. Spurgeon, X. G. Yan and F. R. Rubio

*Abstract*— **This paper considers the design of a variable structure observer for unknown input estimation and/or fault reconstruction in systems where the process measurements are sampled. It is well known that the principle of the equivalent injection signal from the sliding mode domain can be used for reconstruction of unknown inputs but much of the associated theory is predicated on output sampling of infinite frequency. Sample rate may be a physical constraint of the process and the reconstruction properties of such continuous time sliding mode observers degrade under this constraint. This paper explores how a recently developed ultimately bounded stable variable structure discrete time observer can be used for unknown input estimation. The main novelty of the approach is that the design of the observer is written as an optimization problem with linear constraints with the output sampling incorporated explicitly in the model used for observer design. The design methodology is shown to have advantages in terms of reconstruction accuracy when the performance is compared to that of a classical sliding mode observer on a case study.**

## I. INTRODUCTION

Variable structure systems were perhaps originally best known for their potential as a robust control method [1], [2], [3]. They are characterised by a suite of feedback control laws and a decision rule. The decision rule, termed the switching function, has as its input some measure of the current system behaviour and produces as an output the particular feedback controller which should be used at that instant in time. In sliding mode control, variable structure control systems are designed to drive and then constrain the system state to lie within a neighbourhood of the switching function. The paradigm has several advantages: the dynamic behaviour of the system may be specified by the choice of switching function and the system is completely insensitive to an important class of uncertainties. A disadvantage of the methodology has been the fundamentally discontinuous control signal which, in theoretical terms, must switch with infinite frequency to provide total rejection of uncertainty. Control implementation via approximate, smooth strategies is widely reported, but in such cases total invariance is routinely lost.

In contrast, the application of sliding mode methods to the observer problem is less mature and has some fundamentally different properties [4]. The discontinuous injection signals which were perceived as problematic for many control applications have no disadvantages for software based observer frameworks. The ability to generate a sliding motion on the error between the measured plant output and the output of the observer ensures that a sliding mode observer produces a set of state estimates that are precisely commensurate with the actual output of the plant. Further, analysis of the average value of the applied observer injection signal, the so-called equivalent injection signal, contains useful information about the mismatch between the model used to define the observer and the actual plant [5]. This property has been employed for general unknown input estimation as well as for fault reconstruction [6], [7], [8]. The results obtained to date most frequently require that an ideal sliding motion is attained in finite time and the effects of sampling on the physical measurements used to drive the observer are typically not considered within the observer design frameworks. However, in the presence of a sampled output, the ideal sliding mode cannot be achieved. Indeed, the error dynamics in the observer may become unstable if the sampling frequency is reduced significantly. The effect of output sampling on the performance of a sliding mode observer designed using classical continuous variable structure control theory has been discussed by several authors, see for example [9], where the fast sampling required for fault reconstruction via such a sliding mode observer on a motor experiment is reported.

In practice, the sample rate is not always a parameter that can be selected by the designer and in this case consideration must be given to developing design methods that incorporate the sampling characteristics if good estimates are to be obtained for the unknown inputs. Recent work has considered the development of a sliding mode observer in the presence of sampled output information and its application to fault reconstruction by using the delayed continuous-time representation of the sampled-data system, for which a set of Linear Matrix Inequalities (LMIs) provide conditions for ultimate boundedness of the solution [10]. An alternative approach is to consider a discrete time observer design methodology. Compared to the continuous time case, the literature in this area is sparse. Several contributions develop sliding mode observers for systems with a single output [11], [12], [13]. More recently, [14] studied sliding mode observers for a class of discrete-time multi-output systems, but the design of the observer is largely heuristic, and it is not possible to ensure *a priori* the stability of the observer. A variable structure observer design framework for discrete-time multi-output systems which uses Linear Matrix Inequalities to constructively exploit the degrees of freedom

within the design has been recently developed [15].

This paper extends this later framework to incorporate the estimation of faults and/or unknown inputs as a design requirement and assesses the degree to which the methodology overcomes problems of sampled data implementation frameworks for variable structure based signal reconstruction.

The paper is structured as follows. The problem is stated in Section II. The variable structure observer is proposed in Section III. The estimation of unknown inputs using the discrete-time observer is studied in Section IV. Some examples are presented in Section V. The paper ends with conclusions and a discussion of future research directions.

## II. PROBLEM STATEMENT

Consider the multi-output, discrete-time linear system described by

$$\begin{aligned} x(k+1) &= Ax(k)+Dw(k), && (1)\\ y(k) &= Cx(k), && (2) \end{aligned}$$

where $x \in \mathcal{R}^n$ is the state, $y \in \mathcal{R}^p$ is the output and $w \in \mathcal{R}^m$ is the unknown input. Matrices $A, D, C$ are known with appropriate dimensions. It is assumed that the pair $(A, C)$ is observable. Note that no control input affects the system, as the observer problem is the focus of this paper. The inclusion of the control signal can be trivially dealt with, as both the observer and the system are subject to the same input and thus the control signal has no affect on the dynamics of the error between the system and observer.

Assume that $rank(CD) = m$ and the invariant zeros of the triple $(A, D, C)$ lie inside the unit circle. Then, there exists a linear change of coordinates $T_o$ (see [3]) such that the system can be written as:

$$\begin{aligned} x_1(k+1) &= A_{11}x_1(k)+A_{12}z(k)+D_1w(k), && (3)\\ z(k+1) &= A_{21}x_1(k)+A_{22}z(k)+D_2w(k), && (4)\\ y(k) &= z(k), && (5) \end{aligned}$$

where $z(k) \in \mathcal{R}^p$, $x_1 \in \mathcal{R}^{n-p}$ and $D_2 \in \mathcal{R}^{p\times m}$. Matrix $A_{11}$ is stable and $D_2$ has full column rank.

Unlike [10] and similar approaches, the disturbance process or unknown input $w(k)$ affects both dynamics. The classical nomenclature used in sliding mode theory, namely, unmatched and matched disturbances has been adopted (see [3]). It is assumed to be bounded by

$$\|w(k)\| \leq \xi,\ \forall k,$$

where $\xi$ is a known positive scalar.

The following section is devoted to the design of an ultimately bounded variable structure observer for the system (1), by driving the observation error $e(k)$ to the vicinity of the equilibrium point $e(k) = 0$ in finite time and maintaining it in the neighbourhood thereafter. Due to the presence of the disturbances, asymptotic stability is not possible. However, the proposed observer reduces the ultimate bound on the response when compared to classical observation strategies. In Section IV, the properties of this observer will be used in order to estimate the unknown input $w(k)$.

## III. VARIABLE STRUCTURE OBSERVER

The proposed variable structure observer for the multi-output system (3)-(5) is defined as

$$\begin{aligned} \hat{x}_1(k+1) &= A_{11}\hat{x}_1(k)+A_{12}y(k) && (6)\\ \hat{z}(k+1) &= A_{21}\hat{x}_1(k)+A_{22}\hat{z}(k) && (7)\\ & \quad -(A_{22}-A_{22}^s)e_z(k)+\nu(k) \end{aligned}$$

where $e_z(k) = \hat{z}(k) - y(k)$ and $A_{22}^s \in \mathcal{R}^{p\times p}$ is a design matrix. The variable structure term $\nu(k)$ is defined by:

$$\nu(k) = Bf_{sat}(e_z(k),\Delta) = B\begin{bmatrix} sat\left(\frac{e_{z1}(k)}{\Delta}\right)\\ sat\left(\frac{e_{z2}(k)}{\Delta}\right)\\ \vdots\\ sat\left(\frac{e_{zp}(k)}{\Delta}\right) \end{bmatrix} \quad (8)$$

where $\Delta$ is a positive scalar and $B \in \mathcal{R}^{p\times p}$ is also a design matrix. The function $sat(.)$ is defined as:

$$sat\left(\frac{e_{zi}(k)}{\Delta}\right) = \begin{cases} sgn(e_{zi}(k)), & |e_{zi}(k)| > \Delta\\ \frac{e_{zi}(k)}{\Delta}, & |e_{zi}(k)| \leq \Delta \end{cases}$$

It can be viewed as a set of $p$ unidimensional switching functions. Each one switches whenever the associated component of the output observation error $e_{zi}$, $i = 1..., p$ crosses the boundary of the region.

Let the state estimation errors be $e_1(k) = \hat{x}_1(k) - x_1(k)$ and $e_z(k) = \hat{z}(k) - z(k)$. It follows that the error dynamics are

$$\begin{aligned} e_1(k{+}1) &= A_{11}e_1(k){-}D_1w(k), && (9)\\ e_z(k{+}1) &= A_{21}e_1(k){+}A_{22}^se_z(k){-}D_2w(k){+}\nu(k). && (10) \end{aligned}$$

where $y(k) = z(k)$ in (5) is used to obtain the equations above.

In order to study the stability of the observer, a Lyapunov framework is used. Defining $\Delta$ as the ultimate boundedness, the objective of this section is to design the variable structure observer in such a way that $\Delta$ is minimized ensuring that the forward increment of the Lyapunov function is negative for all $k$ such that $|e_z(k)| \geq \Delta$. Consider the following Lyapunov function:

$$V(k) = e_1^T(k)P_1e_1(k) + e_z^T(k)P_2e_z(k), \quad (11)$$

where $P_1, P_2$ are positive definite matrices of appropriate dimensions.

Due to the presence of the saturation, $\nu(k)$ is a nonlinear function. A linear representation of the saturation is introduced which will be useful when designing the observer via linear matrix inequalities. This idea was presented in [15].

Denote by $\mathfrak{E}_\beta$ the set of states such that

$$\begin{aligned} \mathfrak{E}_\beta = \{&(e_1(k), e_z(k)) \mid e_1(k) \in \mathcal{R}^{n-p}, e_z(k) \in \mathcal{R}^p,\\ &V(k) = e_1^T(k)P_1e_1(k) + e_z^T(k)P_2e_z(k) \leq \beta^{-1}\}, \end{aligned}$$

for a positive scalar $\beta$. The following lemma gives the linear representation of the nonlinear dynamics.

**Lemma 1. [15]** Given $\beta > 0$, assume that there exists a matrix $H_z \in \mathcal{R}^{p\times p}$, such that $|h_{zi} e_z| \leq 1$, for all $e_z \in \mathfrak{E}_\beta$, where $h_{zi}$ denotes the $i$-th row of $H_z$. Then, for $(e_1, e_z) \in \mathfrak{E}_\beta$, the observation error dynamic system (9)-(10) with switching function (8) admits the following representation:

$$\begin{aligned} e_1(k+1) &= A_{11}e_1(k) - D_1 w(k), \\ e_z(k+1) &= A_{21}e_1(k) + A_{22}^s e_z(k) - D_2 w(k) \\ &+ B\sum_{j=1}^{2^p} \lambda_j(k) A_j e_z(k), \end{aligned}$$

where:

$$\begin{aligned} A_j &= F_j K + F_j^- H_z, \quad j = 1, .., 2^p, \\ \sum_{j=1}^{2^p} \lambda_j(k) &= 1, \quad \lambda_j(k) \geq 0, \forall k > 0, \\ K &= diag\{1/\Delta, ..., 1/\Delta\}, \end{aligned}$$

with $F_j$ a diagonal matrix with diagonal elements that are either 1 or 0, and $F_j^- \triangleq I_m - F_j, \forall j$.

From Lemma 1, it can be concluded that the linear representation for the saturation is valid only if the region $\mathfrak{E}_\beta$ (defined by the parameter $\beta$) and a corresponding matrix $H_z$ can be found such that the error remains in $\mathfrak{E}_\beta$ for all $k$. Hence, this must be an additional constraint in the design of the observer.

The following theorem presents the main result of this section.

**Theorem 1.** Given the disturbance bound $\xi$ and the size $\beta$ of the set $\mathfrak{E}_\beta$, if positive definite matrices $P_1, P_2$, matrices $A_{22}^s, B, H_z$ of appropriate dimensions and scalar $\tau > 0$ solve the following optimization problem

$$\min_{A_{22}^s, B, P_1, P_2, H_z, \tau} \Delta \tag{12}$$

subject to (13)-(14), then the observation error dynamic system (9)-(10) is ultimately bounded stable. The minimum boundedness is $\Delta$.

**Proof.** It is first proved that conditions (13)-(14) imply that, given a positive $\Delta$, the forward increment of the Lyapunov function (11) decreases for all $|e_z(k)| \geq \Delta$.

The inequalities (14) guarantee that $|h_{zi} e_z| \leq 1$, $(i = 1, ..., p)$ for all $(e_1, e_z) \in \mathfrak{E}_\beta$. This results from the fact that any error belonging to $\mathfrak{E}_\beta$ satisfies

$$\begin{aligned} \beta e_1^T(k) P_1 e_1(k) + \beta e_z^T(k) P_2 e_z(k) \leq 1 \\ \Rightarrow \beta e_z^T(k) P_2 e_z(k) \leq 1 \end{aligned}$$

Then, for $(e_1, e_z) \in \mathfrak{E}_\beta$, the following inequalities

$$2 \geq 1 + \beta e_z^T(k) P_2 e_z(k) \geq 2|h_{zi} e_z|$$

imply that $|h_{zi} e_z| \leq 1$ for $i = 1, ..., p$. The latter inequality, which can be written as

$$\begin{bmatrix} 1 & \pm e_z^T \end{bmatrix} \begin{bmatrix} 1 & h_{zi} \\ * & \beta P_2 \end{bmatrix} \begin{bmatrix} 1 \\ \pm e_z \end{bmatrix} \geq 0,$$

is satisfied by (14).

As the assumption of Lemma 1 is verified, the polytopic description of the system given in that lemma holds. Using this linear representation, the Lyapunov function (11) at $k+1$ for vertex $j$ of the polytope is[1]

$$\begin{aligned} & V_j(k+1) = \\ & = (A_{11}e_1 - D_1 w)^T P_1 (A_{11}e_1 - D_1 w) \\ & + \big(A_{21}e_1 + M_{2j}e_z - D_2 w\big)^T P_2 \big(A_{21}e_1 + M_{2j}e_z - D_2 w\big), \end{aligned}$$

where

$$M_{2j} = A_{22}^s + BF_j K + BF_j^- H_z.$$

The forward increment of the Lyapunov function will be

$$\begin{aligned} \Delta V_j(k) = {} & V_j(k+1) - V_j(k) \\ & = -e_1^T Q_1 e_1 - 2e_1^T A_{11}^T P_1 D_1 w + w^T D_1^T P_1 D_1 w \\ & + e_1^T A_{21}^T P_2 A_{21} e_1 + 2e_1^T A_{21}^T P_2 M_{2j} e_z \\ & - 2e_1^T A_{21}^T P_2 D_2 w + e_z^T (M_{2_j}^T P_2 M_{2j} - P_2) e_z \\ & - 2e_z^T M_{2_j}^T P_2 D_2 w + w^T D_2^T P_2 D_2 w \end{aligned} \tag{15}$$

where $-Q_1 \triangleq A_{11}^T P_1 A_{11} - P_1$. The positive term $\tau w^T(k) w(k)$ can be bounded by:

$$\tau w^T(k) w(k) \leq \tau\xi^2 \leq \frac{\tau\xi^2}{\Delta^2} e_z^T(k) e_z(k),$$

taking into account that $\|e_z(k)\| \geq \Delta$. Therefore,

$$\frac{\tau\xi^2}{\Delta^2} e_z^T(k) e_z(k) - \tau w^T(k) w(k) \geq 0 \tag{16}$$

From (15) and (16), it follows that

$$\begin{aligned} \Delta V_j(k) & = V_j(k+1) - V_j(k) \\ & = -e_1^T \left(A_{11}^T P_1 A_{11} - P_1 + A_{21}^T P_2 A_{21}\right) e_1 + \\ & 2e_1^T A_{21}^T P_2 M_{2j} e_z - 2e_1^T \left(A_{11}^T P_1 D_1 + A_{21}^T P_2 D_2\right) w \\ & + e_z^T \left(M_{2_j}^T P_2 M_{2j} - P_2\right) e_z - 2e_z^T M_{2_j}^T P_2 D_2 w \\ & + w^T \left(D_1^T P_1 D_1 + D_2^T P_2 D_2\right) w \\ & + \frac{\tau\xi^2}{\Delta^2} e_z^T(k) e_z(k) - \tau w^T(k) w(k) \end{aligned}$$

Then, the increment of the Lyapunov function can be written in the following quadratic manner:

$$\Delta V_j(k) \leq \zeta^T(k) \Xi_j \zeta(k),$$

where the stacked state vector is

$$\zeta(k) = \begin{bmatrix} e_1(k) \\ e_z(k) \\ w(k) \end{bmatrix}$$

and the symmetric matrix $\Xi_j$ is given in equation (13).

The inequalities (13) imply that matrices $\Xi_j$ are negative definite for all the vertices of the polytope, and then, the forward increment of the Lyapunov function will be negative for all $\zeta(k) \neq 0$ (see [16]), which ensures the asymptotic stability of the system.

[1] The time script $k$ has been removed for ease of exposition.

$$\begin{bmatrix} A_{11}^T P_1 A_{11} - P_1 + A_{21}^T P_2 A_{21} & A_{21}^T P_2 M_{2j} & -A_{11}^T P_1 D_1 - A_{21}^T P_2 D_2 \\ * & M_{2j}^T P_2 M_{2j} - P_2 + \frac{\tau \xi^2}{\Delta^2} I & -M_{2j}^T P_2 D_2 \\ * & * & -\tau I + D_1^T P_1 D_1 + D_2^T P_2 D_2 \end{bmatrix} < 0, j = 1, ..., 2^p, \quad (13)$$

$$\begin{bmatrix} 1 & h_{zi} \\ * & \beta P_2 \end{bmatrix} \geq 0, i = 1, ..., p. \quad (14)$$

where

$$M_{2j} = A_{22}^s + BF_j K + BF_j^- H_z.$$

Finally, it must be ensured that the state of the system remains in $\mathfrak{E}_\beta$. To demonstrate this, the fact that the set $\mathfrak{E}_\beta$ is an invariant set is utilised so that from any initial condition $e_1(0), e_z(0)$ in $\mathfrak{E}_\beta$, any error $e_1(k), e_z(k)$ will belong to $\mathfrak{E}_\beta$, for all $k \geq 0$. The reason is clear as $\Delta V(k)$ is negative definite, then $V(k) \leq V(0) \leq \beta^{-1}$.

Finally, the optimization problem is introduced to minimize the size of the ultimate boundedness $\Delta$. This concludes the proof. □

Theorem 1 does not give any insights into the design of the observer. There are many unknown matrices that must be designed: some related to the observer dynamics $A_{22}^s, B$ and some are needed for stability considerations such as $P_1, P_2, H_z$. There are also constants $\Delta, \beta, \tau$ to be selected. In the following subsection some modifications on the conditions of Theorem 1 are introduced in such a way that some Linear Matrix Inequalities (LMIs) are obtained, which can be efficiently solved using appropriate software tools.

### A. OBSERVER DESIGN VIA LMI

Assume that the matrices $A_{22}^s$ and $H_z$ have been well designed. Imposing a particular choice of $A_{22}^s$, define the dynamics of the observation error when there are no disturbances (see eq. (10)). The following lemma can be used to design the observer.

**Lemma 2.** Given matrices $A_{22}^s, H_z$ and scalars $\beta, \xi$, if positive definite matrices $P_1, P_2$, matrix $W$ of appropriate dimensions and scalar $\tau > 0$ solve the following optimization problem

$$\min_{P_1, P_2, W, \tau} \Delta$$

subject to

$$\begin{bmatrix} -P_1 & 0 & 0 & A_{11}^T P_1 & A_{21}^T P_2 \\ * & -P_2 + \tau \frac{\xi^2}{\Delta^2} I & 0 & 0 & \Theta_j \\ * & * & -\tau I & -D_1^T P_1 & -D_2^T P_2 \\ * & * & * & -P_1 & 0 \\ * & * & * & * & -P_2 \end{bmatrix} < 0,$$

$$j = 1, ..., 2^p, \quad (17)$$

$$\begin{bmatrix} 1 & h_{zi} \\ * & \beta P_2 \end{bmatrix} \geq 0, \quad i = 1, ..., p. \quad (18)$$

with

$$\Theta_j \;\; = \;\; A_{22}^{sT} P_2 + K^T F_j W^T + H_z^T F_j^- W^T,$$

then the observation error dynamic system (9)–(10) is ultimately bounded stable by taking $B = P_2^{-1} W$. Matrix $h_{zi}$ denotes the i-th row of $H_z$.

**Proof.** See Appendix.

The optimization of scalar $\Delta$ can be easily carried out by means of a bisection algorithm or similar. The conditions are linear matrix inequalities with design parameters $P_1, P_2, W, \tau$, so the problem can be easily solved using appropriate software.

## IV. UNKNOWN INPUT ESTIMATION

This section is devoted to the unknown input estimation properties of the variable structure observer designed previously. Specifically, the switching function $\nu(k)$ contains useful information about the mismatch between the model used to define the observer and the actual plant.

Let $\bar{w}(k)$ denote the estimate of the unknown input. From the dynamics of the observation error (9), the actual error can be estimated as

$$e_1(k) = A_{11}^k e_1(0) + \sum_{i=0}^{k-1} (A_{11}^{k-1-i} D_1 \bar{w}(i)).$$

As $A_{11}$ is stable, the first term vanishes in some steps, so:

$$e_1(k) \approx \sum_{i=0}^{k-1} (A_{11}^{k-1-i} D_1 \bar{w}(i)). \quad (19)$$

Note that actual $e_1(k)$ depends on past values of $\bar{w}(k)$. On the other hand, using the output error dynamics (10), and assuming that slow disturbances will imply slow $e_z$, then:

$$\begin{aligned} e_z(k) &\approx e_z(k+1), \\ &\approx A_{21} e_1(k) + A_{22}^s e_z(k) - D_2 \bar{w}(k) + \nu(k). \end{aligned}$$

As the observer is asymptotically stable when $|e_z(k)| > \Delta$, it can be assumed that it is evolving inside the ball for sufficiently large $k$. In that case,

$$\nu(k) = \frac{B}{\Delta} e_z(k) \quad \Rightarrow \quad e_z(k) = \Delta B^{-1} \nu(k),$$

assuming nonsingular $B$. Substituting in the previous equation:

$$D_2 \bar{w}(k) \approx A_{21} e_1(k) + [\Delta(A_{22}^s - I) B^{-1} + I] \nu(k).$$

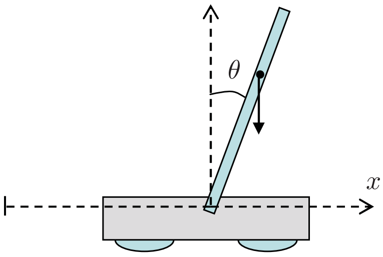

Fig. 1. Scheme of the inverted pendulum with cart

By least squares, the unknown input can be estimated using the $e_1(k)$ given in (19) and the actual value of $\nu(k)$:

$$\bar{w}(k) \approx M\left(A_{21}e_1(k) + [\Delta(A_{22}^s - I)B^{-1} + I]\nu(k)\right),$$

where $M = (D_2^T D_2)^{-1}D_2^T$. Here the matrix $D_2^T D_2$ is nonsingular because $D_2$ has full column rank.

## V. EXAMPLE: INVERTED PENDULUM

The problem of the inverted pendulum with a cart constitutes a benchmark study for the application of nonlinear design methods, [17]. The problem also lends itself to assessment of linear frameworks, as linearization errors are a motivation for control engineers to employ robust control techniques and observers. Consider the inverted pendulum with a cart shown in Figure 1. Using the same model given in [3], the equations of motion are

$$\begin{aligned} (M+m)\ddot{x} + F_x\dot{x} + ml(\ddot{\theta}\cos\theta - \dot{\theta}^2\sin\theta) &= u, (20) \\ J\ddot{\theta} + F_\theta\dot{\theta} - mlg\sin\theta + ml\ddot{x}\cos\theta &= 0, (21) \end{aligned}$$

where the values of the physical parameters used are given in Table I.

TABLE I
MODEL PARAMETERS FOR THE INVERTED PENDULUM WITH CART

| | | | | | |
|---|---|---|---|---|---|
| $M$ | $(kg)$ | 3.2 | $F_x$ | $(kg/s)$ | 6.2 |
| $m$ | $(kg)$ | 0.535 | $F_\theta$ | $(kg\ m^2)$ | 0.009 |
| $J$ | $(kg\ m^2)$ | 0.062 | $g$ | $(m/s^2)$ | 9.8 |
| $l$ | $(m)$ | 0.365 | | | |

To evaluate the performance of the proposed unknown input observer, it will be compared with the continuous sliding mode observer proposed in [3]. However, to make an appropriate comparison, additional sampling will be introduced between the plant and observer in this continuous version to reflect the practical situation whereby signals from the plant are sampled. In both cases, the system must be linearised around the equilibrium point at the origin. Using $x, \theta, \dot{x}$ and $\dot{\theta}$ as system states, and assuming that only $\theta, x$ and $\dot{x}$ are available as measured outputs, the discrete-time model with sampling time $T_m = 0.1s$ is given by the triple

$$A = \left[\begin{array}{c|ccc} 0.1051 & 0 & -7.4143 & 2.5489 \\ \hline -0.0003 & 1 & -0.0119 & 0.0915 \\ 0.1053 & 0 & 2.2255 & -0.3016 \\ -0.0084 & 0 & -0.2681 & 0.8447 \end{array}\right], B = \left[\begin{array}{c} 0.0435 \\ \hline 0.0015 \\ -0.0049 \\ 0.0293 \end{array}\right]$$

$$C = \left[\begin{array}{c|ccc} 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{array}\right]$$

It is assumed that in both cases, the same control signal is used. Specifically, a sliding mode controller is implemented. Furthermore, it is assumed that the unknown inputs enter the system through the same channel as the control input, that is, $D = B$. Using Lemma 2 with $\beta = 0.01$ and $\xi = 0.15$, the optimization problem leads a minimum bound of $\Delta = 0.02$. The variable structure observer is defined by

$$\begin{aligned} A_{22}^s &= \begin{bmatrix} 0.3000 & 0 & 0 \\ 0 & 0.2000 & 0 \\ 0 & 0 & 0.4000 \end{bmatrix}, \\ B &= \begin{bmatrix} -0.0062 & 0.0000 & -0.0000 \\ 0.0000 & -0.0042 & 0.0000 \\ -0.0000 & 0.0000 & -0.0088 \end{bmatrix} \end{aligned}$$

Figures 2 and 3 compare the results of both observers. The simulations have been performed using the nonlinear model for the pendulum given in equations (20)-(21). The sum of two sinusoidal functions has been applied as the unknown input.

Figure 2 shows that the proposed observer exhibits an initial transient time after which a good estimate of the unknown input is obtained. This is because some of the assumptions made in Section IV are correct only if the observation error is close to zero. Moreover, linearization errors are more apparent at the transient, when the pendulum is far from the equilibrium. However, after this transient time, Figure 3 reveals that the discrete-time observer produces a better estimate than its continuous counterpart. Comparing the error in the steady state, the continuous observer has a maximum absolute error of $0.0295$ units whereas the discrete observer achieves a maximum error of $0.0183$. There is thus a circa $60\%$ difference in the error bound, with the proposed observer providing the greater accuracy of reconstruction.

## VI. CONCLUSIONS

Following the same framework as in [15], an unknown input observer has been presented for sampled systems. The proposed method has several advantages. On the one hand, the design exploits all the degrees of freedom available in the observer framework proposed in [15] in a positive way. On the other hand, the quality of the estimate of the unknown inputs is higher when compared with a classical continuous sliding mode observer. In the nonlinear bench mark inverted pendulum with cart example, a circa $60\%$ improvement in the error bound is achieved with the proposed synthesis. It is clear that the current methodology relies upon knowledge of the sample rate used for implementation and development of methods which incorporate sampling of uncertain or variable rate must now be considered.

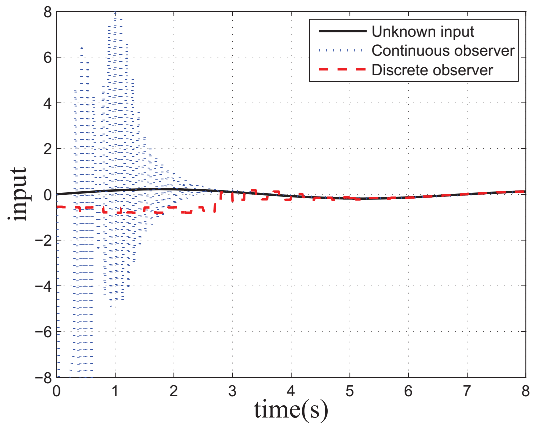

Fig. 2. Unknown input estimation with the continuous SMO (dotted line) and the discrete VSO (dashed line)

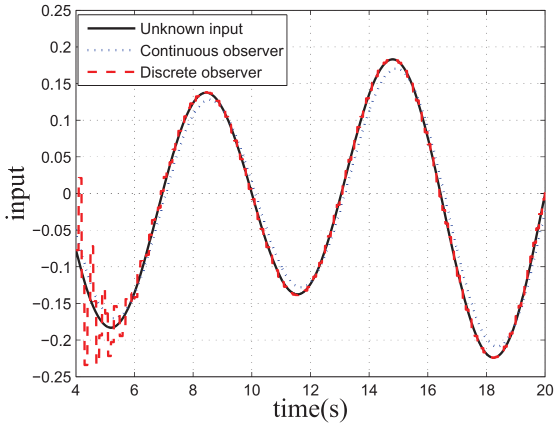

Fig. 3. Unknown input estimation with the continuous SMO (dotted line) and the discrete VSO (dashed line)

## Appendix

It will be shown that the conditions given in Lemma 2 and in Theorem 1 are equivalent. The first set of inequalities (13), $\Xi_j < 0$ can be rewritten as:

$$\begin{bmatrix} -P_1 & 0 & 0 \\ * & -P_2+\tau\frac{\xi^2}{\Delta^2}I & 0 \\ * & * & -\tau I \end{bmatrix} + \\ + \begin{bmatrix} A_{21}^T \\ M_{2j}^T \\ -D_2^T \end{bmatrix} P_2 \begin{bmatrix} A_{21} & M_{2j} & -D_2 \end{bmatrix} + \\ + \begin{bmatrix} A_{11}^T \\ 0 \\ -D_1^T \end{bmatrix} P_1 \begin{bmatrix} A_{11} & 0 & -D_1 \end{bmatrix} < 0,$$

for $j = 1, ..., 2^p$. Using the Schur complement, the previous inequalities are equivalent to

$$\begin{bmatrix} -P_1 & 0 & 0 & A_{11}^T & A_{21}^T \\ * & -P_2+\tau\frac{\xi^2}{\Delta^2}I & 0 & 0 & M_{2j}^T \\ * & * & -\tau I & -D_1^T & -D_2^T \\ * & * & * & -P_1^{-1} & 0 \\ * & * & * & * & -P_2^{-1} \end{bmatrix} < 0,$$

for $j = 1, ..., 2^p$. Pre- and post-multiplying the previous inequalities by $diag\{I, I, I, P_1, P_2\}$ and its transpose, conditions (17) are obtained. Then, the proof is finished by direct application of Theorem 1. □

***Abstract*—The goal of this paper is to develop a new approach for the Free Flight concept based on neighbouring Optimal Control (NOC) that can deliver an aircraft to its designated position safely and reliably when faced with conflicts, and to have some form of recovery measure when the pilot is faced with uncertainty that are due to wind and other uncertainties in the FF environment. The benefits of the algorithm are that it reduces fuel consumption, and it achieves optimal safe inter-aircraft separation while maintaining near-optimality under disturbances.**

***Index Terms*—NOC, Air Traffic Control, Fuel Consumption, Conflict Detection, Separation Constraints.**

## I. Introduction

Recent advancements in navigation aids, communication technologies, and computing power makes it possible for new concepts of Air Traffic Control (ATC) to be implemented, namely the Free Flight (FF), which is an environment where pilots have the liberty to select their routes in real time, and also define their own cruising altitudes and speeds for better fuel efficiency [2]. The workload of ATC would be greatly reduced, since pilots would be responsible for immediate threat avoidance when encountered. ATC then would be responsible for higher level tasks, such as monitoring traffic flow, airspace control, sectorisation, and scheduling runways. In the current centralised environment, ATC has to deal with potentially thousands of aircraft spread over a vast geographic area in order to ensure resolution of all possible conflicts [2]. Furthermore, as the number of aircraft increases, the complexity of conflict resolution grows and quickly becomes computationally intractable. Similarly, the possibility that a single failure could disable a significant portion of the centralized system creates a highly undesirable risk.

One of the most important tasks for ATC is conflict detection and resolution (CDR). Much of the current research for automating ATC focuses on this problem. Solutions for Conflict Resolution (CR) that are based on fixed rule sets that dictate actions based on situational geometry has been widely studied in both centralized and distributed algorithms. Very few of these techniques incorporate free flight rules in the algorithm, and that FF research has mainly been focused on the concept rather than defining automation tools for this concept. The goal of this paper is to exploit an approach based on neighbouring Optimal Control (NOC) to achieve a near-optimal FF air traffic control when faced with conflicts, and to have some form of recovery measure when the pilot is faced with uncertainty that are due to wind and other uncertainties in the FF environment. In addition, reduction in fuel consumption is desirable, and to achieve near-optimal safe inter-aircraft separation while maintaining near-optimality under disturbances.

The rest of the paper is organized as follows. Section II presents the Free Flight concept and its associated rules and conditions and some previous work that was carried out will be described. Section III outlines a multi aircraft model used, its associated constraints and a subsection also outlines fuel efficient resolution maneuvers. Subsequent sections will outline a derivation for Trajectory redirection using NOC and it also shows that feasible trajectories exist when faced with uncertainties that the pilot may experience. Finally a simulation example with a worst case scenario will be shown. A summary (Pseudo Code) of the algorithm is also shown on Section V.

## II. The Free Flight Concept

The following definition was defined in the Report of the Radio Technical Commission for Aeronautics (RTCA) Board of Directors' Select Committee on Free Flight [2]. ”Free Flight” was defined as :

*”A safe and efficient flight operating capability under instrument flight rules (IFR) in which the operators have the freedom to select their path and speed in real time. Air traffic restrictions are only imposed to ensure separation, to preclude exceeding airport capacity, to prevent unauthorized flight through special use airspace, and to ensure safety of flight. Restrictions are limited in extent and duration to correct the identified problem. Any activity which removes restrictions represents a move towards free flight.”*

Sometimes the words ”Free Flight” are used for concepts, which include direct routing but no airborne separation. ATC will be overseeing traffic flow management (TFM) and intervening only when there is a loss of separation.

### A. Conditions and Rules of Free Flight

The FF definition used by RTCA roughly defines the concept. To define the context, a more detailed definition and rules are required. The following questions need to be clarified after applying the RTCA definition:

1) What is the role & responsibility of ATC?
2) How is an alert zone and protected zone defined?

Based on the questions above, the following choices and assumptions were made:

1) NO ATC: An inflexible proposition of FF is chosen with no ATC on the ground. The idea behind this concept is to explore the limits of the FF concept.

2) ALL AIRCRAFT FULLY EQUIPPED: All aircraft are assumed to be set up with Automatic Dependent Surveillance-Broadcast (ADS-B) transmitter & receiver and CDR advisory modules. The transmitter sends the aircraft's position and intent information needed by the CD module to all other aircraft. The ADS-B receiver collects all the information of the traffic within a certain range in the FF sector. The scenarios of mixed equipage is not considered here even though it is required for the transition to FF.

3) UPPER AIRSPACE ONLY: This work is limited to the uppermost airspace only, in order to concentrate on general conceptual problems. In other flight phases, a transition to controlled flight is foreseen and required. Where and how that transition should be implemented is not addressed in this work, since more benefit is attained when contemplating direct routing of aircraft(s) through FF in the uppermost airspace, so the feasibility for this airspace is a desirable result in itself.

4) PROTECTED ZONE: A conflict is defined in this work as an intrusion of a protected zone. The protected zone is defined using current ATC standards to be able to relate to existing traffic densities, even though studies have shown that the protected zone can be smaller. The protected zone must not be entered by any other aircraft. The task of the CD module is to predict an intrusion of the protected zone. This protected zone was chosen to reflect current ATC separation standards, which is 5 nautical mile radius and a height of 2000 feet ($-1000ft \leqslant altitude \leqslant +1000ft$). This means the ratio diameter to height is about 30 to 1.

The following section outlines the aircraft model & objective function formulation with its associated constraints.

## III. Multi Aircraft Model & Constraints Formulation

Consider $I$ aircraft flying within an area of interest, their continuous-time dynamics for level flight cruise is outlined in [9]. An aircraft in level flight can be modelled as a four state Point Mass Model (PMM). The states considered in this model are the following

- horizontal position $(X)$ and $(Y)$
- the true airspeed $(V)$
- flight path angle $(\psi)$

The control inputs considered for the model are the engine thrust $(T)$, and the bank angle $(\phi)$. Assuming a PMM, and that the applied forces acting on the aircraft will lead to the following equations of motion [9]:

$$\begin{bmatrix} \dot{X}_i \\ \dot{Y}_i \\ \dot{V}_i \\ \dot{\psi}_i \end{bmatrix} = \begin{bmatrix} V_i \cos(\psi_i) \\ V_i \sin(\psi_i) \\ \frac{-C_{D_i} S_i \rho}{2} \frac{V_i^2}{m_i} + \frac{1}{m_i} T_i \\ \frac{C_{L_i} S_i \rho V_i}{2m_i} \sin(\phi_i) \end{bmatrix} = f(t,x,u) \qquad (1)$$

for $i \in \Upsilon \triangleq \{1, ....., I\}$ and $S$ is the surface area of the wings, $\rho$ is the air density and $C_D$, $C_L$, are aerodynamic lift and drag coefficients. Since we are considering commercial aircraft, it is assume that the aircraft operates on a near trimmed flight conditions [9]. Eurocontrol's Base of Aircraft Database (BADA) [9] manual defines this as Total Energy Model (TEM) [9]. The TEM combines the rate of work done by all the forces that is affecting the aircraft to the rate of increase in its total energy (Potential and Kinetic).The aircraft motion has four states $(X, Y, V, \psi)$ and two inputs $(T_i, \phi_i)$. For a specific aircraft, the values of such bounds can be derived from the BADA database [9]. There are many models available in the literature when it involves predicting the current and future positions of an aircraft. For example in [8], an interpolating algorithm was developed to fit a vector field to the observed velocities at aircraft positions and at given sample times. Worst case techniques were used in [2] to estimate aircraft's position. Probabilistic modeling was covered and outlined in [1,3]. In this paper we are using a four state point mass model to estimate the aircraft's position.

### A. Velocity and acceleration constraints

Aerodynamics impose physical constraints on the minimum and maximum speeds an aircraft can fly at each altitude. In addition, passenger comfort and other factors impose constraints on the acceleration and the turning rate. These constraints can be expressed in the following form:

$$V_{max} \geqslant V_i(t) \geqslant V_{min} \qquad (2)$$

$$|\dot{V}_i(t)| \leqslant \delta V \qquad (3)$$

$$|\dot{\psi}_i(t)| \leqslant \delta\psi \qquad (4)$$

### B. Maneuvering constraints

Considering enroute traffic, the speed range of an aircraft is narrow. Passenger comfort is also taken into consideration which requires smooth trajectories, so in this case additional constraints are required for the maneuvers. The approach was proposed in [2], and was also used in [8] where constraints are imposed on speed changes that are bounded on a set around the current aircraft speed. The possible changes is the convex set of possible speed commands and can be described by a combination of quadratic and linear constraints as follows:

$$\|V_{0i} + \dot{V}_i\| \leq V_{max} \tag{5}$$

$$(V_{0i} + \dot{V}_i)^T \frac{V_{0i}}{\|V_{0i}\|} \geq V_{min} \tag{6}$$

Values of $V_{max}$ and $V_{min}$ can be obtained from the BADA database [15] but generally for most commercial aircraft cruising at high altitudes it can be approximated by:

$$\frac{V_{max} - V_{min}}{V_{max}} \leq 0.1 \tag{7}$$

### C. Conflict Avoidance Constraints & Overall Cost Function

Conflict avoidance constraints can be mathematically formalised in numerous ways. Many authors express collision avoidance constraints in terms of a given minimum miss distance, and it appears to be the most attractive option from a geometrical point of view, In this work, a time-based separation criterion is considered. All aircraft should remain separated at all times, by at least a minimum distance, which is set to $d_s = 5nm$ for cruising altitudes. This constraint can be described as follows:

$$\left\| [X_i, Y_i]^T - [X_j, Y_j]^T \right\|_2 \geqslant d_s \tag{8}$$

for all times $t > 0$ and for all aircraft pairs $i \neq j$ , where $(i, j) \in \Upsilon$. The constraint described by (8) is not convex and, in order to be able to handle it computationally, it requires tightening. One approach would be using the norm inequality $\|\bullet\|_2 \geq \|\bullet\|_\infty$ where $\|\bullet\|$ is the euclidean norm, then the so-called "*big-M*" technique (Refer to the formulation in [1]) can be used. This will ensure that at least one of the inequality constraints is active, and consequently that the two aircraft are separated by the required distance along at least one of the axes. The problem with this approach is that a model mismatch may be prevalent and there is a possibility that aircraft will encounter a situation where a solution satisfying both the dynamics and the separation constraints may no longer exist.

So, in this case an alternative separation constraint which was adopted in [8] is considered. For notational convenience, let's define $P_i = [X_i, Y_i]^T$, $P_j = [X_j, Y_j]^T$ which denotes the aircraft position and $P_{ij} = P_i - P_j$ is the relative position. $V_{ij} = V_i - V_j$ is the relative speed and $\dot{V}_{ij} = \dot{V}_i - \dot{V}_j$ is the relative velocity $P_{i,0}$ and $V_{i,0}$ are the initial position and initial speed of aircraft $i$ respectively. the constraint can be described as:

$$P_{0ij}^T (V_{0ij} + \dot{V}_{ij}) + \|V_{0ij} + \dot{V}_{ij}\| \sqrt{\|P_{0ij}\|^2 - d_s^2} \geq 0 \tag{9}$$

Non-convexity is also prevalent in the above formulation, so a new slack variable is introduced $\varphi_{ij}$ where $\|V_{0ij}\|^2 \geq \varphi_{ij}$ and $\varphi_{ij} \geq 0$ which leads to

$$P_{0ij}^T (V_{0ij} + \dot{V}_{ij}) + \varphi_{ij} \sqrt{\|P_{0ij}\|^2 - d_s^2} \geq 0 \tag{10}$$

It can be seen that the above constraints and cost function form a non-convex quadratic program of the form

$$\begin{array}{ll} \min & h^T P_0 h + 2\xi_0^T h + r_0 \\ s.t & h^T P_i h + 2\xi_i^T h + r_i \leq 0 \end{array} \tag{11}$$

Although the above quadratic program can be very difficult to solve in general, it has received a fair share of research attention. Approximate solutions can be obtained based on convex optimization. We also have $H = [\dot{V}_1, \dot{V}_2, ....., \dot{V}_n, \varphi_{12}, ......, \varphi_{(n-1),n}]^T$. If the optimal solution $H$ to the semi-definite relaxation has unit rank, then $\overline{h}$ is the solution. If not, then a form of randomization procedure must be applied. If we consider a gaussian distribution with mean $\overline{h}$ and $cov(H - \overline{h}\,\overline{h}^T)$ then samples can be chosen in accordance to the distribution. As outlined in [8] a linearisation procedure is required to pick the crossing pattern for each aircraft pair by computing the following

$$C_p = sgn(P_{0ij} \times (V_{0ij} + \dot{V}_{ij})) = \frac{P_{0ij} \times (V_{0ij} + \dot{V}_{ij})}{|P_{0ij} \times (V_{0ij} + \dot{V}_{ij})|} \tag{12}$$

If $C_p = 1$ the crossing pattern is then chosen to be counter-clockwise and clockwise if $C_p = -1$. We will assume that the crossing pattern is clockwise in the very unlikely case when $C = 0$. Subsequently, the corresponding convex optimization problem can be solved using barrier methods.

### D. Fuel Efficient Resolution Maneuvers

In this section, a formulation for fuel resolution maneuvers outlined in [10] is considered. The strategic encounter is concerned with minimizing the economics of a CR. Economics defined in this context by considering direct operating cost (DOC), which comprises of fuel and flight time costs involved in maneuvering to avoid a conflict. Only trajectory solutions that geometrically pass around the Protected Airspace Zone of an intruder aircraft is considered. In the FF context, it is assumed that the heading maneuver will consist of a series of standard vectoring heading, and speed changes. in such a way that straight line motion materialises in between heading, and speed. The DOC penalty function used incorporates both fuel and time elements. Included in the DOC are

1) The additional fuel required due to the increased drag and flight path distance traveled during a maneuver [10].
2) The additional operating costs due to the additional time required to execute the maneuver and return back to course [10].

$$DOC = C_{Fuel}\Delta W_{Fuel} + C_{Time}\Delta T \quad (13)$$

where $C_{Fuel}$ is the cost of fuel, $\Delta W_{Fuel}$ is the additional fuel used in the maneuver, $C_{Time}$ is the time dependent aircraft operating cost and $\Delta T$ is the additional time used in the maneuver. This DOC is investigated by [10], where $C_{Fuel} = £0.10/lb$ and $C_{Time} = £15.22/min$. Another issue that needs to be considered is the additional DOC incurred by neighbouring traffic that may be affected by CR maneuvers; however, it's not considered here. The fuel burn equation is:

$$\frac{dW}{dT} = T_R C_j \quad (14)$$

where $W$ is the weight, $C_j$ is the specific fuel consumption, and $T_R$ is the required thrust. The required thrust can be described as:

$$T_R = D + sin(\psi_{ss}) \quad (15)$$

where $D$ is the drag and $\psi_{ss}$ is the steady state flight path angle. The fuel consumption model varies linearly with airspeed. The lift coefficient $C_L$, is described in terms of the aircraft weight $W$ and speed $V$ as follows:

$$C_L = \frac{2Wcos(\psi_{ss})}{S_w V^2 \rho} \quad (16)$$

where $\rho$ is air density, and $S_w$ is the reference wing area. The drag is described as:

$$D = \frac{C_D V^2 \rho W S_w}{S_w V^2 \rho} \quad (17)$$

$C_D$ is the drag coefficient which is approximated by:

$$C_D = C_{D0} + K^2_{CL} \quad (18)$$

$C_{D0}$ is the zero lift drag coefficient, $K = \frac{1}{ARe\pi}$ is the induced drag factor, $e$ is Oswald's efficiency factor, and $AR$ is the wing aspect ratio. Furthermore, the thrust specific fuel consumption of a turbojet or turbofan engine increases nearly linearly with Mach number [10]. For this reason, the fuel consumption can be modeled as:

$$C_j = \sigma V \quad (19)$$

where $\sigma$ is the coefficient. Next, these endurance equations can be combined to obtain the fuel burn:

$$\frac{dW}{dT} = -\left[0.5\rho V^2 S_w (C_{D0} + K\left(\frac{2Wcos(\psi_{ss})}{\rho V^2 S_w}\right)^2 + \quad (20) \right.$$
$$\left. Wsin(\psi ss)\right]\sigma V$$

Equation (20) is integrated to calculate the fuel burn, given the geometry the previously defined heading maneuvers or speed control maneuvers. For the acceleration case, the equation is integrated numerically [10].

## IV. Trajectory redirection using neighboring optimal control (NOC)

Solving a nonlinear optimal control problem with a long horizon is generally computationally expensive, especially when FF concepts are considered, since there is limited computation power onboard an aircraft. If a nominal optimal solution is known, it is advantageous to approximate the optimal control solution when the parameters of the optimal control problem are slightly perturbed. The Neighbouring optimal control (NOC) method provides a first order approximation to the optimal solution corresponding to an initial state perturbed from the nominal value. When a disturbance significantly affect the forces on an aircraft, and modifies the flight path, redirecting the trajectory may recover the aircraft. Disturbances considered here may correspond to the wind or cross track errors, so in this case the nominal states and controls can be used to redirect the trajectory [11]. An off-line optimal trajectory is always assumed to be found from a feasible trajectory database. When a failure occurs, NOC is used to determine its neighbouring feasible trajectory on-line. If such a neighboring feasible trajectory exists, the aircraft may then be recovered from that failure in real time [11]. The formulation outlined in [11,4] is outlined in this section, and they are applicable to the formulation of FF concepts.

### A. Off-line trajectory optimization for the Shortest Path Evaluation

A shortest path problem can be used for the off-line optimal trajectory search. To find the shortest path, several algorithms can be used. In the free flight concept, Dijkstra's algorithm [5] is a reasonable choice since it guarantees to find an optimal path by repeatedly selecting a vertex with the minimum shortest-path estimate. The weight is defined by the mean value of the angle of attack of the aircraft. The reader is reffered to [5] for further information.

### B. On-line trajectory optimization using NOC

Based on the off-line optimal trajectory, a small perturbation is imposed on each state variable and new control can be obtained by NOC. The aircraft can be recovered from the disturbances. The NOC approach was outlined by Bryson and Ho (1975) [4], Consider the following nonlinear system

$$\dot{x}(t) = f(t, x, u), x(t_0) = x_0 \quad (21)$$

where $x(t)$ are the state variables and $u(t)$ control inputs and the cost function is defined as

$$\min \qquad J(u) = \phi(t_f, x_f, u_f) \quad (22)$$

s.t. Dynamical, Separation constraints, Velocity and acceleration constraints.

"$f$" denotes the final time. An assumption is made that the optimal solution $(x^*(t), u^*(t))$ can be determined, in which the optimal control is $u^*(t) = g(t, x^*(t), \lambda(t))$ under the following constraints

$$x_{min} \leq x^*(t) \leq x_{max} \ , \ u_{min} \leq u^*(t) \leq u_{max} \quad (23)$$

when small perturbations $\delta x(t_0)$ and small variations $\delta\lambda$ imposed on $x_0$ and $\lambda$, then the neighbouring feasible trajectory $z(t)$ and new optimal control $\nu(t)$ can be found by $\delta x(t_0, \delta\lambda)$ and $\dot{x}(t)$. In order to ensure that a neighbouring trajectory exists the following assumptions are made:

- **Assumption 1.** For the nonlinear system (22), $f(t, x, u)$ is continuous.
- **Assumption 2.** The open loop optimal solution $x^*(t)$ and optimal control $u^*(t)$ is well defined for system (22).

For a neighbouring feasible initial condition $z(t_0)$ which will be equal to $x_0$, there will be a neighbouring feasible trajectory $z(t)$ and neighbouring optimal control $\nu(t)$ and satisfies

$$\sup\|z(t) - x^*(t)\| \leq K \tag{24}$$

Where $K$ is an upperbound. And when system parameters varies from$\lambda_1$ to $\lambda_2$ and $\lambda_2 = \lambda_1 + \delta\lambda$ then the neighbouring feasible state trajectory $z(t)$ and neighbouring optimal control $\nu(t)$ is:

$$\nu(t) = u^*(t) + G(t)(Z(t) - X{*}(t)) \qquad or \tag{25}$$

$$\nu(t) = u^*(t) + G(t)\Delta X(t), \tag{26}$$

Where $Z(t) = [z(t), \lambda_2]^T$ , $X^*(t) = [x^*(t), \lambda_1]$, and $\Delta X(t)$ is a deviation vector of the new state vector $Z(t)$ from the open loop nominal state trajectory $X^*(t)$, $G(t)$ is the feedback gain matrix which is given by

$$G(t) = \delta U(t)\delta\overline{X}^{-1}(t) \tag{27}$$

Where $\delta U(t)$ are the control errors caused by the perturbation on the state vector $X(t)$ and $\delta\overline{X}(t)$ is a perturbation matrix in the initial states $x_{t_0}$ and initial system parameter $\lambda_1$. Since the control law can be put in the form of $u = g(t, x, \lambda)$ then system (22) becomes an unforced system $\dot{x} = \overline{f}(t, x, \lambda), x(t_0) = x_0$, under the above conditions the controller can satisfy the constraints in. In order to ensure that that initial value problem does exist then theorem 3.5 outlined in [6] proves that the conditions are satisfied then in this case perturbations can be imposed.

In the neighbourhood of $x^*$, the state vector $z$ can be defined as $z = x^* + \delta x$. It was mentioned above that the parameters changed from $\lambda_1$ to $\lambda_2$ and $\lambda_2 = \lambda_1 + \delta\lambda$. Carrying out a Taylor series expansion for $\nu^*$ is the following

$$\nu^* = g(t, z, \lambda_2) = g(t, x^* + \delta x, \lambda_1 + \delta\lambda) \tag{28}$$

$$= g(t, x^*, \lambda_1) + \frac{\partial g}{\partial x}\partial x + \frac{\partial g}{\partial \lambda}\partial\lambda + H.O.T \tag{29}$$

$$= u^* + \frac{\partial g}{\partial x}(z - x^*) + \frac{\partial g}{\partial \lambda}(\lambda_2 - \lambda_1) + H.O.T \tag{30}$$

$$= u^* + \begin{bmatrix} \frac{\partial g}{\partial x} & \frac{\partial g}{\partial \lambda} \end{bmatrix} \left( \begin{bmatrix} z \\ \lambda_2 \end{bmatrix} - \begin{bmatrix} x^* \\ \lambda_1 \end{bmatrix} \right) + H.O.T \tag{31}$$

H.O.T denotes higher order terms. If the perturbation $\delta x$ is small enough or $z$ is in the neighbourhood of $x^*$ then the higher order terms of $\delta x$ and $\delta y$ must be small as well. Therefore the higher order terms can be neglected at this point. The new controller now is $\nu = u^* + G(Z - X^*)$, where $Z \in \mathbb{R}^{m\times(n+p)}$ and $X^* \in \mathbb{R}^{n+p}$. If closed loop system was to be considered, the perturbations $\delta x$ and $\delta\lambda$ will be the measured deviations, in this case the gain matrix is defined by:

$$G = \begin{bmatrix} \frac{\partial g}{\partial x} & \frac{\partial g}{\partial \lambda} \end{bmatrix} = \frac{\partial g}{\partial X} \in \mathbb{R}^{m\times(n+p)} \tag{32}$$

The gain matrix $G$ can be calculated numerically at every time $t \in [t_0, t_f]$. The reason for this being is that no partial derivatives will be evaluated. Now from the $u = g(t, x, \lambda)$ and $X = [x^T, \lambda^T]^T$, the differential of $u$ is $du = \frac{\partial g}{\partial X}dX + \frac{\partial g}{\partial t}dt$. For a known perturbation, the perturbation vectors are $\delta X = X_{perturbed} - X^*$ and $\delta u = u_{perturbed} - u^*$. If a linear approximation is used and also noting that $\delta t = 0$ for all $t \in [t_0, t_f]$, $\delta u$ can be obtained by

$$\delta u = \frac{\partial g}{\partial X}\delta X + \frac{\partial g}{\partial t}\delta t = G\delta X \tag{33}$$

Next an $(n + p) \times (n + p)$ square matrix is constructed for $\delta\overline{X}$, and another for $\delta U$ which is an $m \times (n + p)$:

$$\delta\overline{X} = [\delta X^1 .........\delta X^{n+p}] \in \mathbb{R}^{(n+p)\times(n+p)} \tag{34}$$

$$\delta U = [\delta u^1 .........\delta u^{n+p}] \in \mathbb{R}^{m\times(n+p)} \tag{35}$$

Where $\delta X^i$, $i = 1, 2, ....., n + p$ and $\delta u^i$, $i = 1, 2, ....., n + p$ are the $ith$ perturbation of $\delta X$ and $\delta u$ then equation () can be expressed by the following:

$$\delta U = G\delta\overline{X} \tag{36}$$

If the perturbations are chosen to be linearly independent and at the same time small enough, then $\delta\overline{X}$ can be guaranteed to be invertible at every instance of time.

## V. NOC Application to the Aircraft trajectory retargeting under conflict

It was shown above that a neighbouring feasible trajectory exists when applying NOC to an aircraft [11,4]. Since we have four states $(X, Y, V, \psi)$ and two control variables $(T, \phi)$. If $C_L$ and $C_D$ are the parameters that vary then a neighbouring solution exists. As mentioned above that a nominal optimal solution exists using Dijikstra's algorithm [5] then a new controller is calculated $\Psi^*$ then the perturbed controller is calculated as $\Psi_{perturbed} = \Psi^* + G(Z - X^*)$. Since it is required to enforce the aircraft to meet a final time, then the state $X$ is chosen as an independent variable. So five perturbations are used which are $V, \psi, Y, C_L, C_D$. Define $\delta\overline{X} = [V^1 - V^* - \psi^1 - \psi^* x^1 - x^* C_{L1}^1 - C_{L1}^* C_{D1}^1 - C_{D1}^*]^T$............$[V^5 - V^*, \psi^5 - \psi^* x^5 - x^* C_{L1}^5 - C_{L1}^* C_{D1}^5 - C_{D1}^*]^T$ and $\delta\alpha = [\Psi^1 - \Psi^*, ...., \Psi^5 - \Psi^*]^T$ and $n = 1, ..., 5$ which is the perturbation instances for each state and parameter. Then the gain matrix can be evaluated as $G = \delta\Psi\delta\overline{X}^{-1}$. The algorithm can be summarised below:

**Algorithm** Free Flight Concept Exploiting NOC

```
Require: $P_{i0}(t)$ and $P_i(t)$ for all $i \in 1, ..., I$
Require: $T_i$ and $\phi_i$ for the nominal shortest path
While $\exists i \; P_{0ij}^T(V_{0ij} + \dot{V}_{ij}) + \|V_{0ij} + \dot{V}_{ij}\| \sqrt{\|P_{0ij}\|^2 - d_s^2} \geq 0$ do
    Solve the Optimisation problem (11)
    Compute the matrix Gain $\delta\overline{X}$ and $\delta U$ from (34),(35)
    Compute the matrix Gain $G(t)$ from (36)
    Measure new aircraft position $p_i(t)$
End While
```

## VI. Simulation

A conflict situation with five aircraft are initially located on a circle of 400 km radius and are heading to mid air collision. Without any corrective action, all aircraft would collide at the center. Although unrealistic, this scenario allowed us to test the effectiveness of our method. All conflict constraints are enforced, and fuel consumption maneuvers are computed.

In order to differentiate between the nominal solution and the perturbed on,the results are shown as a box-and-whisker diagram in Figure 1 & 2. Qualitatively, both solutions are very similar, except for the fuel consumption of the aircraft which is outlined in Fig. 2, as the average fuel consumption in the perturbed case is lower than the nominal case which is an excellent demonstration of the ability of NOC to achieve near-optimal results without resorting the need to recompute the optimal solution. On the other hand, in both the nominal and perturbed case one conflict occurred which was not detected but resolved by the algorithm. However, there is a clear disadvantage that introducing any additional constraint in this formulation may impose restrictions when implementation issues are considered since computational times becomes higher, and intractability is also apparent sometimes in the simplest of optimisation problems. While the fuel savings is not very significant, the important point is that a near-optimal conflict resolution that maintains separation has been performed without increasing fuel use.

## VII. Conclusion

A Free Flight formulation was presented to deal with conflict detection and resolution. A point mass model for aircraft dynamics was used that allowed a quadratic program formulation for the problem. A new approach based on neighbouring Optimal Control (NOC) that can deliver an aircraft to its designated position safely when faced with conflicts and uncertainties was outlined. A simulation example was provided that illustrated the effectiveness of our approach. The benefits of the algorithm are that it reduces fuel consumption, and it achieves optimal safe inter-aircraft separation while maintaining near-optimality under disturbances. Ongoing research focuses on combining this algorithm with complexity metrics that defines the level of disorder are being explored.

*Abstract*—**This paper presents an alternative approach of designing a guidance controller for a small Unmanned Aerial Vehicle (UAV) to achieve path following in the presence of wind disturbances. The wind effects acting on the UAV are estimated by a nonlinear disturbance observer. Then the wind information is incorporated into the nominal path following controller to formulate a composite controller so as to compensate wind influences. The globally asymptotic stability of the composite controller is illustrated through theoretical analysis and its performance is evaluated by various simulations including the software-in-the-loop. Initial flight tests using a small aircraft are carried out to demonstrate its actual performance.**

## I. Introduction

The application of Unmanned Aerial Vehicles (UAVs) has been found in various areas not limited to military operations, but also in civil areas such as aerial photography and precision agriculture. Most of the UAV operations essentially are composed of commanding UAVs to fly through a series of spatial locations or paths either with or without a temporal requirement. This requirement categories flight patterns into two types, namely the trajectory tracking and path following [1]. The former suggests that the UAV needs to be in a particular position at a prespecified time, whereas the latter requires the UAV to converge to a geometric path with any feasible speed profile. In this paper, the path following problem is considered because it is less likely to push UAVs to their performance limits [2]. Moreover, with the influences of wind disturbance the trajectory tracking ability of an UAV can be easily compromised, which leaves the path following as an effective way to execute a task.

Path following as one of the motion control problems has been extensively studied especially for wheeled robots. In the field of UAV application, although vehicle dynamics are more complicated, the most recent micro aircraft are equipped with autopilots that provide the inner-loop stabilisation. For example, the UAV used in this study is installed with an Ardupilot autopilot which implements three PID controllers to achieve altitude-hold and airspeed-hold using elevator and throttle and the coordinated turn using aileron and rudder, which endows the UAV the ability to track the heading rate demand from the guidance controller. This means that the out-loop behaviour of the UAV in level flight can be abstracted at a kinematic level by using a unicycle model. To this end, this paper adopts a path following method stemmed from wheeled robots [3], which has since been extended to 3-D case for UAV applications [4]. But the main purpose of this study is to improve path following accuracy under wind conditions.

In terms of the micro fixed-wing aircraft considered in this paper, their light structure and limited power allows wind disturbances to have a strong effect on them. A common strategy to eliminate the influence of wind on path following is to overlook the airspeed of an UAV and focus on the its ground track [5], [6]. In this case, the ground velocity and flight course are required in the feedback signals. This information can be calculated from GPS position by differentiation or more elaborately can be provided by an onboard inertial navigation system (INS). However, for a micro UAV equipped with a low-cost sensor suit, these flight data may be not of good quality, whereas the fast dynamics of small vehicles are highly susceptible to the low rate and delay of the GPS feedback signal. It is therefore more convenient to use the smooth airspeed measurement, magnetic heading and original GPS position data to realise the guidance function.

Another approach to solve wind effects on an UAV is to explicitly take them into account in path planning or control algorithms [7]–[9]. The knowledge of wind conditions is therefore required in such applications. Following on this direction, this paper adopts an alternative approach that exploits the use of a nonlinear disturbance observer [10]. The disturbance observer is designed to provide the estimates of external wind, which are then incorporated into the nominal path following controller. This results in a composite controller for UAV path following. Note that the wind disturbances are assumed to be near constant in the analysis because only these components cause a steady state error. However, the ability of estimating the varying wind are also demonstrated in the simulation section. In addition, the disturbance observer can provide estimates of disturbances other than wind gust such as aircraft trimming errors, which cause the system to behave differently from the nominal model [11].

The composite controller comprising the disturbance observer and the nonlinear guidance law is shown to be globally asymptotically stable by using the control theory on cascaded systems [12]. This suggests that the proposed control system can guarantee the path following accuracy in spite of wind disturbances. The performance of the proposed controller is demonstrated in the simulations as well as in real flight experiments using our newly developed flight test platform.

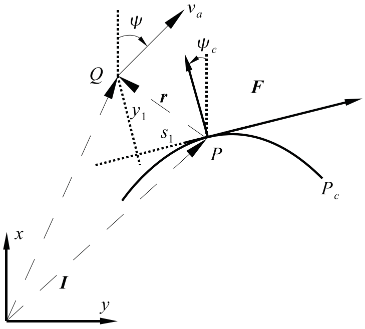

Fig. 1. Frame configuration

## II. Problem formulation

The problem considered in this paper is the accurate path following for UAVs in the presence of wind. The objective of path following is to guide the UAV to converge to a desired geometric path described by some parameters, e.g. the path length. When wind disturbances are introduced to the system, necessary actions need to be taken to prevent their effects on the path following performance.

The kinematics of a fixed-wing UAV can be described using the following unicycle model under the assumptions that the UAV is in level flight with a near constant air speed:

$$\begin{aligned} \dot{x} &= v_a\cos(\psi) + w_x \\ \dot{y} &= v_a\sin(\psi) + w_y \\ \dot{\psi} &= \omega \end{aligned} \tag{1}$$

where $(x, y)$ is the position of the UAV in the inertial frame $\mathcal{I}$, $\psi$ is the UAV heading angle, $v_a$ is the airspeed, $(w_x, w_y)$ is the velocity of the wind disturbance in $x$ and $y$ directions, respectively, and $\omega$ is the heading rate. By constructing a control input $\omega$, the position output should be able to follow a prescribed path $P_c(s) = [\ x_c(s) \quad y_c(s)\ ]^T$, which is a spatial curve and parameterised by its length $s$.

The path following function can be achieved by controlling the UAV to follow a virtual target running along the target path [3], [4]. To this end, it is natural to present the generalised error between the UAV and the virtual target in a moving frame attached to this virtual target. In the inertial frame $\mathcal{I}$, let $Q$ be the UAV position and $P$ denote the point on the path $P_c(s)$ to be followed, i.e. the virtual target. A Serret-Frenet frame $\mathcal{F}$ can be established on the point $P$ as shown in Fig.1, where the signed curvilinear abscissa is the path length $s$. Then, the UAV position $Q$ can be expressed in the frame $\mathcal{I}$ as a vector $\boldsymbol{q} = [\ x \quad y\ ]^T$ and in the frame $\mathcal{F}$ as a vector $\boldsymbol{r} = [\ s_1 \quad y_1\ ]^T$. Note that $\boldsymbol{r} = \boldsymbol{q} - \boldsymbol{p}$ is also the error vector, where $\boldsymbol{p}$ denotes the position vector of $P$ in $\mathcal{I}$.

To minimise the error vector $\boldsymbol{r}$, its dynamics in frame $\mathcal{F}$ need to be investigated. First, by defining the heading rate of the desired path $\dot{\psi}_c = \omega_c$, we have the following relations:

$$\begin{aligned} \dot{\psi}_c &= \omega_c = c_c(s)\dot{s} \\ \dot{c}_c(s) &= g_c(s)\dot{s} \end{aligned} \tag{2}$$

where $c_c(s)$ and $g_c(s) = \frac{dc_c(s)}{ds}$ are the path curvature and its derivative, respectively. Next, the velocity of $P$ in $\mathcal{I}$ can be expressed in frame $\mathcal{F}$, such that:

$$\left(\frac{d\boldsymbol{p}}{dt}\right)_F = \begin{bmatrix}\dot{s} & 0\end{bmatrix}^T \tag{3}$$

For the position $\boldsymbol{q}$ of the UAV, its inertial velocity can be expressed in a moving frame such that:

$$\left(\frac{d\boldsymbol{q}}{dt}\right)_I = \left(\frac{d\boldsymbol{p}}{dt}\right)_I + R_F^I\left(\frac{d\boldsymbol{r}}{dt}\right)_F + R_F^I(\omega_c \times \boldsymbol{r}) \tag{4}$$

where × denotes the vector cross-product and $R_F^I$ is the rotation matrix from frame $\mathcal{F}$ to $\mathcal{I}$. Left multiplying its inverse $R_I^F$ on both side of (4) yields

$$R_I^F\left(\frac{d\boldsymbol{q}}{dt}\right)_I = \left(\frac{d\boldsymbol{p}}{dt}\right)_F + \left(\frac{d\boldsymbol{r}}{dt}\right)_F + \omega_c \times \boldsymbol{r} \tag{5}$$

Using the relations

$$\begin{aligned} \left(\frac{d\boldsymbol{q}}{dt}\right)_I &= \begin{bmatrix}\dot{x} & \dot{y}\end{bmatrix}^T \\ \left(\frac{d\boldsymbol{r}}{dt}\right)_F &= \begin{bmatrix}\dot{s}_1 & \dot{y}_1\end{bmatrix}^T \end{aligned} \tag{6}$$

and the expansion of $\omega_c \times \boldsymbol{r}$, (5) can be rewritten as

$$R_I^F\begin{bmatrix}\dot{x} \\ \dot{y}\end{bmatrix} = \begin{bmatrix}\dot{s}(1 - c_c(s)y_1) + \dot{s}_1 \\ \dot{y}_1 + c_c(s)\dot{s}s_1\end{bmatrix} \tag{7}$$

Solving (7) for $\dot{s}_1$ and $\dot{y}_1$ and combining (1) yields the dynamics of the path following error in the frame $\mathcal{F}$ at the kinematics level:

$$\begin{aligned} \dot{s}_1 &= -\dot{s}(1 - c_c y_1) + v_a\cos(\psi_e) + w_{f_x} \\ \dot{y}_1 &= -c_c\dot{s}s_1 + v_a\sin(\psi_e) + w_{f_y} \\ \dot{\psi}_e &= \omega - c_c\dot{s} \end{aligned} \tag{8}$$

where $\psi_e = \psi - \psi_c$ is the heading error,

$$\begin{aligned} w_{f_x} &= \cos\psi_c w_x + \sin\psi_c w_y \\ w_{f_y} &= -\sin\psi_c w_x + \cos\psi_c w_y \end{aligned} \tag{9}$$

are wind disturbances expressed in the frame $\mathcal{F}$, respectively. The designed path following controller needs to regulate this system to eliminate the state error under the wind disturbances.

It is intuitive to work out that if the wind elements are known, the aircraft can fly into wind with certain trim angle so that the projection of forward speed normal to the track can be used to cancel the wind effect. This basic idea provides the guideline for the designing our path following controller.

## III. Disturbance observer based control

To obtain the estimates of wind disturbances, a nonlinear disturbance observer is first designed. This information is then incorporated into controller design. This design methodology is known as the disturbance observer based control (DOBC) [10].

### A. Disturbance observer design

The UAV kinematic model (1) can be cast into a compact mode:

$$\dot{\boldsymbol{x}} = f(\boldsymbol{x}) + g_1(\boldsymbol{x})\boldsymbol{u} + g_2(\boldsymbol{x})\boldsymbol{d} \tag{10}$$

where state $\boldsymbol{x} = [\ x \quad y \quad \psi\ ]^T$, control input $\boldsymbol{u} = \omega$ and disturbance $\boldsymbol{d} = [\ w_x \quad w_y\ ]^T$. The system functions $f(\boldsymbol{x})$, $g_1(\boldsymbol{x})$ and $g_2(\boldsymbol{x})$ are derived from (1), such that:

$$f(\boldsymbol{x}) = \begin{bmatrix} v_a \sin\psi \\ v_a \cos\psi \\ 0 \end{bmatrix}, \quad g_1(\boldsymbol{x}) = \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix}, \quad g_2(\boldsymbol{x}) = \begin{bmatrix} 1 & 0 \\ 0 & 1 \\ 0 & 0 \end{bmatrix} \tag{11}$$

A disturbance observer is adopted to estimate $w_x$ and $w_y$ under the assumption that they are near constant, i.e. $\dot{w}_x \approx 0$ and $\dot{w}_y \approx 0$. The disturbance observer follows the standard design [10]:

$$\begin{aligned} \hat{\boldsymbol{d}} &= \boldsymbol{z} + p(\boldsymbol{x}) \\ \dot{\boldsymbol{z}} &= -l(\boldsymbol{x})g_2(\boldsymbol{x})\boldsymbol{z} - l(\boldsymbol{x})(g_2(\boldsymbol{x})p(\boldsymbol{x}) + f(\boldsymbol{x}) + g_1(\boldsymbol{x})\boldsymbol{u}) \end{aligned} \tag{12}$$

where $\hat{\boldsymbol{d}} = [\ \hat{w}_x \quad \hat{w}_y\ ]^T$ is the estimate of wind disturbance, $\boldsymbol{z}$ is the internal state of the nonlinear observer, $p(\boldsymbol{x})$ is a nonlinear function to be designed, and $l(\boldsymbol{x})$ is the nonlinear observer gain given by

$$l(\boldsymbol{x}) = \frac{\partial p(\boldsymbol{x})}{\partial \boldsymbol{x}} \tag{13}$$

The estimation error in the above observer is defined as $\boldsymbol{e}_d = \boldsymbol{d} - \hat{\boldsymbol{d}} = [\ e_x \quad e_y\ ]^T$. Under the assumption that the disturbance is slowly varying compared to the observer dynamics and by combining (12)-(13) and the system function (10), it can be shown that the estimation error has the following property:

$$\dot{\boldsymbol{e}}_d = \dot{\boldsymbol{d}} - \dot{\hat{\boldsymbol{d}}} = -\dot{\boldsymbol{z}} - \frac{\partial p(\boldsymbol{x})}{\partial \boldsymbol{x}}\dot{\boldsymbol{x}} = -l(\boldsymbol{x})g_2(\boldsymbol{x})\boldsymbol{e}_d \tag{14}$$

Therefore, the observer design problem is converted to chose an appropriate observer gain $l(\boldsymbol{x})$ such that (14) is globally exponentially stable regardless of state $\boldsymbol{x}$.

In this paper, since the function $g_2$ is a constant matrix, the observer gain can be simply chosen as

$$l(\boldsymbol{x}) = \begin{bmatrix} l_x & 0 & 0 \\ 0 & l_y & 0 \end{bmatrix} \tag{15}$$

where $l_x$ and $l_y$ are positive constants to be tuned. Correspondingly, the nonlinear function $p(\boldsymbol{x})$ can be calculated by integrating $l(\boldsymbol{x})$ with respect to $\boldsymbol{x}$ based on (13).

### B. Control synthesis

After the wind estimates are obtained, the next step is to design a path following controller that regulates the error system (8) to its origin. According to the design guideline, the UAV can fly into wind with a trimming angle $\psi_0$ so that the side component of the forward velocity neutralises the wind component that drives the UAV away from the desired path.

Given that the wind estimates are available, the estimated trimming angle can be written as $\psi_{\hat{0}} = -\sin^{-1}\frac{\hat{w}_{f_y}}{v_a}$. Furthermore, the error dynamics (8) can be reformulated to facilitate the control design:

$$\begin{aligned} \dot{s}_1 &= -\dot{s}(1 - c_c y_1) + v_a\cos(\psi_{\hat{w}} + \psi_{\hat{0}}) + \hat{w}_{f_x} + e_{f_x} \\ \dot{y}_1 &= -c_c\dot{s}s_1 + v_a\sin(\psi_{\hat{w}} + \psi_{\hat{0}}) + \hat{w}_{f_y} + e_{f_y} \\ \dot{\psi}_{\hat{w}} &= \omega - c_c\dot{s} - \dot{\psi}_{\hat{0}} \end{aligned} \tag{16}$$

where $\psi_{\hat{w}} = \psi_e - \psi_{\hat{0}}$, $\hat{w}_{f_x}$ and $\hat{w}_{f_y}$ are calculated from (9) after $\hat{w}_x$ and $\hat{w}_y$ are estimated in (12), such that $\hat{w}_{f_x} + e_{f_x} = w_{f_x}$, $\hat{w}_{f_y} + e_{f_y} = w_{f_y}$. Carrying out the differentiation of $\psi_{\hat{0}}$ with respect to time gives:

$$\begin{aligned} \dot{\psi}_{\hat{0}} =& \frac{1}{\sqrt{v_a^2 - \hat{w}_{f_y}^2}} \underbrace{(\cos\psi_c\hat{w}_x + \sin\psi_c\hat{w}_y)}_{\hat{w}_{f_x}} c_c\dot{s} + \\ & \frac{1}{\sqrt{v_a^2 - \hat{w}_{f_y}^2}}(\sin\psi_c l_x e_x - \cos\psi_c l_y e_y) \end{aligned} \tag{17}$$

where the relations $\dot{\hat{w}}_* = \dot{w}_* - \dot{e}_* = -\dot{e}_*$ and $\dot{e}_* = -l_* e_*$ are used while '$*$' denoting $x$ and $y$. Moreover, one can define $\dot{\psi}_{\hat{0}} = \dot{\psi}_{\tilde{0}} + e_\psi$, where

$$\dot{\psi}_{\tilde{0}} = \frac{\hat{w}_{f_x}}{\sqrt{v_a^2 - \hat{w}_{f_y}^2}} c_c\dot{s} \tag{18}$$

and

$$e_\psi = \dot{\psi}_{\hat{0}} - \dot{\psi}_{\tilde{0}} = \frac{\sin\psi_c l_x e_x - \cos\psi_c l_y e_y}{\sqrt{v_a^2 - \hat{w}_{f_y}^2}} \tag{19}$$

At this stage, the problem of path following in the presence of wind can be solved by driving the states of system (16) to zero. This objective can be embodied in the Lyapunov function candidate:

$$V = \frac{1}{2}k_1 s_1^2 + \frac{1}{2}k_1 y_1^2 + \frac{1}{2}\psi_{\hat{w}}^2 \tag{20}$$

Its derivative can be calculated by invoking (16)-(19) as:

$$\begin{aligned} \dot{V} =& -k_1 s_1(\dot{s} - v_a cos\psi_e - \hat{w}_{f_x} - e_{f_x}) \\ & + k_1 y_1(v_a\sin\psi_e + \hat{w}_{f_y} + e_{f_y}) \\ & + \psi_{\hat{w}}(\omega - c_c\dot{s} - \dot{\psi}_{\tilde{0}} - e_\psi) \end{aligned} \tag{21}$$

where $k_1$ is a positive constant. In the observation of (21), a nonlinear control law is proposed for path following in conjunction with the disturbance observer (12):

$$\begin{aligned} \dot{s} &= k_2 s_1 + v_a\cos\psi_e + \hat{w}_{f_x} \\ \omega &= -k_3\psi_{\hat{w}} - k_1 y_1\frac{v_a\sin\psi_e + \hat{w}_{f_y}}{\psi_{\hat{w}}} + c_c(s)\dot{s} + \dot{\psi}_{\tilde{0}} \end{aligned} \tag{22}$$

where $k_2$ and $k_3$, together with $k_1$ are positive parameters to be tuned in the controller. It also can be shown that:

$$\lim_{\psi_{\hat{w}} \to 0} \frac{v_a\sin\psi_e + \hat{w}_{f_y}}{\psi_{\hat{w}}} = v_a\cos\left(\frac{\psi_e + \psi_{\hat{0}}}{2}\right) \tag{23}$$

The closed-loop stability under the composite controller needs to be investigated. In the following, we will first show the stability with no estimation error, and the stability with the disturbance observer.

*Proposition 1:* Given the estimation error $\boldsymbol{e}_d = 0$, i.e. the exact wind knowledge is available, the time-varying system (16) under the control of (22) is globally asymptotically stable.

*Proof:* Consider the Lyapunov function candidate (20). Substituting (22) into its time derivative (21) and using the assumption that $\boldsymbol{e}_d = 0$ gives:

$$\dot{V} = -k_1 k_2 s_1^2 - k_3 \psi_{\hat{w}}^2 \le 0 \tag{24}$$

Thus, $V$ is non-increasing, and this implies the states $s_1$, $y_1$ and $\psi_{\hat{w}}$ are bounded and $V$ converges to some limited value. According to Barbalat's Lemma, $\dot{V}$ converges to zero since it is uniformly continuous. From the observation of (24), $s_1$ and $\psi_{\hat{w}}$ asymptotically converge to zero.

Furthermore, by inserting the control law (22) into the system (16), it can be found that

$$\dot{\psi}_{\hat{w}} = -k_3 \psi_{\hat{w}} - k_1 y_1 \frac{v_a \sin \psi_e + \hat{w}_{f_y}}{\psi_{\hat{w}}} \tag{25}$$

As $\psi_{\hat{w}}$ approaches zero, $\dot{\psi}_{\hat{w}}$ also tends to zeros according to Barbalat's lemma. Because $\frac{v_a \sin \psi_e + \hat{w}_{f_y}}{\psi_{\hat{w}}} \neq 0$, $y_1$ is shown to converge to zero. ■

However, in practice the exact wind information is unknown, and its estimates are provided by the disturbance observer. Although the estimation error converges to zero regardless of the system states, the transit period still needs to be investigated. Thus, the stability of the overall system needs to take into account the observer dynamics. Such a system can be considered as a cascaded time-varying system:

$$\dot{\boldsymbol{x}}_1 = f_1(t, \boldsymbol{x}_1) + h(t, \boldsymbol{x}_1, \boldsymbol{x}_2)\boldsymbol{x}_2 \tag{26a}$$

$$\dot{\boldsymbol{x}}_2 = f_2(t, \boldsymbol{x}_2) \tag{26b}$$

where $\boldsymbol{x}_1 = [\begin{array}{ccc} s_1 & y_1 & \psi_{\hat{w}} \end{array}]^T$ and $\boldsymbol{x}_2 = [\begin{array}{cc} e_x & e_y \end{array}]^T$. The upper system corresponds to the system (16) and the lower system is (14), where function $f_1$ and $f_2$ represent the corresponding terms in these equations, respectively. The function $h(t, \boldsymbol{x}_1, \boldsymbol{x}_2)$ can be explicitly written as

$$h(t, \boldsymbol{x}_1, \boldsymbol{x}_2) = \begin{bmatrix} \cos \psi_c & \sin \psi_c \\ -\sin \psi_c & \cos \psi_c \\ \frac{-\sin \psi_c l_x}{\sqrt{v_a^2 - \hat{w}_{f_y}^2}} & \frac{\cos \psi_c l_y}{\sqrt{v_a^2 - \hat{w}_{f_y}^2}} \end{bmatrix} \tag{27}$$

This cascaded system can be examined by using the Theorems in [12], from which the following lemma can be drawn:

*Lemma 2:* [12] Consider the cascaded system (26). Assume that the upper system is globally uniformly asymptotically stable with a Lyapunov function of the form $V(t, \boldsymbol{x}) = k \|\boldsymbol{x}\|^p$, for all $k > 0$ and $p > 1$, whose derivative only needs to be negative-semi-definite and the lower system is global exponentially stable. If the function $h(t, \boldsymbol{x}_1, \boldsymbol{x}_2)$ satisfies

$$\|h(t, \boldsymbol{x}_1, \boldsymbol{x}_2)\| \le \theta_1(\|\boldsymbol{x}_2\|) + \theta_2(\|\boldsymbol{x}_2\|)\|\boldsymbol{x}_1\| \tag{28}$$

where $\theta_1$ and $\theta_2$ are continuous, then the cascaded system is globally uniformly asymptotically stable.

*Theorem 3:* Assume the wind disturbances are bounded and smaller than the airspeed $v_a > 0$, the error dynamics (16) of the path following problem is globally uniformly asymptotically stable under the control of the composite control law (22) and (12).

*Proof:* The proof follows the Lemma 2 to verify all the assumptions in it. First, from Proposition 1, the upper system is globally uniformly asymptotically stable and the Lyapunov function (20) satisfies the related assumptions. Then, the lower system is exponentially stable by choosing the observer gain according to (15). At last, the function $\|h(t, \boldsymbol{x}_1, \boldsymbol{x}_2)\| \le (2 + \frac{l_x^2 + l_y^2}{v_a})^{\frac{1}{2}}$ from its definition. ■

## IV. Simulations and Experiments

### A. Simulation results

The proposed path following controller based on the disturbance observer was first verified in simulation. A comparison test is presented here to compare it with the nominal controller without wind correction and two PID-like controllers based on the cross-track error [13] and the cross-track angle [14], respectively. In this test, the desired path is composed of line segments connecting four waypoints. The UAV was flying at a low airspeed of 5m/s with the wind condition $w_x = 1.5$m/s and $w_y = 2$m/s, and the yaw rate is saturated at 0.5rad/s.

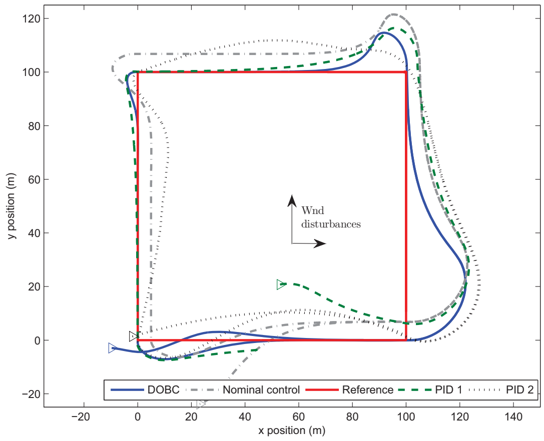

Fig. 2. Simulation Results

The simulation results are given in Fig.2. It can be seen that the proposed controller outperforms the others in terms of the path following accuracy, although the wind speed is 50% of the airspeed. The nominal controller without wind correction is able to follow the path but with steady state error due to the wind. The first PID controller based on the cross-track error can provide a competitive result but it suffers practical issues because noisy feedback signals [13]. The second PID control is based on the cross-track angle so that it aims at the next waypoint and converges to the path slowly. Note that all the controllers exhibit large converging errors at the lower right corner. This is because that the UAV heading deviated towards negative $y$ direction before the corner and need to fly into wind towards negative $x$ direction after the corner, so that a large heading change is experienced during the turning.

### B. Software-in-the-loop test

Before applying this new algorithm on the real UAV, more realistic tests need to be carried out to further evaluate its performance and minimise the risk in flight experiment. The software-in-the-loop (SIL) test is therefore performed to bridge up the gap between the numerical simulation and the practical experiment.

The structure of the SIL used in this study is shown in Fig 3. The test environment comprises three main components, namely the proposed algorithm to be tested, the Ardupilot code for the inner-loop stabilisation and the UAV dynamic model with a flight environment. The path following controller is implemented in the Simulink environment so that it can be easily debugged and tuned during the test. The Ardupilot is a commercial-of-the-shelf autopilot for inner-loop control of the UAV dynamics. It is also an open source project with the onboard code available in C/C++. Hence, its function can be simulated by recompiling its source code on a virtual machine based on a standard PC. On the other hand, although it does not belong to a flight control function to be designed, the UAV dynamic model plays an important role in the SIL test, since it needs to replicate the behaviour of the real aircraft in a software environment. To this end, the X-Plane software is adopted due to its ability to simulate realistic aircraft models and flight environment like wind conditions. The three components are connected and synchronised through the TCP/IP network connection and the flight data are transferred using a dedicated protocol.

X-Plane

Fig. 3. Software-in-the-loop configuration

In the SIL simulation, an aircraft model with a similar dimension and power of the test UAV, which has a high fidelity of dynamics, was adopted in the X-Plane environment as the plant. The control gains in Ardupilot were then tuned to provide stabilisation for this aircraft. To mimic wind disturbances in reality, the weather condition in X-Plane was set up such that the wind was 6m/s towards north with the variances of ±2m/s on the speed and ±20deg on the direction.

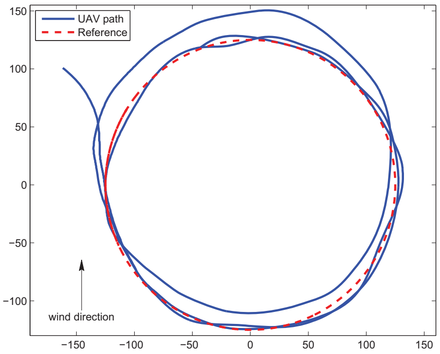

Fig. 4. SIL simulation result

One of the simulation results is presented in Fig.4. The UAV was required to follow a circle path at the airspeed of 15m/s, where the first circle was flown by the nominal control, then DOBC was switched on. It can be seen that the nominal control exhibits steady state error, whereas the proposed DOBC is able to provide accurate path following in spite of the varying wind disturbances. In addition to evaluate the performance of the proposed algorithm, the SIL simulation also verifies the integration of the high-level algorithm and the inner-loop autopilot control. This process helps to find out the potential software faults and mitigates the risk of applying the new algorithm on real UAV platform.

### C. Flight experiment

After the proposed algorithm has been tested thoroughly in simulations, it can be applied on the test UAV equipped with the Ardupilot hardware. In the flight experiment the proposed algorithm is located on a ground station and is implemented in Simulink with a sampling rate of 30Hz. The ground station is equipped with the ZigBee communication module connecting to the Ardupilot, so that the real-time fight data can be transferred back to ground station and control commands can be sent to Ardupilot. The flight experiment configuration is shown in Fig.5

Initial fight tests have been conducted with some promising results. Flight test results of using the nominal control and the DOBC are given in Fig.6 and 7, respectively, which are collected from the same test flight. The wind conditions during testing were southerly at approximately 5m/s, whose influence can be observed from Fig.6. In the flight test the DOBC was turned on after 100s, and its performance can be seen from Fig.7 where the path following accuracy was massively improved. However, there also shows oscillations on the path when the UAV flew into wind. This is because the light airframe and limited power of the test UAV and it can be alleviated by further tuning the inner-loop controller in the future flight test.

## V. Summary

This paper describes a disturbance observer based design of a path following controller for small UAVs in the presence of wind. The proposed controller incorporates the wind estimates into the nominal path following controller in an intuitive way such that the UAV flies into wind with a trimming angle to cancel the wind component perpendicular to the path. The formulated composite controller including the disturbance observer is proven to be globally asymptotically stable in the theoretical analysis. Its performance is evaluated in the simulation against some other control strategies and is shown to be effective. The SIL simulation is then carried out to verify its function in a more realistic environment. The initial flight experiment is also performed and some promising results are obtained. Future work following the proposed approach include the extension to 3-D case and the incorporation of UAV's lateral dynamics.

*Abstract* - **This paper introduces the design of a charge blended energy management control system for use within a plugin hybrid electric vehicle. The approach taken extends the local cost function optimization routine associated with an Equivalent Fuel Consumption Method (EFCM) in which the charge-sustaining penalty factor is calculated online from an integrated PI controller rather than being derived from a pre-calibrated lookup table. The performance of the controller for a hybrid vehicle exercised over a number of different drive-cycles is presented. The powertrain model used to design and evaluate the system is derived from data logged onboard a number of different electric vehicles under real-world driving conditions.**

**Plugin Hybrid Electric Vehicle (PHEV), Energy Management, Equivalent Fuel Consumption Medthod (EFCM) , Controller Optimization**

## I. INTRODUCTION

Within the automotive and road transport sector, one of the main drivers for technological development and innovation is the need to reduce the vehicle's fuel consumption and the emission of Carbon Dioxide ($CO_2$) [1]. Legislative requirements are motivating manufacturers and subsystem suppliers to develop new and innovative electric vehicles (EV) and hybrid electric vehicles (HEV) concepts. In recent years, plug-in hybrids (PHEV) have also attracted considerable interest from both academia and industry.

A PHEV will typical have two primary modes of operation, namely a charge depleting mode (CD) and a charge sustaining mode (CS). Within a CD mode the vehicle operates as a zero emissions vehicle and the battery is depleted until it reaches a lower threshold. Conversely within a CS mode, an internal combustion engine (ICE), or equivalent is used to maintain the battery state of charge (SoC) within the required range. For a given journey that exceeds the zero emissions range of the vehicle, a number of publications describe a PHEV operating initially in its CD mode until the battery has depleted and then transitioning to the CS mode until the vehicle has reached its destination. Research published in [2] advocates a third mode of operation, the charge blended (CB) mode in which both the ICE and the electrical subsystems are optimally used throughout the entire journey. Because the ICE is able to operate in its most efficient region for comparatively longer, simulation results presented in [2] demonstrate an overall reduction in $CO_2$ for the journey.

The aim of this paper is to design and evaluate a CB energy management strategy for a PHEV. The instantaneous power split between the electrical subsystems and the ICE is calculated using the established Equivalent Fuel Consumption Method (EFCM) of local cost function optimization. However, the ECFM is extended by means of integrating it with a Proportional plus Integral (PI) controller in order to obtain the required SoC trajectory for the high voltage (HV) battery throughout the trip. In order to benchmark the performance of this new approach, the resulting powertrain efficiency is compared against that achieved from both a conventional EFCM controller and a thermostat strategy in which the ICE is only activate during the CS mode of vehicle operation.

This paper is structured as follows; Section II describes the derivation of the PHEV plant model employed as the foundation of this study. Sections III and IV present the design of the different energy management control systems for the PHEV. Section V describes the method of comparison used to simulate and evaluate the different control systems. Section VI presents the Results and Discussion. Conclusions and Further work are discussed in Section VII.

## II. DEVLOPMENT OF THE PHEV POWERTRAIN MODEL

### A. *Model Aims and Structure*

In order to support the evaluation of the different energy management techniques, a powertrain model for the PHEV is required of appropriate fidelity to facilitate vehicle simulations over the different drive-cycles. With simulation times in excess of 2000 seconds, a pseudo steady-state model is required in which the primary elements of the powertrain are represented by their non-linear efficiency characteristics. The powertrain model is designed to be an *enhanced* backward-facing model. Power calculations *flow* from the wheels to the main system components. However, forward-facing constraints are imposed to ensure that none of the component power ratings are invalidated. The simulation terminates if the required velocity trace cannot be met.

## B. Data Source

Parameterization of the electrical subsystems is based on the real-world vehicle usage data obtained from the Smart Move 2 Electric Vehicle Trail. As part of this program, 7 Smart Electric Drives (Smart EDs) were employed as the test vehicles. A full description of the vehicle trail is provided in [3] and will therefore not be repeated here. Over the course of 4268 km of driving, values of battery current ($i_b$), battery terminal voltage ($v_t$), vehicle speed ($v$) and inverter current ($i_m$) were recorded from the vehicle's Controller Area Network or CAN bus. As presented below, this data forms the basis for the derivation of the efficiency maps for both the electrical machine and HV battery. The remainder of this section describes the three main elements of the PHEV powertrain model, namely the vehicle mass, the electrical architecture and the ICE.

## C. Vehicle Mass

A vehicle coast down curve was experimentally obtained for the Smart ED. The coast down curve defines the resistive force ($F_r$) within the powertrain as a function of vehicle speed. The equation below defines the 3rd order polynomial best-fit approximation to the test data. The final term of 146.8 N represents the tire rolling resistance of the vehicle. The slope of the terrain (α) during the test was calculated using the measured height data obtained from the onboard GPS.

$$F_r = \left(8\times10^{-5}\right)v^3 + \left(0.0241\right)v^2 + \left(0.1456\right)v + 146.8\cos\left(\alpha\right) \quad (1)$$

The associated wheel power ($P_w$) for the vehicle is given below:

$$P_w = M_v\frac{dv}{dt} + F_r + \sin\left(\alpha\right) \quad (2)$$

The mass of the vehicle ($M_v$) was measured as 1036 kg.

## D. Electrical Architecure

### 1) Electrical Machine Model and Efficiency

The Smart ED employs a 50 kW brushless DC machine. For the PHEV model, the electric machine and the associated inverter have been considered as a single integrated system. Equation (3) was employed to calculate the efficiency of the electrical drive system $(\eta_e)$:

$$\eta_e = \frac{P_w}{v_t i_b} \quad (3)$$

The values of $v_t$ *and* $i_b$ were recorded during the EV evaluation trail under a number of different driving conditions [3]. *Fig.1* shows the mean efficiency for the electrical machine as a function of both shaft torque $\left(\tau_m\right)$ and rotor velocity $\left(\omega_m\right)$.

### 2) Battery Model and Efficiency

The Smart ED employs a 16.5kWh Lithium Ion battery, with a peak power rating of 30kW during discharge and 10kW for charge. A steady-state, equivalent circuit model is employed to represent the efficiency of the HV battery. This method is widely reported within the literature [4]. *Fig.2* presents the circuit, which comprises of a controlled open circuit voltage ($v_{oc}$) in series with a non-linear variable resistance ($R$).

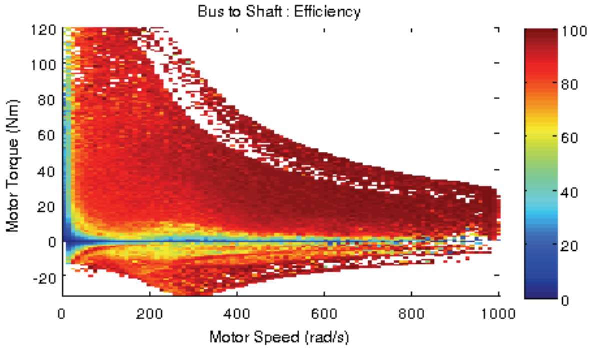

Fig. 1: Measured efficiency of the electrical drive system

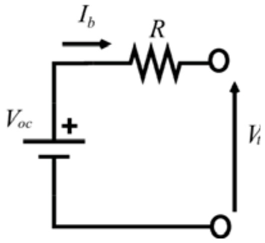

Fig. 2: Battery model

The value of $v_{oc}$ was estimated using the data recorded from [3]. The data was analyzed and the points in which $i_b$ is zero were noted. Under these conditions $v_{oc} = v_t$. *Fig.3* shows the results of this exercise and presents the estimated $v_{oc}$ as a function of measured pack temperature and recorded SoC. From Figs. 2 and 3, it is possible to derive an expression for the efficiency of the HV battery $(\eta_b)$:

$$\eta_b = \frac{v_{ocv} i_b}{v_t i_b} \quad (4)$$

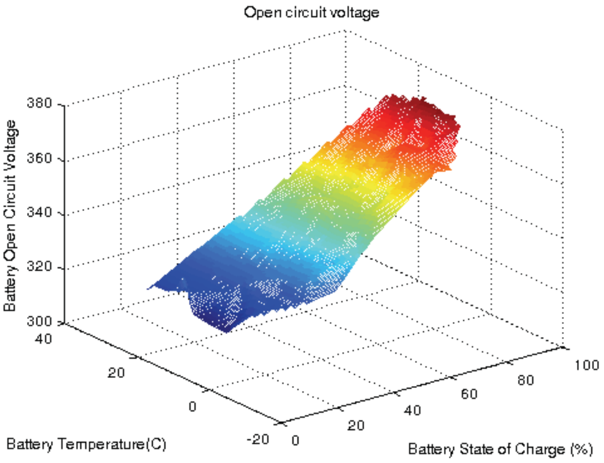

Fig. 3: Estimated battery open circuit voltage

As reported in [5] above 20% SoC, the internal resistance of lithium cells is largely insensitive to variations in battery SoC. However, battery efficiency does varies considerably due to changes in ambient temperature. *Fig. 4* presents the efficiency of the battery system as a function battery current and SoC. For the purpose of this study, battery pack temperature was assumed constant at 20 $^0$C.

## *E. The ICE Model and Efficiency*

When considering the design of an ICE model there are various levels of possible fidelity. As reported in [6], for a backward facing model in which the emphasis is on fuel economy estimation rather than transient load prediction, the ICE is often represented as a steady-state look-up table. This map defines the instantaneous mass flow rate of fuel and Best Specific Fuel Consumption (BSFC) line for the ICE. *Fig. 5* presents the engine BSFC map employed within this study. The map defines the steady-state performance for a 0.7 liter naturally aspirated 4 cylinder spark ignition engine with a maximum power of 46kW. The characteristics of this ICE are typical of the low power ICE variants often employed as a “range-extender” or Auxiliary Power Unit (APU) within a PHEV.

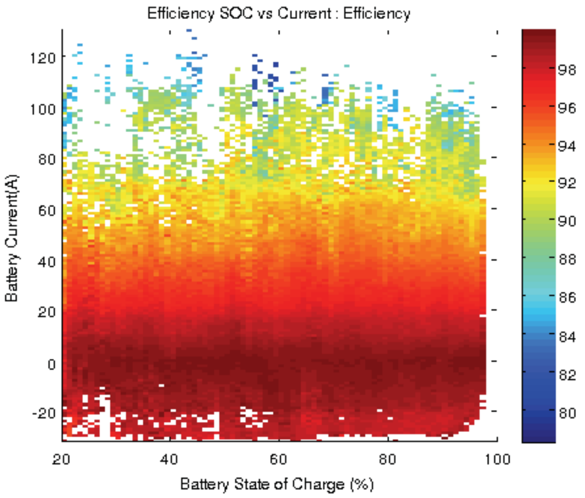

Fig. 4: Estimated battery efficiency as a function of SoC

## *F. Summary of Model Equations*

Given the non-linear parameterization data and efficiency characteristics given above, for the battery discharge conditions, equations (5)-(16) summaries the PHEV plant model employed within the control study discussed in the proceeding sections.

Based on the input drive-cycle, the wheel power ($P_w$) can be calculated directly from (1) and (2). Taking into account the efficiency of the electrical drive system including the efficiency of the final drive, the power on the HV bus can be calculated as follows:

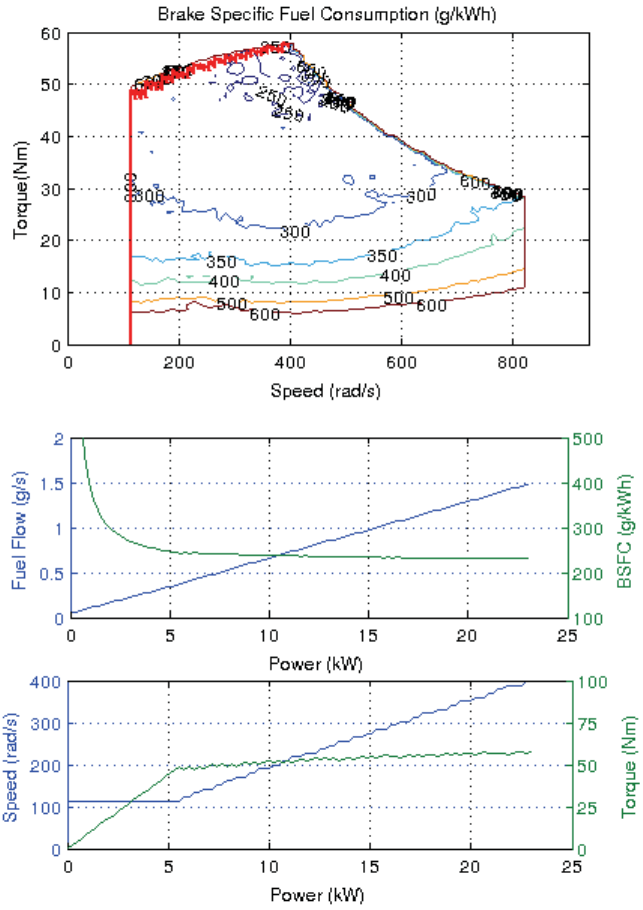

Fig. 5: Engine and Generator.

(a) Brake Specific Fuel Consumption Map (b) Best Fuel Consumption Operation Line (c) Target for engine controller

$$P_B = \frac{P_w}{\eta_e} \qquad (5)$$

$$\eta_e = f^n(\tau_m, \omega_m) \qquad (6)$$

$$\tau_m = F_r r_w \qquad (7)$$

$$\omega_m = \frac{v}{r_w} \qquad (8)$$

The term $r_w$ defines the rolling radius of the wheel. All other parameters are as previously defined. Given the power on the HV bus, the total battery power can be calculated as follows:

$$P_{Bat} = P_B + P_{aux} + P_{ICE} \qquad (9)$$

The term $P_{aux}$ defines an average auxiliary power demand for the vehicle and $P_{ICE}$ the power contribution from the ICE. Given $P_{Bat,}$ it is possible to calculate the required values of battery current ($i_b$) and battery SoC:

$$i_b(t-1) = \frac{P_{Bat}}{v_t(t-1)} \tag{10}$$

$$v_{oc} = f^n\left(SoC, T\right) \tag{11}$$

$$SoC = SoC_{ic} - \frac{1}{3600Q}\int_{t=0}^{t=STOP} i_b \, dt \tag{12}$$

$$i_b = \frac{v_{oc} - v_t}{R_{Bat}} \tag{13}$$

$$v_t = v_{oc} - i_b R_{Bat} \tag{14}$$

where Q defines the manufacturers rated battery capacity, $R_{Bat}$ defines the equivalent value of battery internal resistance derived from *Fig. 4*, t represents simulation time and finally, $SoC_{ic}$ the initial conditions for the battery SoC at the start of the simulation. All other parameters are as previously defined.

The required power from the ICE is a function of the energy management strategy and will be discussed in the following Section. With respect to *Fig. 5,* given $P_{ICE}$, the instantaneous mass flow rate of fuel ($g$) and the total fuel consumed over the cycle ($g_{total}$) can be calculated as shown below:

$$g = f^n\left(P_{ICE}\right) \tag{15}$$

$$g_{total} = \int_{t=0}^{t=stop} g \, dt \tag{16}$$

Numerical simulations and validation of the above model is provided in [5] and will therefore not be repeated again here.

## III. Design of a Thermostate energy management strategy

When designing a thermostat energy management strategy, there is relatively little analytical work that can be undertaken. The lower and upper thresholds for the strategy are defined that determine when the ICE / APU is switched on to replenish battery SoC and turned off respectively. Additional rules are often added to the heuristic control system to prevent the APU from rapidly switching, thereby causing unwanted noise, vibration and harshness (NVH) or driveability concerns within the vehicle. For the purpose of this study a simple thermostat strategy is employed in which the upper and lower SoC thresholds are defined in addition to a hysteresis function to prevent excessive cycling of the APU.

Within industry, much of the effort when integrating a thermostat approach relates to the calibration of the upper threshold. The significance of this parameter for achieving a low value of $CO_2$ is discussed further in Section VI. *Fig. 6* presents the sensitivity for the final $CO_2$ output of the PHEV over the New European Drive-Cycle (NEDC), for a lower threshold of 25% SoC to a range of different upper thresholds. Since there is an inherent coupling between the physical size of the energy storage medium, the useable SoC range and the characteristics of the journey profile (distance or kWh demand) the final $CO_2$ is highly variable and non-deterministic.

For the purpose of this study, two calibrations for the thermostat controller have been employed; the first relates to a strategy that has been optimized for use over the NEDC. The second, relates to a modified calibration that is optimized for each route under investigation. *Fig. 6,* shows the controller calibration options for a controller tuned specifically to achieve the best Tank to Wheel (TTW) emissions from the vehicle over the legislative, NEDC, drive-cycle.

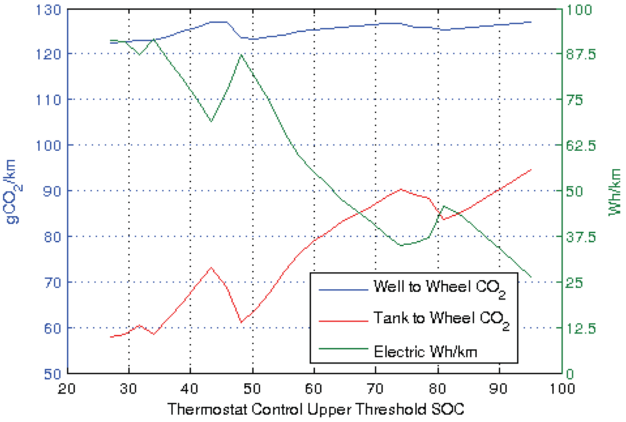

Fig. 6: Calibration of the thermostat controller (lower SoC threshold set to 25%)

## IV. Design of a EFCM energy management strategy

The EFCM is a real-time, local optimization technique that was first proposed in [8] and has been subsequently refined and extended in a number of further publications, for example [7]. The technique has also been applied to a wide range of different HEV powertrain architectures, each employing different degrees of hybridization and subsystem technologies.

### *A. Derivation of the EFCM Strategy*

The aim of this section is to present the structure, cost function and constraints associated with the proposed EFCM.

The primary function of the energy management controller is to ascertain the optimized value of $P_{ICE}$. For a given value of $P_B$, at each time-step, the strategy calculates the power demands to be sent to both the ICE and the electrical machine:

$$\begin{aligned} P_{ICE} &= (\beta) P_B \\ P_m &= (1-\beta) P_B \end{aligned} \tag{17}$$

where β represents the power split ratio. A controller sample rate of 100 ms was selected. Given this constraint, 100 unique values of β are computed for each iteration of the controller. The normalized values of β are calculated such that the following constraints are not invalidated:

$$\begin{aligned} &P_{ICE\_MIN} \le P_{ICE} \le P_{ICE\_MAX} \\ &P_m \le P_{m\_MAX} \\ &P_{B\_MIN} \le P_B \le P_{B\_MAX} \end{aligned} \tag{18}$$

The locally optimized value of β that provides the most efficient power split between the ICE and electrical machine is calculated at each time-step, by minimizing the following cost function ($J$):

$$J = MIN\left(g + g_{equiv}\zeta\right) \tag{19}$$

where $g$ is calculated from (15), $g_{equiv}$ represents the equivalent fuel consumption of the energy sunk and sourced from the HV battery taking into account the battery efficiency presented in *Fig. 4.* Finally ζ defines the charge-sustaining penalty function:

$$0 \leq \zeta \leq \zeta_{\max} \tag{20}$$

In the majority of published research, ζ represents a static look-up table that is either a linear or sigmoidal function of SoC. For the purpose of this study, two approach's to the definition of ζ have been investigated. The first is to define ζ as a linear function of SoC that weights the use of the electrical subsystems for progressively lower values of SoC (similar approaches have been discussed in [7,9]). The second is to employ a time varying value of ζ(t), in which the value is calculated from an outer PI control loop. *Fig. 7* presents the structure of the integrated PI-EFCM control system.

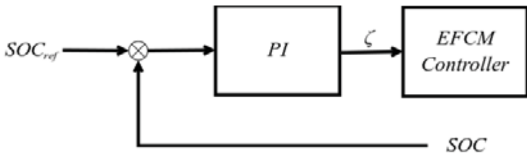

Fig. 7: Integrated PI–EFCM energy management approach

In order for this technique to be successfully applied to a PHEV as part of a CB energy management strategy, the desired set-point trajectory of SoC across the trip ($SoC_{ref}$) must be known in advance.

## V. Method of evaluation for control system performance

The aim of this Section is to introduce the method of control system evaluation employed within this study. Three drive-cycles have been used; the NEDC, the Artemis cycle and a real-world mixed urban-highway cycle that has ben logged as part of the evaluation of the Smart Move 2 trail. The speed profile of this latter cycle is 29.83 km long, it has a top speed of 28 $ms^{-1}$ and a number of start-stop events. Further information is presented in [3]. For each drive-cycle, four sets of simulations have been undertaken and the $CO_2$ output of the PHEV recorded for each study:

**Study 1:** A thermostat controller with an SoC range optimized for each specific cycle under investigation.

**Study 2:** A thermostat controller with an SoC range of 25 - 34% (i.e.: tuned for the NEDC) used on each cycle.

**Study 3:** A controller based on the EFCM in which the target SoC is fixed at 25%

**Study 4:** A controller based on the EFCM and the target SoC is managed across the cycle to facilitate a CB strategy.

In order to draw the final comparisons between a CB strategy and the different forms of a CD-CS strategy, the final energy content of the HV battery is equalized back to the initial SoC value. Using a value of $CO_2$ equal to 594 $gCO_2$ / kWh for the UK electrical grid mix, the total $CO_2$ output of the powertrain can be calculated:

$$CO_2 = CO_2\left(ICE\right) + CO_2\left(grid - kwh\right) \tag{21}$$

## VI. Results and discussuion

Table 1 presents the $CO_2$ output for each of the four studies introduced above. For each drive-cycle and control method, the Table shows the overall well-to-wheel (WTW) $CO_2$ value. In addition, Table 1 also presents how this value is broken down into the corresponding TTW $CO_2$ and the $CO_2$ contribution from the electrical supply network. The final SoC of the HV battery is also shown for completeness.

| | Study 1 | Study 2 | Study 3 | Study 4 |
|---|---|---|---|---|
| | Thermostat | Thermostat<br>(tuned controller) | EFCM<br>(CS-Mode) | EFCM<br>(CB-Mode) |

| Final SoC (%) | 27.86 | 26.39 | 25.04 | 25.04 |

Table 1: PHEV efficiency results for different energy management techniques

For the real-world drive-cycle, *Fig. 8* presents the simulation results from studies 2-4. The figure shows the vehicle speed profile, the instances in which the PHEV is operating as an EV or when additional power is supplied from the ICE. From Table 1, given the variations in the TTW $CO_2$ values obtained, one of the main drawbacks of the thermostat approach are highlighted. For a PHEV, final $CO_2$ achieved for the trip or drive-cycle, is highly dependent on the nature of the journey (distance, level of driver demand), the physical size of the battery (kWh) and the upper turn-off threshold for the controller. The ideal calibration for the control system is one that ensures the battery at its lowest allowable SoC point at the end of the journey.

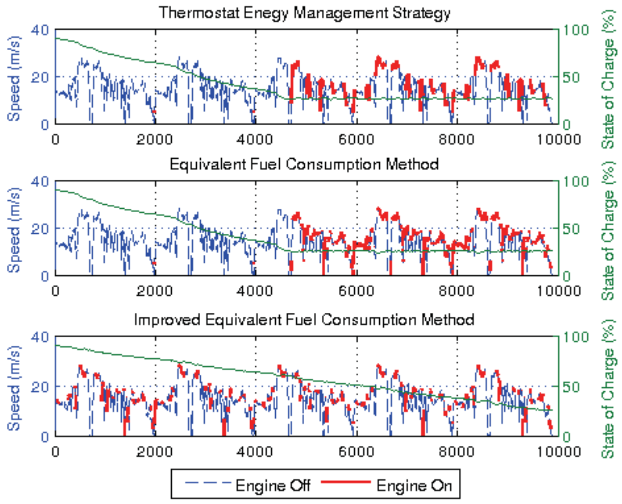

Fig. 8: Drive-cycle results for the PHEV

From Table 1, the primary conclusion that can be drawn is that the CB strategy, designed using an EFCM, consistently results in a PHEV powertrain system with the lowest WTW $CO_2km^{-1}$ values. For each cycle, this is true even when compared against a thermostat strategy that has been calibrated to optimize the performance of the vehicle over that cycle. Even though the differences presented here are marginal (in the order of 1-2%) two points should be noted. Firstly, this improvement is achieved simply by adopting a new control methodology. No change to the physical design of the vehicle has been assumed. The second point to note, is that if consideration is restricted to the TTW analysis, then the differential between the different control methods is considerably greater. The $CO_2$ reduction possibilities are in the order of 4-10%. While the TTW comparisons do not take into account the residual energy content of the HV battery, this method of evaluation is inline with current EU fuel economy measurement processes for PHEVs [10]. Within Regulation 101, two fuel economy metrics are cited, the $CO_2km^{-1}$ from the vehicle over the cycle and separately a $Whkm^{-1}$ is also published representing the energy required from the grid to replenish the battery. Currently within the UK only the former is employed when setting vehicle taxation levels and to alleviate congestion charges.

The improvement in efficiency when comparing either a CS or CB control system using EFCM can be seen from *Fig. 8.* When a closed-loop CB control system is employed, the ICE is consistently used more to support the high power demands from the driver and hence more power is fed directly to the road wheels. With a CS strategy, in which the ICE is used only when the battery SoC has depleted to its lower threshold, the ICE is forced to operate for longer periods within it's more inefficient low power regions.

## VII. CONCLUSIONS AND FURTHERWORK

A PHEV powertrain model has been developed to support the design and optimization of a CB energy management control system. The electrical subsystems within the model have been calculated from data logged from a Smart ED vehicle under real-world usage conditions.

The energy management technique extends a conventional EFCM controller by integrating it with a closed loop PI control system. The output of the PI controller is a time-varying charge sustaining penalty function that allows for a more robust control of the battery SoC, irrespective of the nature of the drive-cycle or the physical size of the battery.

In order to implement this CB control system, it has been assumed that the control system knows the distance of the journey that the vehicle is traversing. This assumption is valid for a number of applications such as public transportation or vehicle fleet operation. In order to support the wider application of this control method, research is currently ongoing to investigate the accuracy of on-line estimation techniques in which the required SoC trajectory for a CB strategy across a trip can be calculated as a function of the different road types, traffic congestion levels and the differing energy demands from with the driver.

## VIII. ACKNOWLEDGEMENTS

The research presented within this paper is supported by the UK Technology Strategy Board (TSB) through the Knowledge Transfer Partnership (KTP) scheme in collaboration with the Morgan Motor Company .

# Modelling Channel Flow over Riblets: Calculating the Energy Amplification

Aditya Kasliwal, Stephen Duncan and Antonis Papachristodoulou

*Abstract*— **Riblets have been considered as a passive method for drag reduction. Riblets are structures on a surface that run parallel to one another, which are aligned longitudinally to the flow. It has been shown experimentally that when the shape, spacing and height of the riblets are optimized, the drag coefficient over the surface can be reduced by up to 10%. These results have also been confirmed by direct numerical simulation studies. Although the benefits of riblets have been known since the early 1980's, the mechanism of drag reduction is still not fully understood. This paper examines the effect of riblet structures on the amplification of background noise within channel flow between two parallel plates (Poiseuille flow), where riblets are present on the surface of one of the plates. A linearized version of the Navier-Stokes equation about the steady flow is developed and through a coordinate transformation, the boundary conditions associated with the riblets are transferred into the partial differential equations. Previous work has used spectral methods to discretize these equations, leading to a large-scale state space model, and the energy amplification was calculated for the streamwise constant component of the flow from the controllability gramian. However, solving the associated Lyapunov equation can be computationally prohibitive, which limits the density of the discretized grid. This paper shows how the problem can be transformed to decouple the system, so that the gramian can be obtained by solving a set of smaller Lyapunov equations, which has the potential to allow the energy amplification to be calculated for systems with a dense discretization grid.**

*Index Terms*— **Fluid flow, drag reduction, Lyapunov equation, energy amplification, riblets**

## I. Introduction

One approach that has been considered in the past that results in a significant reduction in the drag caused by a fluid flowing past a body is the introduction of riblet structures on the surface of the body [1], [2], [3]. Riblets are structures that run parallel to one another, that are positioned longitudinally to the flow and usually have a triangular cross-section in the transverse direction. By contrast with approaches such as suction/blow mechanisms, riblets can be regarded as a passive drag reduction mechanism [4]. Previous research has shown that riblet structures can be optimized to produce a reduction in the drag coefficient of up to 10% [2]. It is believed that the mechanism responsible for this level of drag reduction is the interaction of the riblets with the structure of the boundary layer, which leads to a reduction in drag, despite the significant increase in the area of the modified surface that is in contact with the flow compared to a smooth surface. This drag-reduction mechanism is observed widely in nature, for example on shark skin and scallop shells [5], [6]. Static riblet structures (often in the form of films that cover the surface) have been used in a number of fields and in the 1990's tests on a scale model of an Airbus A320 cruising at Mach 0.7 have shown reductions in viscous drag of 4.85% [7], [8]. However, despite these benefits, there has not as yet been a satisfactory explanation for the mechanism of drag reduction using riblet structures. Experimental and Computational Fluid Dynamics (CFD) studies have suggested that riblets induce streamwise vortices that sit within the riblets [9], [10], although recent work has shown that riblets induce spanwise vortices close to the riblet surface and it is these that change the drag over the surface [11], [12].

The results presented here build on previous work [13], [14] that combines ideas from control theory and aerodynamics, by extending an existing direct numerical simulation of the flow between two parallel plates (Poiseulle flow), where riblets are present on the surface of one of the plates. The model uses concepts from linear control theory to determine the transient growth of background noise energy amplification in the linearized Navier-Stokes equations [15], [16]. We investigate how the transient growth in energy alters with the introduction of riblet structures by using the model to predict how the shape and positioning of the riblets affect this transient energy growth. The model calculates the amplification of background noise energy, together with the drag on the surface of the plates, for a given riblet geometry, by using a transformation of coordinates that will 'passes' the non-uniformity of the boundary associated with the riblet structure on one of the walls, into the equations of motion. Once this equation is obtained, a numerical model is developed using a Chebyshev discretization approach in the wall-normal direction and a Fourier representation in the streamwise and spanwise directions and estimates of the reduction in energy amplification are obtained as a function of different geometries. Previous work [13], [14] has modelled the flow at relatively low Reynolds numbers due to the computational complexity of the problem, because in order to find the energy amplification, it was necessary to solve a high dimension Lyapunov equation, which is a computationally intensive step. However, by exploiting the inherent structure of the problem that is associated with the Fourier representation in the spanwise direction, it is possible to decompose the problem into a set of decoupled Lyapunov equations of lower dimension. This has the potential to allow the flow to be modelled at higher Reynolds numbers and reduced riblet spacing that require denser discretization grids, which is where the benefits of the riblets structures are

observed. It will also allow comparison with experimental results and with CFD simulations that have been reported in the literature.

The paper is organized as follows. Section II develops the equations describing the channel flow and uses a coordinate transformation to convert the boundary conditions associated with the riblet structures into a uniform domain. In Section III, the equations describing the linearized flow about the steady flow are derived. Section IV shows how Fourier methods can be used to create a large-scale, finite-dimensional state space model and describes how the structure of the model can be exploited to calculate the amplification of the energy associated with background noise in a computationally efficient manner. Section V gives the results for the effect on the energy amplification of introducing riblets for a specific flow regime and Section VI concludes the paper.

## II. Transforming the Equations of Motion

We consider channel flow between two stationary plates with the geometry of the problem as shown in Fig. 1, where $\tilde{x}$, $\tilde{y}$ and $\tilde{z}$ are the coordinates of the streamwise, wall-normal and spanwise directions, respectively. The upper wall is a flat plate, while the lower wall is a plate with riblets aligned with the streamwise direction. The dimensions of the problem are normalized, so that the upper boundary of the flow occurs at the plate positioned at $\tilde{y} = 1$, while the lower boundary is at

$$\tilde{y} = -1 + f(\tilde{z}) \tag{1}$$

where $f(\tilde{z})$ describes the “shape” of the riblets. The analysis will be restricted to riblets that are aligned with the streamwise direction and are independent of $\tilde{x}$.

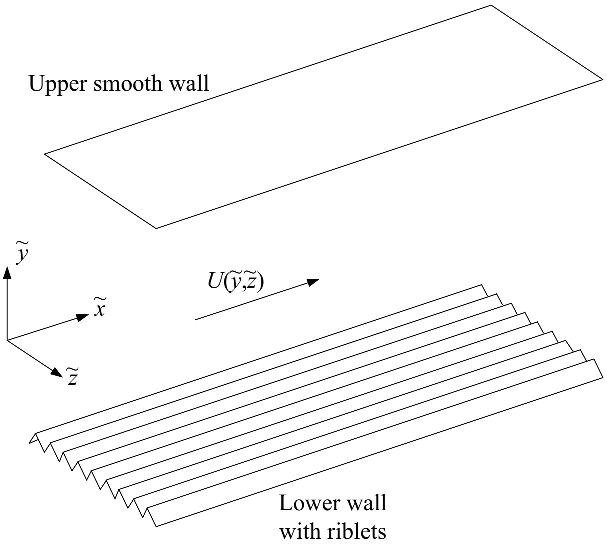

Fig. 1. Three-dimensional view of computational domain showing riblet structure on lower wall of channel. $U(\tilde{y}, \tilde{z})$ denotes the direction of the steady, streamwise flow.

The streamwise, wall-normal and span-wise components of the flow in the coordinate system $(\tilde{x}, \tilde{y}, \tilde{z})$ are denoted by $u(\tilde{x}, \tilde{y}, \tilde{z}, t)$, $v(\tilde{x}, \tilde{y}, \tilde{z}, t)$ and $w(\tilde{x}, \tilde{y}, \tilde{z}, t)$ respectively, and the non-dimensionalised Navier-Stokes equations in this coordinate system are given by

$$\left(\frac{\partial}{\partial t} + u\frac{\partial}{\partial \tilde{x}} + v\frac{\partial}{\partial \tilde{y}} + w\frac{\partial}{\partial \tilde{z}}\right) u = -\frac{\partial p}{\partial \tilde{x}} + \frac{1}{\mathrm{Re}}\tilde{\Delta} u \tag{2}$$

$$\left(\frac{\partial}{\partial t} + u\frac{\partial}{\partial \tilde{x}} + v\frac{\partial}{\partial \tilde{y}} + w\frac{\partial}{\partial \tilde{z}}\right) v = -\frac{\partial p}{\partial \tilde{y}} + \frac{1}{\mathrm{Re}}\tilde{\Delta} v \tag{3}$$

$$\left(\frac{\partial}{\partial t} + u\frac{\partial}{\partial \tilde{x}} + v\frac{\partial}{\partial \tilde{y}} + w\frac{\partial}{\partial \tilde{z}}\right) w = -\frac{\partial p}{\partial \tilde{z}} + \frac{1}{\mathrm{Re}}\tilde{\Delta} w \tag{4}$$

$$\frac{\partial u}{\partial \tilde{x}} + \frac{\partial v}{\partial \tilde{y}} + \frac{\partial w}{\partial \tilde{z}} = 0 \tag{5}$$

where $p$ is the pressure, $\mathrm{Re}$ is the Reynolds number and

$$\tilde{\Delta} = \frac{\partial^2}{\partial \tilde{x}^2} + \frac{\partial^2}{\partial \tilde{y}^2} + \frac{\partial^2}{\partial \tilde{z}^2} \tag{6}$$

For the smooth wall at $\tilde{y} = 1$, the boundary conditions are

$$u(\tilde{x}, 1, \tilde{z}) = v(\tilde{x}, 1, \tilde{z}) = w(\tilde{x}, 1, \tilde{z}) = 0 \tag{7}$$

together with

$$\left.\frac{\partial v}{\partial \tilde{y}}\right|_{\tilde{y}=1} = 0 \tag{8}$$

while for the riblet wall at $\tilde{y} = -1 + f(\tilde{z})$, the boundary conditions are

$$\begin{aligned} u(\tilde{x}, -1 + f(\tilde{z}), \tilde{z}) &= v(\tilde{x}, -1 + f(\tilde{z}), \tilde{z}) \\ &= w(\tilde{x}, -1 + f(\tilde{z}), \tilde{z}) = 0 \end{aligned} \tag{9}$$

with

$$\left.\frac{\partial v}{\partial n}\right|_{\tilde{y}=-1+f(\tilde{z})} = 0 \tag{10}$$

where $n$ is the normal to the surface of riblets.

We now apply a change of coordinates

$$\begin{aligned} x &= \tilde{x} \\ y &= F(\tilde{y}, \tilde{z}) \\ z &= \tilde{z} \end{aligned} \tag{11}$$

where

$$y = F(\tilde{y}, \tilde{z}) = \frac{2\tilde{y} - f(\tilde{z})}{2 - f(\tilde{z})} \tag{12}$$

which has the effect of mapping $\tilde{y} \in [-1 + f(\tilde{z}), 1]$ to $y \in [-1, 1]$.

The Navier-Stokes equations in the new coordinate system then become [14]

$$\left(\frac{\partial}{\partial t}+u\frac{\partial}{\partial x}+v\frac{\partial F}{\partial \tilde{y}}\frac{\partial}{\partial y}+w\frac{\partial F}{\partial \tilde{z}}\frac{\partial}{\partial y}+w\frac{\partial}{\partial z}\right)u = -\frac{\partial p}{\partial x}+\frac{1}{\mathrm{Re}}\tilde{\Delta}u \tag{13}$$

$$\left(\frac{\partial}{\partial t}+u\frac{\partial}{\partial x}+v\frac{\partial F}{\partial \tilde{y}}\frac{\partial}{\partial y}+w\frac{\partial F}{\partial \tilde{z}}\frac{\partial}{\partial y}+w\frac{\partial}{\partial z}\right)v = -\frac{\partial F}{\partial \tilde{y}}\frac{\partial p}{\partial y}+\frac{1}{\mathrm{Re}}\tilde{\Delta}v \tag{14}$$

$$\left(\frac{\partial}{\partial t}+u\frac{\partial}{\partial x}+v\frac{\partial F}{\partial \tilde{y}}\frac{\partial}{\partial y}+w\frac{\partial F}{\partial \tilde{z}}\frac{\partial}{\partial y}+w\frac{\partial}{\partial z}\right)w = -\frac{\partial p}{\partial z}-\frac{\partial F}{\partial \tilde{z}}\frac{\partial p}{\partial y}+\frac{1}{\mathrm{Re}}\tilde{\Delta}w \tag{15}$$

$$\frac{\partial u}{\partial x}+\frac{\partial F}{\partial \tilde{y}}\frac{\partial v}{\partial y}+\frac{\partial F}{\partial \tilde{z}}\frac{\partial w}{\partial y}+\frac{\partial w}{\partial z}=0 \tag{16}$$

where

$$\begin{aligned}\tilde{\Delta} &= \frac{\partial^2}{\partial x^2}+\left(\frac{\partial F}{\partial \tilde{y}}\right)^2\frac{\partial^2}{\partial y^2}+\left(\frac{\partial F}{\partial \tilde{z}}\right)^2\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2}\\ &\quad+\frac{\partial}{\partial \tilde{y}}\left(\frac{\partial F}{\partial \tilde{y}}\right)\frac{\partial}{\partial y}+\frac{\partial}{\partial \tilde{z}}\left(\frac{\partial F}{\partial \tilde{z}}\right)\frac{\partial}{\partial y}+2\frac{\partial F}{\partial \tilde{z}}\frac{\partial^2}{\partial y\partial z}\end{aligned} \tag{17}$$

## III. Linearized Equations

The steady state flow, $(U,0,0)$, satisfies

$$U\frac{\partial U}{\partial x} = -\frac{\partial P}{\partial x}+\frac{1}{\mathrm{Re}}\tilde{\Delta}U \tag{18}$$

$$0 = -\frac{\partial F}{\partial \tilde{y}}\frac{\partial P}{\partial y} \tag{19}$$

$$0 = -\frac{\partial P}{\partial z}-\frac{\partial F}{\partial \tilde{z}}\frac{\partial P}{\partial y} \tag{20}$$

$$\frac{\partial U}{\partial x} = 0 \tag{21}$$

Since we are restricting our attention to the case of straight riblets aligned with the streamwise direction, so that $f(\hat{z})$ does not depend upon $\hat{x}$, then $P=P(x)$ and $U=U(y,z)$, where $U(y,z)$ is the solution of

$$\tilde{\Delta}U=-2\mathrm{Re} \tag{22}$$

We now redefine the streamwise flow as $u(x,y,z,t)+U(y,z)$, where $u(x,y,z,t)$ denotes the flow *relative* to the solution of steady flow problem, $U(y,z)$, and the pressure as $p(x,y,z,t)+P(x)$, where $p(x,y,z,t)$ is the pressure *relative* to $P(x)$. Linearizing about this steady solution and applying the change of coordinates, the Navier-Stokes equations become

$$\left(\frac{\partial}{\partial t}+U\frac{\partial}{\partial \tilde{x}}\right)u+v\frac{\partial U}{\partial \tilde{y}}+w\frac{\partial U}{\partial \tilde{z}} = -\frac{\partial p}{\partial \tilde{x}}+\frac{1}{\mathrm{Re}}\tilde{\Delta}u \tag{23}$$

$$\left(\frac{\partial}{\partial t}+U\frac{\partial}{\partial \tilde{x}}\right)v = -\frac{\partial p}{\partial \tilde{y}}+\frac{1}{\mathrm{Re}}\tilde{\Delta}v \tag{24}$$

$$\left(\frac{\partial}{\partial t}+U\frac{\partial}{\partial \tilde{x}}\right)w = -\frac{\partial p}{\partial \tilde{z}}+\frac{1}{\mathrm{Re}}\tilde{\Delta}w \tag{25}$$

$$\frac{\partial u}{\partial \tilde{x}}+\frac{\partial v}{\partial \tilde{y}}+\frac{\partial w}{\partial \tilde{z}} = 0 \tag{26}$$

Introducing

$$\eta=\frac{\partial u}{\partial \tilde{z}}-\frac{\partial w}{\partial \tilde{x}} \tag{27}$$

and rearranging, we obtain

$$\begin{aligned}\left(\frac{\partial}{\partial t}+U\frac{\partial}{\partial \tilde{x}}\right)\eta &- \frac{\partial U}{\partial \tilde{z}}\frac{\partial v}{\partial \tilde{y}}+\frac{\partial U}{\partial \tilde{y}}\frac{\partial v}{\partial \tilde{z}}+v\frac{\partial^2 U}{\partial \tilde{y}\partial \tilde{z}}+w\frac{\partial^2 U}{\partial \tilde{z}^2}\\ &= \frac{1}{\mathrm{Re}}\tilde{\Delta}\eta\end{aligned} \tag{28}$$

The flow is now described by equations that depend upon $v$, $\eta$ and $w$. To eliminate $w$, define

$$\eta=\frac{\partial u}{\partial \tilde{z}}-\frac{\partial w}{\partial \tilde{x}} \tag{29}$$

which leads to

$$w=-\left(\frac{\partial^2}{\partial \tilde{z}^2}+\frac{\partial^2}{\partial \tilde{x}^2}\right)^{-1}\left(\frac{\partial \eta}{\partial \tilde{x}}+\frac{\partial^2 v}{\partial \tilde{y}\partial \tilde{z}}\right) \tag{30}$$

We now assume that the flow is streamwise constant, so that $v$, $\eta$ and $w$ are independent of $\tilde{x}$, and $\frac{\partial}{\partial \tilde{x}}=\frac{\partial}{\partial x}=0$, and following some lengthy manipulations (details are given in [13], [14]), the linearized flow can be described by

$$\frac{\partial}{\partial t}\tilde{\Delta}v = \frac{1}{\mathrm{Re}}\tilde{\Delta}\tilde{\Delta}v \tag{31}$$

$$\frac{\partial}{\partial t}\eta = \tilde{\mathcal{C}}v+\frac{1}{\mathrm{Re}}\tilde{\Delta}\eta \tag{32}$$

where

$$\tilde{\mathcal{C}}=\frac{\partial U}{\partial \tilde{z}}\frac{\partial}{\partial \tilde{y}}-\frac{\partial U}{\partial \tilde{y}}\frac{\partial}{\partial \tilde{z}}-\frac{\partial^2 U}{\partial \tilde{y}\partial \tilde{z}}+\frac{\partial^2 U}{\partial \tilde{z}^2}\left(\frac{\partial^2}{\partial \tilde{z}^2}\right)^{-1}\frac{\partial^2}{\partial \tilde{y}\partial \tilde{z}} \tag{33}$$

## IV. Representation in Spatial Fourier Domain

Using (17), the expression for $\tilde{\Delta}$ and $\tilde{\Delta}\tilde{\Delta}$ can be expressed in terms of the steady-state flow $U$ and the partial differentials of $F(\tilde{y},\tilde{z})$. In order to obtain expressions for these operators, we require

$$y=F(\tilde{y},\tilde{z})=\frac{2\tilde{y}-f(\tilde{z})}{2-f(\tilde{z})} \tag{34}$$

and because $\tilde{z}=z$, then

$$\tilde{y}=y+\frac{f(z)}{2}(1-y) \tag{35}$$

so that

$$\frac{\partial F}{\partial \tilde{y}} = \frac{2}{2 - f(z)} \tag{36}$$

$$\frac{\partial F}{\partial \tilde{z}} = \frac{(y-1)\, f'(z)}{2 - f(z)} \tag{37}$$

where $f'(z)$ denotes the differential of $f(z)$ with respect to $z$. The higher partial derivatives of $F(\tilde{y}, \tilde{z})$ can also be derived, but the resulting expressions for the transformed operators are rather cumbersome and are omitted from this paper. Full details are given in [14].

The operator $\tilde{\Delta}$ can be written as

$$\tilde{\Delta} = K_1(y,z)\frac{\partial}{\partial y} + K_2(y,z)\frac{\partial^2}{\partial y \partial z} + K_3(y,z)\frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \tag{38}$$

with

$$K_1(y,z) = \frac{\partial}{\partial z}\left(\frac{\partial F}{\partial \tilde{z}}\right) + \frac{\partial F}{\partial \tilde{y}}\frac{\partial}{\partial y}\left(\frac{\partial F}{\partial \tilde{y}}\right) + \frac{\partial F}{\partial \tilde{z}}\frac{\partial}{\partial y}\left(\frac{\partial F}{\partial \tilde{z}}\right) \tag{39}$$

$$K_2(y,z) = 2\frac{\partial F}{\partial \tilde{z}} \tag{40}$$

$$K_3(y,z) = \left(\frac{\partial F}{\partial \tilde{y}}\right)^2 + \left(\frac{\partial F}{\partial \tilde{z}}\right)^2 \tag{41}$$

The operators in (31) and (32) depend upon the steady state profile $U(y,z)$. Because the flow is taken to be periodic in the $\tilde{z}$ direction with period $2\pi$, and since $\tilde{z} = z$ then

$$U(y,z) = U(y, z + 2\pi) \tag{42}$$

the spanwise component of the flow can be approximated by a linear combination of Galerkin trial functions, $\mathrm{e}^{\mathrm{i}nz}$ for $n \in \mathbb{Z}$, so that

$$U(y,z) = \sum_{n=-\infty}^{\infty} \hat{U}_n(y)\mathrm{e}^{\mathrm{i}nz} \tag{43}$$

The riblet structure is also taken to be periodic in the $\tilde{z}$ (and $z$) direction, so that $f(z)$ can be expressed as

$$f(z) = \sum_{n=-\infty}^{\infty} \hat{f}_n \mathrm{e}^{\mathrm{i}nz} \tag{44}$$

However, assuming that there are an integer number of riblets, $P \in \mathbb{Z}^+$, in the region $z \in [0, 2\pi]$, then $\hat{f}_n = 0$ for all $n \neq mP$, where $m$ is an integer. When the spacing between riblets is small, as is usually the case for flow with high Reynolds numbers, then $P$ is large, which means that only coefficients $\hat{f}_n$ for values of $n$ that are multiples of $P$ are non-zero, and this sparsity is exploited in the solution of the problem.

The expression in (36) and (37) can be simplified by defining

$$g(z) = \frac{1}{2 - f(z)} \tag{45}$$

Expanding $g(z)$ as a linear combination of powers of $f(z)$

$$g(z) = \frac{1}{2 - f(z)} = \frac{1}{2}\left(1 + \frac{1}{2}f(z) + \frac{1}{4}[f(z)]^2 + \ldots\right) \tag{46}$$

then this is periodic and can be expressed as

$$g(z) = \sum_{n=-\infty}^{\infty} \hat{g}_n \mathrm{e}^{\mathrm{i}nz} \tag{47}$$

where $\hat{g}_n = 0$ for all $n \neq mP$. Since the expressions in (36) and (37) and the higher derivatives are periodic, the terms $K_1(y,z)$, $K_2(y,z)$ and $K_3(y,z)$ can also be expressed in terms of Fourier series of the form

$$K_1(y,z) = \sum_{n=-\infty}^{\infty} \hat{k}_n^{(1)}(y)\,\mathrm{e}^{\mathrm{i}nz} \tag{48}$$

$$K_2(y,z) = \sum_{n=-\infty}^{\infty} \hat{k}_n^{(2)}(y)\,\mathrm{e}^{\mathrm{i}nz} \tag{49}$$

$$K_3(y,z) = \sum_{n=-\infty}^{\infty} \hat{k}_n^{(3)}(y)\,\mathrm{e}^{\mathrm{i}nz} \tag{50}$$

Because both $\hat{f}_n$ and $\hat{g}_n$ are non zero when $n$ is an exact multiple of $P$, then this will also be true for the coefficients, $\hat{k}_n^{(1)}$, in these expansions.

Using these expansions in the flow equation (22) gives

$$\sum_{n=-\infty}^{\infty} \hat{k}_n^{(1)}(y)\,\mathrm{e}^{\mathrm{i}nz}\left(\frac{\partial}{\partial y}\sum_{m=-\infty}^{\infty}\hat{U}_m(y)\mathrm{e}^{\mathrm{i}mz}\right) + \sum_{n=-\infty}^{\infty} \hat{k}_n^{(2)}(y)\,\mathrm{e}^{\mathrm{i}nz}\left(\frac{\partial^2}{\partial y \partial z}\sum_{m=-\infty}^{\infty}\hat{U}_m(y)\mathrm{e}^{\mathrm{i}mz}\right) + \sum_{n=-\infty}^{\infty} \hat{k}_n^{(3)}(y)\,\mathrm{e}^{\mathrm{i}nz}\left(\frac{\partial^2}{\partial y^2}\sum_{m=-\infty}^{\infty}\hat{U}_m(y)\mathrm{e}^{\mathrm{i}mz}\right) + \sum_{n=-\infty}^{\infty}\frac{\partial^2 \hat{U}_n(y)}{\partial z^2}\mathrm{e}^{\mathrm{i}nz} = -2\mathrm{Re} \tag{51}$$

Defining an inner product as

$$\langle p(y,z)q(y,z)\rangle = \int_0^{2\pi} \overline{p(y,z)}\, q(y,z)dz \tag{52}$$

then taking the inner product of the expression in (51) with a Galerkin trial function, $\mathrm{e}^{\mathrm{i}\ell z}$ and exploiting the orthogonality of the trial functions with respect to $z$

$$2\pi \sum_{m=-\infty}^{\infty} \hat{k}_{\ell-m}^{(3)}(y)\frac{\mathrm{d}^2\hat{U}_m}{\mathrm{d}y^2} + \left[\hat{k}_{\ell-m}^{(1)}(y) + \mathrm{i}m\,\hat{k}_{\ell-m}^{(2)}(y)\right]\frac{\mathrm{d}\hat{U}_m}{\mathrm{d}y} - m^2\hat{U}_m(y) = b_\ell \qquad \text{for } \ell \in \mathbb{Z} \tag{53}$$

where

$$b_\ell = \begin{cases} -4\pi\mathrm{Re} & \text{for} \quad \ell = 0 \\ 0 & \text{for} \quad \ell \neq 0 \end{cases} \tag{54}$$

If $U(y,z)$ is approximated by its projection onto a finite basis, then the summation is limited to $2M{+}1$ terms, and (53 reduces to $2M{+}1$ coupled second order, ordinary differential equations. The values of $\hat{U}_m(y)$ can be solved numerically at the Chebyshev points on $y \in [-1, 1]$ by stacking the values of $\hat{U}_m(y)$ at $K$ sample points for each $\ell$ into a vector $\hat{\mathbf{U}} \in \mathbb{R}^{(2M+1)K}$, so that

$$\hat{\mathbf{U}} = \left[\; \hat{\mathbf{U}}_{-M} \; \ldots \; \hat{\mathbf{U}}_{-1} \; \hat{\mathbf{U}}_0 \; \hat{\mathbf{U}}_1 \; \ldots \hat{\mathbf{U}}_M \;\right]^{\mathrm{T}} \tag{55}$$

where $\hat{\mathbf{U}}_m \in \mathbb{R}^K$ are the samples of $U_m(y)$ at the $K$ Chebyshev points [17], [18]. The discretised version of the coupled ODE's in (53) take the form

$$\mathbf{E}\hat{\mathbf{U}} = \mathbf{b} \tag{56}$$

where $\mathbf{b} \in \mathbb{C}^{(2M+1)K}$ contains the terms $b_\ell$. The $\mathbf{E} \in \mathbb{C}^{(2M+1)K\times(2M+1)K}$ consists of a series of blocks $[\mathbf{E}]_{\ell,m} \in \mathbb{C}^{K\times K}$, that satisfy

$$\begin{aligned}[\mathbf{E}]_{\ell,m} = \operatorname{diag}\left\{\hat{\mathbf{k}}^{(3)}_{\ell-m}\right\}\mathbf{D}_K^2 + \operatorname{diag}\left\{\hat{\mathbf{k}}^{(1)}_{\ell-m} + \mathrm{i}m\,\hat{\mathbf{k}}^{(2)}_{\ell-m}\right\}\mathbf{D}_K \\ - \operatorname{diag}\left\{m^2\right\}\end{aligned} \tag{57}$$

where $\mathbf{D}_K \in \mathbb{R}^{K\times K}$ and $\mathbf{D}_K^2 \in \mathbb{R}^{K\times K}$ are the first and second Chebyshev differentiation matrices respectively, and $\hat{\mathbf{k}}^{(1)}_{\ell-m} \in \mathbb{C}^K$, $\hat{\mathbf{k}}^{(2)}_{\ell-m} \in \mathbb{C}^K$, $\hat{\mathbf{k}}^{(3)}_{\ell-m} \in \mathbb{C}^K$ and $\hat{\mathbf{k}}^{(4)}_{\ell-m} \in \mathbb{C}^K$ are vectors obtained by sampling $\hat{k}^{(1)}_{\ell-m}(y)$, $\hat{k}^{(2)}_{\ell-m}(y)$ and $\hat{k}^{(3)}_{\ell-m}(y)$ at the $K$ Chebyshev points.

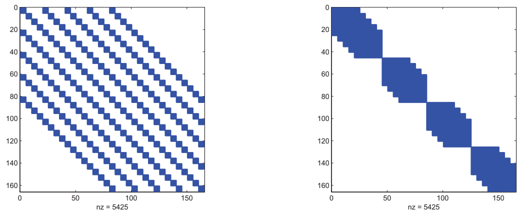

Fig. 2. Structure of $\mathbf{E}$ matrix (a) before reordering and (b) after reordering

The key point is that because $\hat{k}^{(1)}_{\ell-m}(y)$, $\hat{k}^{(2)}_{\ell-m}(y)$ and $\hat{k}^{(3)}_{\ell-m}(y)$ are only non zero when $\ell - m$ is an exact multiple of $P$, the $\mathbf{E}$ matrix has the structure shown in Figure 2(a), where each of the individual blocks has dimension $K$ by $K$. By rearranging the order of the terms in $\hat{\mathbf{U}}$, the structure of the $\mathbf{E}$ matrix can be arranged into the block diagonal form shown in Figure 2(b), which consists of $P$ blocks, each of dimension $[2(M/P)+1]K$ by $[2(M/P)+1]K$. This structure can be exploited to solve the overall problem as a set of $P$ individual sub-problems, which has two advantages. Firstly, solving $P$ smaller problems reduces the computational load by a factor of $P$, and secondly, the problem can be implemented as $P$ sub-problems, which can be solved separately.

*Remark 1.* For the case shown in the Figure 2, the first block has dimension $[2(M/P)+1]K$ by $[2(M/P)+1]K$, but the subsequent blocks have dimension $2(M/P)K$ by $2(M/P)K$. This is a consequence of using $2M+1$ terms in the finite Galerkin expansion in (43). To ensure that all blocks are of equal size, it is necessary to restrict the expansion to $2M$ terms so that $m \in \{-M+1, \ldots, -1, 0, 1, \ldots, M\}$, although this makes the indexing of the matrices more complicated.

*Remark 2.* To solve the steady state problem, it is only necessary to solve the sub-problem associated with the first sub-block, because the elements of the $\mathbf{b}$ vector associated with the other sub-problems are all zero. However, this will not be the case when solving the full linearised problem.

The linearised equations for the flow in (31) and (32) can be expressed in terms of Fourier series for

$$v(y,z,t) = \sum_{n=-\infty}^{\infty} \hat{v}_n(y,t)\mathrm{e}^{\mathrm{i}nz} \tag{58}$$

$$\eta(y,z,t) = \sum_{n=-\infty}^{\infty} \hat{\eta}_n(y,t)\mathrm{e}^{\mathrm{i}nz} \tag{59}$$

We discretize the problem using a Chebyshev grid in the $y$ direction, which reduces the differential operators in (31) and (32) to matrices [19]. Because of the orthogonality of the Galerkin approximation in the $z$ direction, the problem is reduced to a decoupled set of state space models of the form (the procedure is the exactly the same as in the derivation of (57) for the steady state solution, although the expressions are cumbersome, so details are given in [20])

$$\frac{d}{dt}\begin{bmatrix}\hat{\mathbf{v}}_\ell \\ \hat{\eta}_\ell\end{bmatrix} = \begin{bmatrix}\hat{\mathbf{L}}^\ell_{11} & \mathbf{0} \\ \hat{\mathbf{L}}^\ell_{21} & \hat{\mathbf{L}}^\ell_{22}\end{bmatrix}\begin{bmatrix}\hat{\mathbf{v}}_\ell \\ \hat{\eta}_\ell\end{bmatrix} \tag{60}$$

where $\hat{\mathbf{L}}^\ell_{11}$, $\hat{\mathbf{L}}^\ell_{21}$ and $\hat{\mathbf{L}}^\ell_{22}$ are the matrices obtained by discretizing the operators for each Fourier coefficient. The states are not functions of the streamwise position $x$ as it is assumed that the flow is streamwise constant.

The amplification of the energy at the output of the system resulting from the addition of Gaussian white noise at each sampling position in the Chebyshev grid can be found by solving the Lyapunov equation to find the controllability gramian, $\hat{\mathbf{X}}^\ell$ of the (discretized) system associated with each Fourier mode

$$\hat{\mathbf{A}}^\ell\hat{\mathbf{X}}^\ell + \hat{\mathbf{X}}^\ell\hat{\mathbf{A}}^{\ell\,\mathrm{T}} + \hat{\mathbf{Q}}^\ell = 0 \tag{61}$$

where $\mathbf{A}$ matrix is block diagonal

$$\hat{\mathbf{A}}^\ell = \begin{bmatrix}\hat{\mathbf{L}}^\ell_{11} & \mathbf{0} \\ \hat{\mathbf{L}}^\ell_{12} & \hat{\mathbf{L}}^\ell_{22}\end{bmatrix} \tag{62}$$

and $\hat{\mathbf{Q}}^\ell$ is the covariance matrix of the white noise, which has the structure

$$\hat{\mathbf{Q}}^\ell = \begin{bmatrix}\hat{\mathbf{Q}}^\ell_{11} & \mathbf{0} \\ \mathbf{0} & \hat{\mathbf{Q}}^\ell_{22}\end{bmatrix} \tag{63}$$

where $\hat{\mathbf{Q}}^\ell_{11}$ and $\hat{\mathbf{Q}}^\ell_{22}$ are diagonal. The structure of the problem can be exploited to break it into three separate equations [15], each of which can be solved efficiently using Cholesky factorizations [14].

The total amplification of the noise energy is given by the trace of $\mathbf{C}\hat{\mathbf{X}}^\ell\mathbf{C}^\mathrm{T}$, but the maximum amplification is given by the mode associated with the largest eigenvalue of this matrix, where $\mathbf{C}$ is the discretization of the output operators that relate $\hat{u}_\ell(y,t)$ and $\hat{w}_\ell(y,t)$ to $\hat{v}_\ell(y,t)$ and $\hat{\eta}_\ell(y,t)$. In practice, it is more efficient to exploit the structure of the problem by finding the largest singular value of $\mathbf{CR}$, where $\mathbf{R}$ is the Cholesky decomposition of $\hat{\mathbf{X}}^\ell$ in (61). The mode associated with the largest amplification is then given by the corresponding singular vector [13].

## V. Results

As an initial study, the effects of including a sinusoidal riblet for the linearised flow at a Reynolds number Re = 4200 are investigated. The $u(\tilde{y}, \tilde{z})$ component of the mode associated with the maximum amplification when riblets with peak to peak separation of $2\pi/8$ and amplitude 0.15 are introduced onto the lower wall in the channel flow is shown in Fig. 3. It can be seen that in this component, the flow is raised up above the riblets and the largest component of this flow occurs in the upper half of the channel. This has the effect of reducing the flow in the lower half of the channel, which in turn, reduces the gradient of the shear stress at the riblet wall. It should be emphasised that this models the linearised flow; in practice, it is likely that the nonlinear effects will have a more important role at this Reynolds number.

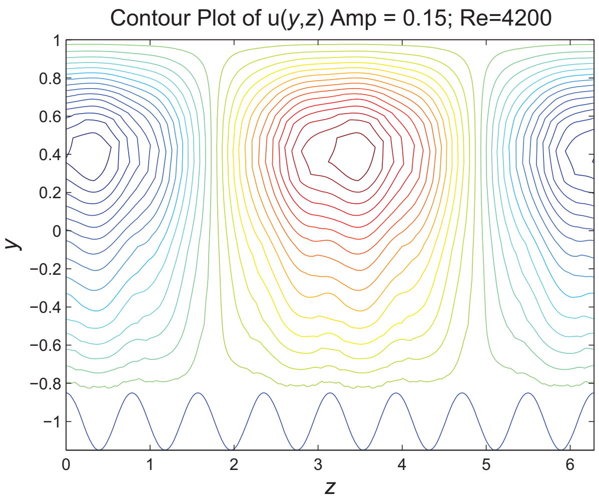

Fig. 3. Contour plot of streamwise velocity $u(\tilde{y}, \tilde{z})$ component of mode associated with maximum amplification for the case with riblets on lower wall.

## VI. Conclusion

This paper has developed a linearized model of the channel flow between two plates, where one of the plates has a riblet structure. The boundary conditions associated with the riblets are transferred into the partial differential equations describing the flow by applying a transformation of coordinates. The number of components in the flow equations are reduced by restricting attention to streamwise constant variations. By expressing the model in terms of spatial Fourier components in the spanwise direction, the structure of the resulting large-scale, finite-dimensional state space model can be exploited, allowing the amplification of noise energy to be obtained by calculating the controllability gramian via a set of decoupled Lyapunov equations. The model shows that for flow at low Reynolds numbers, the inclusion of riblets reduces the maximum amplification of the noise energy and it appears that this reduction in energy amplification may be associated with the presence of counter-rotating vortices at the peaks of the riblet structures. Current work is using the model to examine the effect of riblets on the energy amplification in flows at a range of Reynolds numbers and for a range of riblet amplitudes and separations.

*Abstract*— **this paper studies the key issue of fault tolerance for actively controlled railway wheelsets. It assesses failure modes in such systems, with a focus on actuator failures, and consequence of those hardware failures. It seeks to establish the necessary basis for control reconfiguration to ensure system stability and performance in the event of a faulty, without the need for hardware redundancies. A number of control schemes (with and without faults) are included in the study. Both analytical and simulation results are presented.**

***Keywords-Railway; Wheelset; Active control; Stability; Actuator; Fault tolerance.***

## I. INTRODUCTION

Conventional wheelset for the railway vehicle is composed of the two coned (or profiled) wheels rigidly fixed to a common axle to rotate at the same angular velocity. When an unconstraint wheelset rolling along the track it is displaced laterally due to track irregularities, the rolling radii therefore are different because of the profiles of these two wheelset. Consequently, different forward speeds obtained for each wheelset due to the difference rolling radii to provide a natural centering/curving action. However, an unconstrained wheelset also presents a problem of kinematic instability known as the "Kinematic Oscillation" or wheelset "hunting" [1,2].

Traditionally the wheelset is stabilized by using passive suspensions on conventional rail vehicle, but such additional stiffness affects the pure rolling action of the wheelset around the curve. It has been theoretically proven that to this design conflict between stability and curving performance can be solved by applying active control instead of conventional passive components within the primary suspension of railway vehicle [2].

Passive components in the primary suspensions can be designed in such a way not to fail in order to maintain the stability and steering performance of railway vehicle and they are generally accepted as "safe" in railway industry. However, any new technology must prove that it can cope with any failures to demonstrate that any component faults would not lead to the system failure such that passenger safety is not compromised under such conditions. From a practical point of view, any active control scheme must be also able to maintain an effective operation of a rail system in order to meet the necessary standard of reliability [3]. Hardware redundancy technique may be used in the system to guarantee safety operation of such a system. Whilst it may be acceptable to apply the above technique in sensors due to their relatively low cost, it is far more difficult to justify the use of multiple actuators in a cost effective manner for redundancy or accommodate those within the limited space of railway bogie [3]. There are two main approaches for fault tolerant control systems. The first philosophy relies on the existing system redundancies to achieve acceptable performance in the event of component failures. In this type of systems, once the controllers designed, it will remain stable. It should be noted that the redundancies in such a system are usually in hardware forms. The second methodology takes a completely different approach to achieve fault tolerance. It involves such procedures as real-time fault detection, isolation, and control system reconfiguration. The redundancy in such a system may be an analytical form [4] and help to minimize the use of the hardware redundancies in order to keep the overall cost down [5].

The object of this study is to develop the fault tolerance approaches without using redundant actuators to provide stability across a range of operation conditions with different failure modes. It investigates the possibilities/feasibilities of re-configuring the controller based on the use of remaining actuator(s) in the system. For this study, the paper will review first a number of different control methods for railway wheelsets in the normal condition to understand how control for stability and/or curving performance is achieved. A thorough assessment of failure modes and adverse effect of the faults on the system stability and performance is then carried out, followed by an investigation into control re-tuning/re-configuration for fault tolerance. The paper is organized as following. The mathematical dynamic model of railway vehicle is presented in Section п. Consideration of basic

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

control scheme is given in section ш. Section V demonstrates the different fail modes of railway vehicle with the actuator faults and re-configuration of the controller based on the remaining actuator Finally, conclusion and future work will be discussed.

## II. Mathematical model of the rail way vehicle

A railway vehicle mainly consists of a vehicle body and two bogie frames, and each bogie frame consists of a bogie frame and the two wheelsets. The wheelsets are connected to the bogie frame with springs and dampers in the longitudinal and lateral directions. For this study, only the plan-view dynamics of a half vehicle is used to analysis stability and steering performance of the vehicle, which is the accepted practice in railway industry [6]. Fig.1 gives a plan-view diagram of the half body vehicle model used for this study. The equations of motion for a railway vehicle when running along a track are mainly determined by the creep forces between wheel and rail contact patches. In this paper, a linear model has been considered, which is justified as the active control tends to reduce the effect of non-linearity in the wheelsets [7]. The linear model of the motion contains seven degrees of freedom, i.e. the lateral and yaw motions for each wheelset and for the bogie frame, and a lateral displacement for the vehicle body defined by (1) to (7). The model is therefore 14th order in total, and can be represented in the state space model by (8) [6].

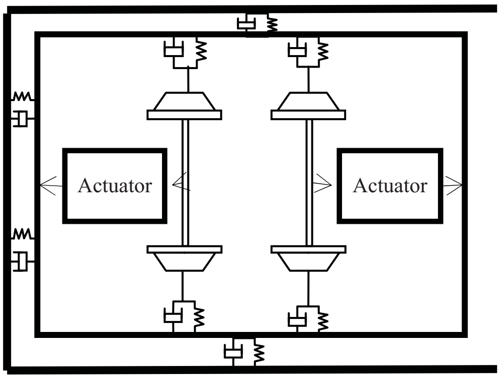

Figure 1: Plane-view of the vehicle

The input vector $u$ represents the control inputs to the wheelsets, and the vector $\mu$ is used to represent the inputs from the railway track, including the lateral displacement, cant, and curvature. The lateral track displacement is a random input, which represents track irregularities along the path track, whereas the track curvature and cant are the deterministic inputs [6]. More details of the vehicle parameters in the equations are provided in the Appendix A.

$$\ddot{y}_{w_1} = -\frac{1}{m_w}[(\frac{2f_{11}}{V_s}+C_s)\dot{y}_{w_1} - K_s y_{w_1} + 2f_{22}\Psi_{w_1} + C_s\dot{y}_g + K_s y_g$$

$$+C_s L_v \dot{\Psi}_g + K_s L_v \Psi_g + m_w(\frac{V_s^2}{R_1} - g\cdot\theta_{c_1})], \tag{1}$$

$$\ddot{\Psi}_{w_1} = -\frac{1}{I_w}[\frac{-2f_{11}L_g^2}{I_w V_s}\dot{\Psi}_{w_1} - \frac{-2f_{11}\lambda L_g}{I_w r_0}y_{w_1} + \frac{2f_{11}L_g^2}{I_w R_1}$$

$$-\frac{-2f_{11}\lambda L_g}{I_w r_0}y_{t_1} + \frac{\tau_{w_1}}{I_w}], \tag{2}$$

$$\ddot{y}_{w_2} = -\frac{1}{m_w}[(\frac{2f_{11}}{V_s}+C_s)\dot{y}_{w_2} - K_s y_{w_2} + 2f_{22}\Psi_{w_2} + C_s\dot{y}_g + K_s y_g$$

$$-C_s L_v \dot{\Psi}_g - K_s L_v \Psi_g + m_w(\frac{V_s^2}{R_2} - g\cdot\theta_{c_2})], \tag{3}$$

$$\ddot{\Psi}_{w_2} = -\frac{1}{I_w}[\frac{-2f_{11}L_g^2}{I_w V_s}\dot{\Psi}_{w_2} - \frac{-2f_{11}\lambda L_g}{I_w r_0}y_{w_2} + \frac{2f_{11}L_g^2}{I_w R_2} \tag{4}$$

$$-\frac{-2f_{11}\lambda L_g}{I_w r_0}y_{t_2} + \frac{\tau_{w_2}}{I_w}],$$

$$\ddot{y}_g = \frac{1}{m_g}[-(2\cdot C_s + C_{sc})\cdot\dot{y}_g - (2\cdot K_s + K_{sc})y_g + C_s\dot{y}_{w_1}$$

$$+K_s y_{w_1} + C_s\dot{y}_{w_2} + K_s y_{w_2} + C_{sc}\dot{y}_v + K_{sc}y_v \tag{5}$$

$$+m_g V_s^2(\frac{1}{R_1}+\frac{1}{R_2}) - m_g g(\frac{\theta_{c_1}}{2}+\frac{\theta_{c_2}}{2})],$$

$$\ddot{\Psi}_g = \frac{1}{I_g}[-2L_v^2 C_s\dot{\Psi}_g - 2L_v^2 K_s\Psi_g + L_v C_s\dot{y}_{w_1} - L_v C_s\dot{y}_{w_2} \tag{6}$$

$$+L_v K_s y_{w_1} - L_v K_s y_{w_2} - (\tau_{w_1} + \tau_{w_2})]$$

$$\ddot{y}_v = \frac{1}{m_v}[-C_{sc}\dot{y}_v - K_{sc}y_v + C_{sc}\dot{y}_g + K_{sc}y_g$$

$$+m_v V_s^2(\frac{1}{2R_1}+\frac{1}{2R_2}) - m_v g(\frac{\theta_{c_1}}{2}+\frac{\theta_{c_2}}{2})], \tag{7}$$

$$\dot{x} = A\cdot x + B\cdot u + \mu\cdot w, \tag{8}$$

$$x = [\dot{y}_{w_1} \quad y_{w_1} \quad \dot{\Psi}_{w_1} \quad \Psi_{w_1} \quad \dot{y}_{w_2} \quad y_{w_2} \quad \dot{\Psi}_{w_2} \quad \Psi_{w_2} \quad \dot{y}_g \quad y_g \quad \dot{\Psi}_g \quad \Psi_g \quad \dot{y}_v \quad y_v]$$

$$u = \lfloor \tau_{w_1} \quad \tau_{w_2} \rfloor,$$

$$\mu = \begin{bmatrix} y_{t_1} & \theta_{c_1} & \frac{1}{R_1} & y_{t_2} & \theta_{c_2} & \frac{1}{R_2} \end{bmatrix},$$

## III. BASIC WHEELSET CONTROL SCHEMES

The railway wheelset can be stabilized by using either passive suspension or through the use of active control. For active approaches, it is possible to achieve this by applying either a yaw torque or lateral force between the bogie and the wheelset, but the yaw control is preferred as it also tends to improve the ride quality experienced by passengers [8]. Therefore, this study only discusses approaches that apply control in the yaw direction to provide desired damping to stabilize the system. The review of the control strategies is to provide a background for the study of fault tolerant control issues and more detail of the controls can be found in the references provided [9,6,10]. The suspension/control schemes are considered in the study are:

- Passive Suspension that uses conventional passive yaw stiffness in the primary suspensions.
- Active Yaw Damping where the two wheelset of the bogie are controlled by applying a yaw torque proportional to the lateral velocity of the wheelset.
- Sky-hook Yaw Stiffness where the control output of each actuator is set to be proportional to the absolute yaw motion of each wheelset
- Optimal Control where the controllers for the two inputs (actuators) are designed with the use of full state feedback (from either direct measurements or through the use of an estimator).

The track input used in the simulation, to study the control performance on curves for both active controllers and passive suspension, represents a curved track with radius of 1250m connected to straight track via a transition of 2sec. The curved track is canted inward by 6 degrees to reduce the lateral acceleration experienced by the passengers (a normal features of railway track). The vehicle speed of 50m/s is used – parameters of the vehicle are provided is Appendix A. The simulation result in Fig.2 and Fig.3 clearly illustrates that active control can provide good curving performances to reduce the longitudinal and lateral creep forces, compared with passive suspension, when both leading and trailing actuator functioning normally.

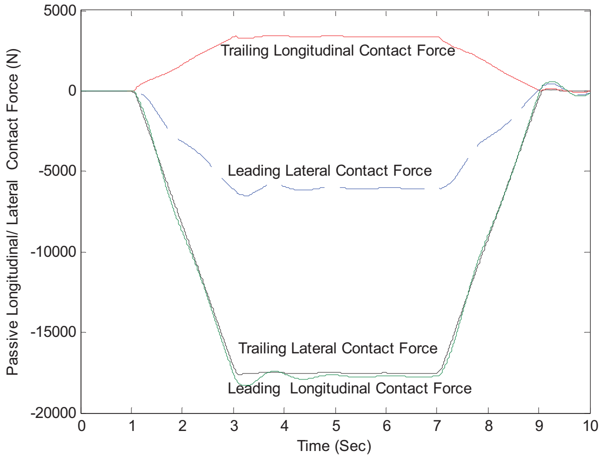

Figure 2: Passive Longitudinal/ Lateral creep forces

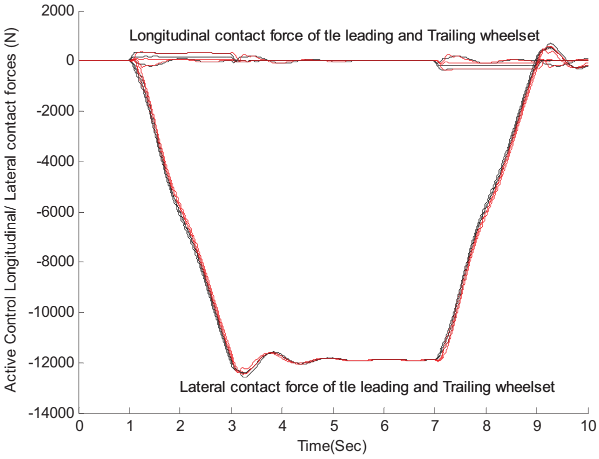

Figure 3: Active control Longitudinal/ Lateral contact forces

However, the active controllers are designed based on the assumption that both actuators function as expected and extra measures (possibly through the use of fault tolerance) will be needed in order to maintain the stability and if possible curving performance if one of the control channels fails to deliver. Therefore, it is essential to establish first a full understanding how the fault(s) affect the bogie dynamics in the system and then define what corrective actions can be taken [3].

## IV. CONTROL ANLYSIS IN FAULT CONDITIONS

In the normal condition with both actuators functioning, the bogie is designed to be stable. Fig.4 shows the minimum damping ratio of the wheelset modes with the different controllers where the stability is achieved across a wide range of speed with a critical speed of over 100m/s in the three of controllers except active yaw damper [3].

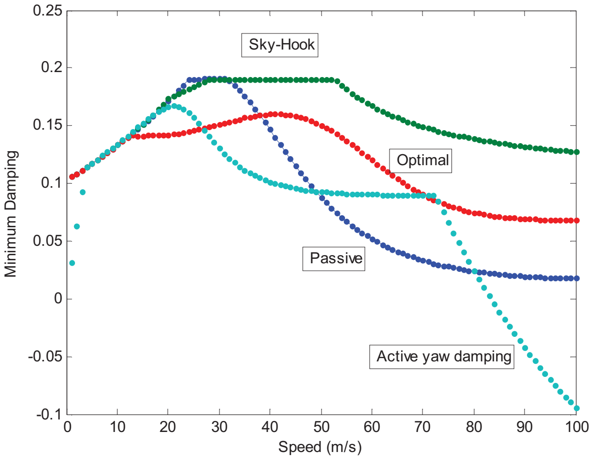

Figure 4: Comparison of different control scheme

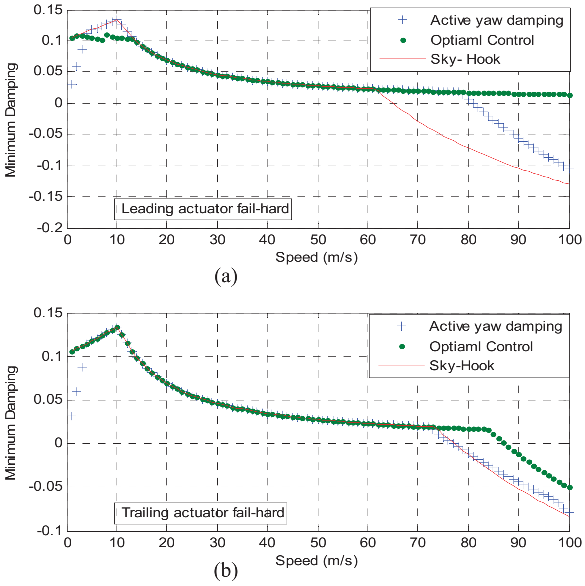
However, this is expected to change dramatically, when one of the actuators fails. In this study, two failure modes are considered – one is fail-hard and the other fail-soft, representing an actuator jam and free-motion respectively.

The aim of fault tolerance for actively control system is to preserve stability conditions and maintain the current curving performance close to desired ones (or at least not worse than the passive system in the normal condition) in the presence of actuator faults. In this study, the full state feedback is considered as a start point and a control gain matrix is designed to control the remaining actuator in order to explore the fault tolerant control possibilities.

### *A. Fail-Hard*

In the fail hard mode, one of the actuators is assumed to be blocked and can be simulated as a spring with very high stiffness between the bogie frame and the axle. The bogie stability at different speed for the selected active control schemes are compared in Figs.5a and 5b, where the fail hard occurs in the leading and trailing wheelset respectively. In Figs.5a and 5b, the critical speed is reduced to 62m/s for the active sky-hook control scheme with the malfunction of the leading actuator and around 75m/s if the trailing actuator fails-hard respectively. A fault in the trailing actuator would result in an even lower critical speed for all three active control schemes. However the fail-hard condition poses a more problem for the curving performance of the bogie.



(a)

(b)

Figure 5: Stability of different control schemes with leading/trailing fault

The simulation result in Fig.6 and Fig.7 indicate clearly that when fail hard occurs in the leading and trailing control input respectively, the original controller will not be able to provide the 'right' control effort as the contact creep forces at the both leading and trailing wheelset increase significantly on the curved track, delivering a poor steering condition. The objective of the fault tolerance in the fail-hard case is therefore is to try and minimize the adverse impact of the actuator failure on the curving performance. It can be seen that the curving performance is more under risk when fail-hard occurs for the leading actuator. The simulation results in Fig. 6 and 7 suggest that the contact forces with the original controller are even worse than that with the passive suspension (Fig.2). However, retuning of the control gains for the remaining actuator does seem to provide a solution to improve curving performance of the bogie in the event of fail-hard in the leading or trailing actuator as evidenced by results in Fig.8 and Fig.9 respectively. The simulation results in Fig.8 and 9 in comparison with Fig.6 and 7 of the original controller indicate that the re-tuned optimal controller for the remaining actuator can reduce the contact forces and maintain curving performance close to that of the passive suspension. In this approach optimal controllers are tuned manually by choosing different values for weighting factor. Although the stability is guaranteed with the optimal control design, the re-design of the other active control schemes is less straight-forward and the research is ongoing to ensure such designs will meet both stability and performance requirements, e.g. by applying optimization technique to search for the best control structures and control gains.

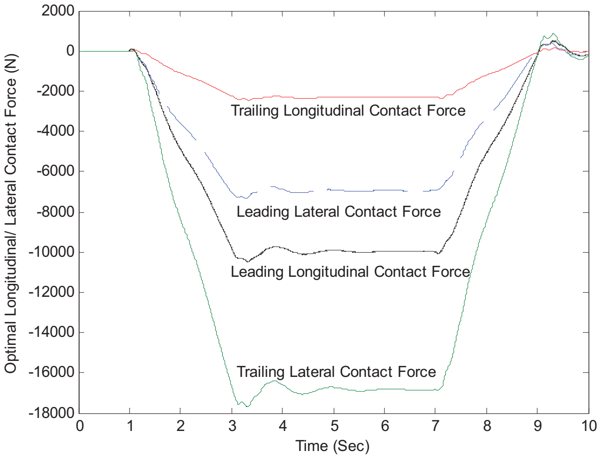


Figure 6: Original controller optimal controller /Leading Fail Hard

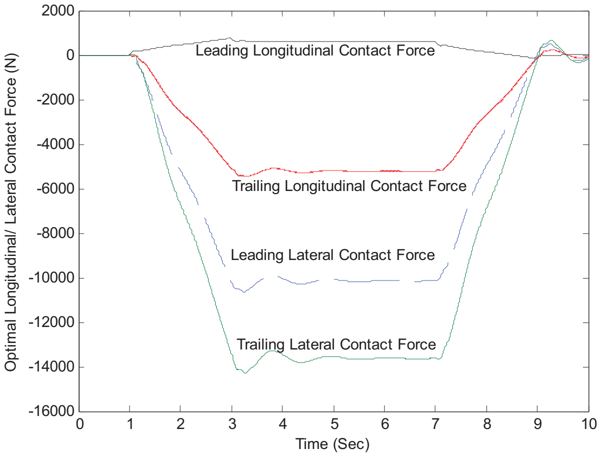

Figure 7: original optimal controller/Trailing Fail Hard

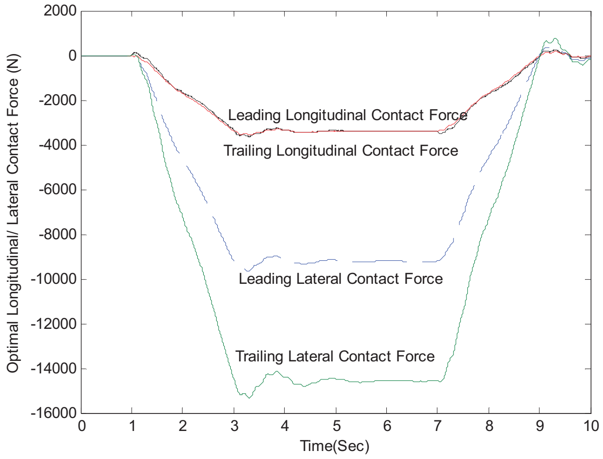

Figure 8: Retune manually optimal controller/ Leading fail Hard

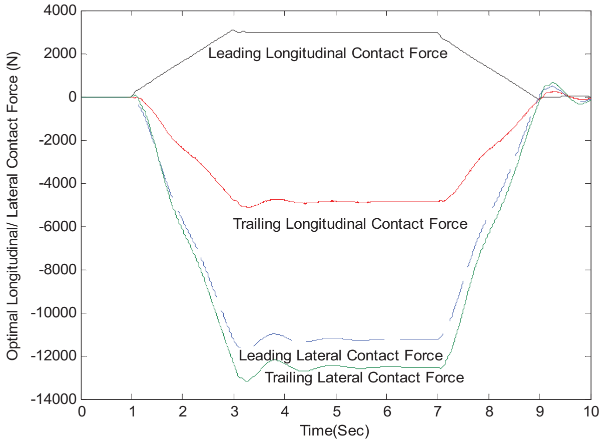

Figure 9: Retune manually Optimal Controller/ Trailing Fail Hard

## B. *Fail-Soft*

The second type of the actuator malfunction is known as fail-soft, which is when one of the actuator is unconstraint from its control input. Control torque for the failed actuator in this scenario is zero and therefore not able to stabilize the kinematic mode of the wheelset. Figs.10a and 10b compares with the stability of the bogie with different active control schemes when one of the actuators fail-soft [3]. In Figs.10a and 10b, the critical speed is reduced to approximately 10m/s for all three active control schemes in the event of an actuator fault. Clearly, in the event of fail-soft condition the active controller would not able to stabilize the system and the operation speed of the system will have to be reduced very quickly to a very low level to avoid potentially dangerous situation if no other corrective actions are taken [3].

Therefore, in this scenario, the priority of fault tolerance for the active control systems is to preserve stability control in the presence of actuator fail-soft, with the curving performance a secondary design issue.

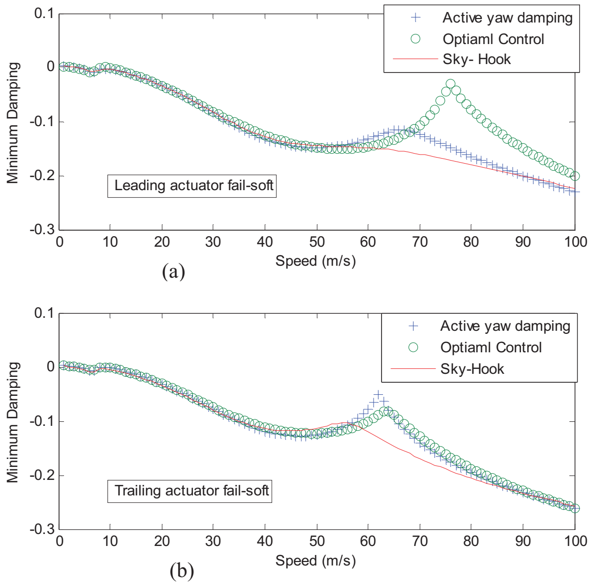

Figure 10: Stability of the different controller with leading/trailing actuator

In the event of fail-soft, the bogie stability is guaranteed if the number of control input is reduced from two actuators to one, and therefore more feedbacks are available for more sophisticated control design to provide desired control torque through the remaining actuator [3]. Fig.11 clearly reveals the bogie stability across a wide range of speed through re-designing of the optimal controller with one control input. It is also necessary to assess performance of redesign controller around the curve. Fig.12 gives the lateral and longitudinal contact forces at the wheel-rail contact points for the leading and trailing wheelset in the event of fail soft at the trailing actuator. The simulation result indicates clearly when the controller is re-designed with one control input (representing the remaining actuator), the perfect steering condition is achieved on the curved track, where the longitudinal contact forces at both leading and trailing wheelset are zero and the lateral contact forces of the two wheelsets are equal [13].

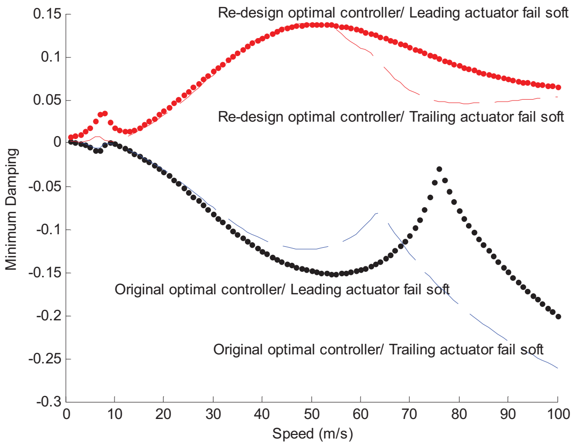

Figure 11: Stability of original / re-design optimal controller with leading/trailing fail soft in actuator

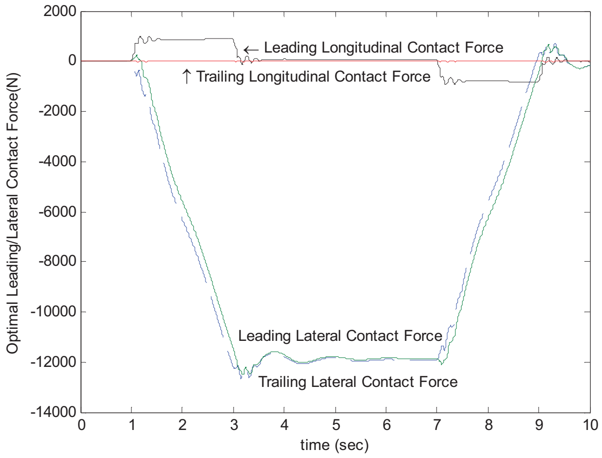

Figure 12: Curving performance of re-design optimal controller with trailing fail-soft

## V. CONCLUTION AND FUTURE WORK

This paper has studied the fundamental fault tolerant control issues for actively controlled railway vehicles through analytical redundancy to guarantee controllability of the system in the event of actuator fault. A reconfiguration based strategy for managing both soft and hard faults has been investigated, focusing on solving instability and curving performance issues respectively. The design reconfiguration controller has been evaluated by their performance capability as evidenced in simulation results.

Research is ongoing to develop optimization technique to search for the best control gain and control structure in the event of fail-hard in such a way that ensure both stability and curving performance. However, there is clearly scope for extending the work other failure modes with different actuator configurations.

*Abstract*— **Thermocouples are the most widely used and most widely misunderstood temperature sensor in industry. This paper will begin with an introduction to thermocouples, how they work and the different types of thermocouple. The commonest and most misunderstood source of uncertainty, thermoelectric homogeneity, will be described. The paper will then discuss the concept of measurement traceability and new calibration methods that can give <1 °C uncertainty up to 1500 °C. The paper will conclude by describing some thermocouple innovations; a) industrial versions of pure thermoelement types (Pt/Pd) and b) self-validating "smart-sensors" which enable thermocouples to remain in calibration even when operating at extreme temperatures e.g. tungsten rhenium (W-Re) refractory metal types (e.g. type C) above 2200 °C.**

***Keywords- energy efficiency, industrial process, process control, smart sensors, high temperatures, thermocouples, calibration, traceability, uncertainty***

## I. Introduction

Thermocouples are used extensively in industry for process control. The reliable manufacture of, for example, iron and steel, glass, semiconductors, carbon and carbon composites, ceramics, refractory metals and nuclear fuel is dependent upon thermocouples. However thermocouples drift and degrade with use. If this drift can be ameliorated or reduced then the processes would run more optimally, so reducing energy consumption and improving product quality. New developments in thermocouples in particular, improved calibration, a new thermocouple type and approaches to self-validation at very high temperatures will lead to improved thermometry for more effective industrial production.

Most thermocouples in common use are identified by a letter designation. Thermocouples for industrial process control at high temperatures fall broadly into three categories, dependent upon the wires used for the thermoelements. Below 1300 °C base metal (nickel alloy) type K and increasingly, due to better stability, type N are used. Above those temperatures and up to about 1700 °C noble metal thermocouples (based on Pt and/or Pt/Rh alloys) are used; these are designated type S, R and B. Then finally, at still higher temperatures refractory metal thermocouples (based on alloys of tungsten (W) and Rhenium (Re)) are used up to approximately 2300 °C.

The foundation of reliable temperature measurement is traceability to an internationally recognized temperature scale. This is currently the International Temperature Scale of 1990 (ITS-90) [1]. All temperature measurement should be traceable to ITS-90 to ensure equivalence. This means that sensors should be calibrated to this temperature scale. In practice (and in particular) base metal thermocouples are manufactured to a specified tolerance and should, at least when new, give reliable temperature measurement. The wires or cables are batch tested before thermocouples are manufactured to ensure that they meet the required specification. Calibration is generally performed against reference thermometers in an isothermal calibration environment. The noble metal thermocouples, which are often the reference sensors, are calibrated against fixed points of known temperature. Recent innovations in the approach to thermocouple calibration, and in particular the advent of completely new fixed points, have meant that lower uncertainty and more reliable calibrations can be performed – at least to 1500 °C - for noble metal thermocouples.

In addition, it is known that type S, R and B thermocouples drift due to the alloy nature of one or both of the thermoelements. The recently developed pure thermoelement robust thermocouple based on platinum and palladium wires (the Pt/Pd thermocouple) is not subject to this source of drift and can give considerably more reliable results than the traditional noble metal thermocouples to 1500 °C.

At higher temperatures, and in particular above 1700 °C, refractory metal thermocouples (based on alloys of W and Re) are used for process control. However this type of thermocouple can experience significant drift in use leading to non-optimal control. Very recent work, particularly at NPL, has led to the development of self-validation where thermocouples such as these can be continually calibrated in process leading to a factor 10 or more improvement in their in-use performance.

Beginning with a short introduction to the temperature scale and the calibration of thermocouples this paper will describe how new high temperature fixed points (HTFPs) have improved thermocouple calibration to 1500 °C, how the

978-1-4673-1560-9/12/$31.00 ©2012 Crown

innovation of robust Pt/Pd thermocouples opens up the possibility of better temperature sensing and control to that temperature and how the implementation of self-validation at very high temperatures will make a step change improvement in the practice of high temperature contact thermometry.

## II. The International Temperature Scale of 1990 (ITS-90) and Calibration

### *A. The ITS-90*

The ITS-90 is the current temperature scale in use throughout the world, and all reliable temperature measurement is established through traceability to it. The ITS-90 ranges from 0.65 K above absolute zero, or -272.50 °C, to the highest temperatures (>3000 °C) for practical thermometry. The purpose of the ITS-90 is to define procedures by which certain specified practical thermometers can be calibrated in such a way that the values of temperature obtained from them are precise and reproducible, while at the same time approximating the corresponding thermodynamic (ideal) values as closely as possible. The "specified practical thermometers" are platinum resistance thermometers (PRT) from about 13.8 K (-259.4 °C) to the freezing point of pure silver (961.78 ºC) and radiation thermometers at higher temperatures. These thermometers are calibrated against a series of fixed points which are generally either triple points (e.g. argon, mercury, water), freezing points (e.g. silver, zinc, tin, indium) and in one case (gallium) a melting point. These have defined temperatures, formally with zero uncertainties. Below the silver point a calibration essentially determines the resistance ratio of the PRT at a specified set of fixed points relative to the water triple point. At and above the silver point the ITS-90 is established by non-contact thermometry using Planck's law in ratio form. A blackbody of either Ag, Au or Cu is used to provide the foundation for the ITS-90 in that range. The interested reader should consult references [1, 2] for further information about the ITS-90.

### *B. The calibration of thermocouples*

Calibration as applied to temperature measurement can be defined as *'the set of operations which establish, under specified conditions, the relationship between values indicated by a thermometer and the corresponding known values of temperature'* adapted from [3].

There are two principal types of calibration: comparison calibration, and fixed-point calibration. In a comparison calibration, the environment may be a variable-temperature bath or furnace which can be controlled at the desired uniform temperature. The thermometers to be calibrated are inserted into the environment along with standard thermometers which are calibrated in terms of the ITS-90, and measurements are made in an appropriate sequence. In this way the readings of the thermometers under calibration are related to the temperature as determined by the standards.

Fixed-point calibrations are generally more precise and demanding than comparison calibrations. Typically the fixed-point temperature is given by the freezing points (except gallium where the melting point is used) of pure materials, whose temperatures are defined in the ITS-90 (see Section II.*A* above). Generally the metallic fixed-points are in a state of near-equilibrium between the liquid and solid phases of a pure substance at a pressure of one standard atmosphere. The only exception to this is the mercury fixed-point where the triple point is realised. The freezing point technique requires heating the cell to about 5 to 10 °C above the melting temperature, insertion of a monitoring thermometer which indicates when the metal ingot is completely melted. The ingot is then slowly cooled while continuously logging the output of the monitoring thermometer. After an initial supercool the temperature rises to the freezing-point. The calibration measurements are made in the ensuing flat portion, or plateau, of the freezing curve, so giving the calibration of the thermometer at the freezing point. Typical fixed point materials used in the calibration of thermocouples are zinc (419.527 °C), aluminium (660.323 °C), silver (961.78 °C) and copper (1084.62 °C).

A discussion of what thermocouples are and how they work is deferred until Section IV.

## III. High Temperature Fixed Points, HTFPs

For the purpose of clarity HTFPs are those that operate above the freezing point of Cu (1084.62 °C) and are based on various types of binary alloys of metal (or metal-carbide) and carbon [4, and references therein]. These are new fixed points, under development in the last 10 years, and as such they have not yet had formal temperatures assigned to them. Table 1 lists the reported fixed-points to date, with their nominal transition temperatures.

The performance of HTFPs has been well characterised, particularly the repeatability and the reproducibility of their realised temperatures. A typical melt and freeze curve for a HTFP (Co-C) is given in Fig. 1.

Repeatability is a measure of how repeatable the temperature of an individual HTFP is when realized in quasi-identical conditions. That is, if a HTFP was melted in a furnace, then immediately frozen and melted again in the same furnace, repeatability is a measure of the agreement between the two melt temperatures. It is clear that individual HTFPs are highly repeatable, of the order of 0.02 °C even at the highest temperatures [4].

Reproducibility is a more exacting criterion than repeatability. It is a measure of the agreement in the melting temperature of two samples of HTFP material, especially if manufactured by two different suppliers. Good reproducibility is attainable when impurities in the metal of the ingot are carefully controlled. For example it has been shown that for Co-C, Pt-C and Re-C reproducibility of better than 0.1 °C can easily be achieved [5].

TABLE 1: METAL-CARBON, METAL-CARBIDE-CARBON AND METAL-CARBIDE-CARBON PERITECTICS WITH NOMINAL TEMPERATURES [6]

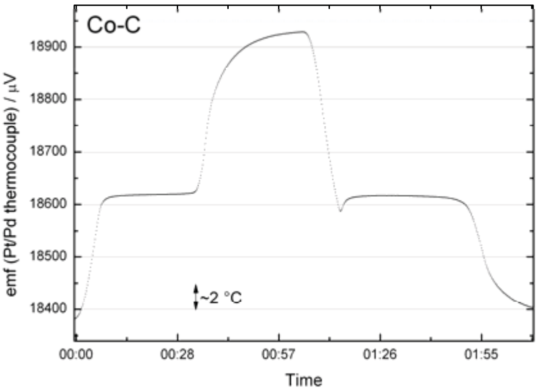

Figure 1: Melting and freezing curve of an NPL Co-C point as measured by a Pt/Pd thermocouple. The x-axis is time in hours:minutes..

The main use of HTFPs to date has been comparing high temperature scales for radiation thermometry [e.g. 5] and the calibration of thermocouples to 1500 °C. NPL now has fully implemented ISO 17025 calibration of noble metal thermocouples using HTFP ingots of Co-C and Pd-C. The accredited uncertainty of noble metal thermocouple calibrations is 0.5 °C (*k*=2) at 1324 °C (the Co-C point) and 0.7 °C (*k*=2) at 1492 °C (the Pd-C point). To obtain the lowest uncertainty calibration for industrial customers accredited laboratories are beginning to implement HTFPs within their calibration process as well [7].

## IV. THERMOCOUPLES

In this section we describe briefly what thermocouples are, how they work and the various types. The common and often largest source of uncertainty, that due to inhomogeneity is discussed. Then the pure thermoelement thermocouple based on Pt and Pd will be introduced and its superior performance described.

### *A. Thermocouples what they are and how they work*

Thermocouples are made of two dissimilar wires joined together at the measurement junction. As the wires pass through a region where the temperature changes (i.e. where there is a temperature gradient) they generate an emf, or thermovoltage. This is the Seebeck effect, named after its discoverer, and its magnitude, typically about 10-40 μV/°C, depends on the Seebeck coefficients of the thermocouple wires and the temperature difference along the total length. The emf can be measured by connecting the wires to a voltmeter. However, it depends on the temperature at the cold end, so for the most accurate measurements the wires are connected to copper leads and placed in melting ice to form the 'reference junction', and the copper wires are then connected to the voltmeter. Fig. 2 is a schematic circuit diagram of a thermocouple of wires *a* and *b* measuring temperature $t_1$, with reference junctions connected to copper wires at temperature $t_{ref}$, generating an emf , *E*.

It is important to remember that the emf is not generated at the measurement junction but in the region where the thermocouple experiences a temperature gradient. So for example when a thermocouple is being calibrated in a furnace most of the emf is generated in the region where the thermocouple emerges from the furnace, not in the isothermal part where the measuring junction is [8].

This is such an important point it is worth discussing in detail. The emf generated at any point along the wire can be written as the product of the Seebeck coefficient, *S(t)* and the temperature gradient at that point *dt*. The total emf is found by adding the emfs *S(t)dt* generated at all points along the length, starting from the reference junction and continuing to the measuring junction. Mathematically this is expressed as integrating *S(t)dt* from $t_{ref}$ to $t_1$. As what is measured is the difference between the emfs generated in the two wires of the thermocouple, with different Seebeck coefficients $S_a$ and $S_b$, the total emf, *E*, is the difference between two integrals (1):

$$E = \int_{t_{ref}}^{t_1} S_a dt - \int_{t_{ref}}^{t_1} S_b dt = \int_{t_{ref}}^{t_1} (S_a - S_b) dt \qquad (1)$$

In the simple case where the two Seebeck coefficients are independent of temperature, the equation reduces to (2)

$$E = (S_a - S_b)(t_1 - t_{ref}) \qquad (2)$$

so the emf is just the product of the difference in the two Seebeck coefficients and the temperature difference between the ends of the wires. This does not mean that the emfs are generated at the junctions but, as we have emphasized, the two junction temperatures are just the start and finish of the integration, or summation of emfs in the circuit.

Note that in the circuit of Fig. 2, the two copper wires, *c*, ideally produce equal and opposite emfs, so they do not contribute to the total result. Note also that, rather than use ice, these days an automatic electronic ice-point is often used. More commonly, however, the thermocouple wires are directly connected to instrumentation that has automatic ‘cold-junction compensation’.

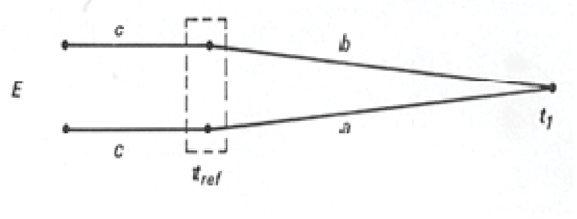

Figure 2: Schematic circuit diagram of a thermocouple being used to measure $t_1$, from [9]. The letters *a* and *b* represent two different types of thermoelement, letter *c* represents the copper wires and $t_{ref}$ the reference temperature – usually the ice point.

Provided that the junctions are isothermal, i.e. that there are no temperature gradients near them, the way in which they are made is not important; they can be twisted, clamped, soldered or welded together. The important point is that they must be isothermal and sufficiently robust to keep the wires connected together thus completing the circuit.

### B. *Types of thermocouples*

There are many types of thermocouple, and several are standardized and recognized by a letter designation. They also fall into three broad categories depending upon the metal the thermoelements are made from; these are base metal, noble (or precious) metal and refractory metal.

In base metal types for relatively low temperature applications, designated type T, J and E, the thermoelements are made of copper or copper-nickel alloys. For example the type T has a positive thermoelement of pure Cu and a negative thermoelement made of copper alloyed with about 45% nickel. This thermocouple is known as the copper-constantan thermocouple. Base metal types for higher temperature applications, up to 1300 °C, are designated types K and N. Here the thermoelements are based on nickel alloys. The type N positive thermoelement is Nicrosil from an alloy of Ni, Cr and Si, the negative thermoelement is Nisil, made from an alloy of Ni, Si and Mg.

Noble metal thermocouples (generally for high temperature applications) can be used continuously in oxidizing atmospheres up to about 1600 °C. They are designated types S, R and B and the thermoelements are based on pure platinum and varying proportions of Pt-Rh alloy. For example the type R thermocouple has a positive thermoelement of Pt alloyed with 13%Rh and a negative thermoelement made of pure Pt. There is also the pure thermoelement thermocouple Pt/Pd (see Section IV:*D* below) which has superior performance to other the noble metal alloy types, in particular circumstances, but its top temperature is limited to 1500 °C.

Refractory metal thermocouples are generally used above 1300 °C where noble metal thermocouples are too expensive for the application, and above 1600 °C to approximately 2300 °C where no other thermocouples are available for use. They are designated types C, G and D and the thermoelements are constructed from tungsten and/or various alloys of tungsten and rhenium. The most common refractory metal thermocouple, type C, is made from W5%Re (positive thermoelement) and W26%Re (negative thermoelement).

Thermocouples are manufactured to different tolerance classes depending on how closely they match the specified emf. The best is tolerance class I ranging to tolerance class III for some thermocouples. More details can be found elsewhere [10] but for illustrative purposes a tolerance class I type R thermocouple has a tolerance value of ±1 °C in the temperature range 0 °C to +1100 °C.

The purpose of this section was to give an introduction to the operation of thermocouples and the standard thermocouple types. More information can be found in classic texts such as Kinzie [8] or at [9, 10, 11]. The rest of this section will describe a common source of uncertainty, often the largest, and often not identified, the thermoelectric inhomogeneity and will conclude by describing the construction and performance of the non-letter designated Pt/Pd thermocouple.

### C. *Uncertainty arising from thermoelectric inhomogeneity*

As discussed in Section IV:*A* the thermovoltage from a thermocouple is generated where it experiences temperature gradients. In industrial applications this means that the thermovoltage is usually generated when the thermocouple passes through a furnace wall to the outside environment.

The manufacture of thermocouple wires is carefully controlled so that when new the wires are homogenous (uniform) in alloy and (particularly noble metal types) are generally annealed so that strain is removed. However in use several things happen to disturb the freshly constructed state. Examples are; non-uniform contamination of the wires from the external environment, movement of the alloying materials within the wires and crystal growth within the wires. These effects mean that after use the wires are no longer homogeneous in composition, and the effect of this is magnified when used at high temperatures.

The consequence of the wire being non-uniform in composition or crystal structure (or both) is that the Seebeck coefficient varies with position along the wire. This means that if the affected part of the thermocouple is where the temperature gradient is, the generated thermovoltage will be in error with a consequent error in the measured temperature. This effect can be quite severe, in base and refractory metal thermocouples, >10 °C errors are not uncommon.

Finally the problem of inhomogeneity means that it is not appropriate to remove base metal thermocouples for re-calibration. Unless the thermocouple experiences the same thermal environment as in use, a recalibration will fail to properly account for inhomogeneities. To effect a proper re-calibration the thermocouple should be calibrated *in-situ* with a freshly calibrated thermocouple brought alongside in the same thermal environment. However it is usually more cost effective to replace the used thermocouple with a new one of the same type and tolerance classification according to a set maintenance schedule.

### D. Pt/Pd thermocouples

A relative newcomer is a thermocouple based on thermoelements of pure platinum and palladium, the Pt/Pd thermocouple [12]. Although this has been around for some time it has not been widely used outside the laboratory environment because the measurement junction has up to now been made using a stress relieving coil of very fine platinum wire (typically 0.1-0.2 mm diameter) to accommodate the dissimilar thermal expansivities of the thermoelements. If this had not been allowed for, unacceptable strain would have been introduced into the thermocouple leading to a failure of the measurement junction. The introduction of the coil was gave access to the full performance of the thermocouple but its drawback was that it made the thermometer very fragile and unsuited to industrial applications.

Recent innovations in design, without the stress-relieving coil, have been trialed and demonstrate similar performance to the original versions [e.g. 13]. This development opens up very interesting application possibilities for these sensors that were not possible previously. It can be envisaged that in the near term these robust thermocouple versions will act as scale transfer devices from National Measurement Institutes to accredited laboratories – but with lower uncertainties than are possible with current type S, R or B thermocouples. It can also be envisaged that they will be used as the high temperature scale comparison device of choice between NMIs to 1500 °C. In the longer term it is envisaged that use of Pt/Pd thermocouples in industry may well become widespread as the lower sensor cost and improved process control overcome industries' inertia to change.

To take full advantage of the performance of this thermocouple a means had to be found to calibrate it at the highest temperature of operation (about 1500 °C). Until HTFPs became available this was not possible because there were no fixed points that could be used, but, with the advent of fixed points of Co-C (1324 °C) and Pd-C (1492 °C) Pt/Pd thermocouples can now be calibrated with low uncertainties over their whole operating range, as described in the preceding section, with remarkably low uncertainties.

A study of robust Pt/Pd thermocouples in an industrial laboratory environment showed that they exhibited no significant drift, compared to type R thermocouples, from their as-new calibrated state, even when experiencing over 300 hours of high temperature exposure (to 1300 °C) [14].

## V. SELF VALIDATION OF THERMOCOUPLES AT VERY HIGH TEMPERATURES

It is well known that thermocouples drift significantly at high temperatures. For example Fig. 3 shows the drift of a W-Re thermocouple (type C) when exposed to temperatures near 2000 °C over a number of hours [15]. There is a dramatic shift of about 90 °C in the first 5 hours but even after that large shift there is still an erratic output – e.g. the step upwards in output of about 20 °C at about 30 hours.

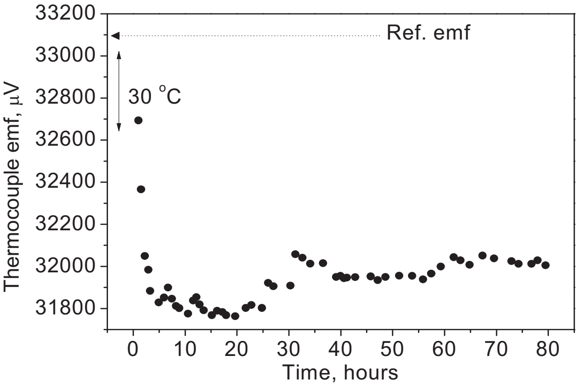

Figure 3. The emf of a new type C thermocouple as a function of time at temperature > 1950 °C. An emf shift is about 90 °C after about only 5 h is clearly observable.

This large and often undetected drift can be very detrimental to the control of an industrial process, particularly in terms of energy efficiency and product quality. The self-validation of temperature sensors has been implemented at lower temperatures for a number of years [16], but this was not really possible at higher temperatures until the advent of HTFPs. Here we introduce the principles of self-validation and then how this is implemented in practice with W-Re thermocouples.

### A. The principle of self-validation

Refractory metal thermocouples are the only practical contact temperature sensor above 1700 °C. However there are several problems with their implementation that currently limits their attainable uncertainty. When new the standard tolerance of such thermocouples is 1%, that is 20 °C at 2000 °C [17]. Removal for recalibration is not possible for two reasons. Firstly on use the thermoelements become very brittle: if the sensor was then removed it would almost certainly break. Secondly when used the W-Re thermocouple experiences strong inhomogeneity growth rendering, as described above, any calibration except *in-situ* calibration of little or no use.

It is clear that the W-Re thermocouple is beset with major performance limitations. One way to overcome all of these is to implement self-validation. That is to incorporate within the thermocouple a reference of known temperature. Then every time the sensor passes through the melting point of the temperature reference its thermovoltage is calibrated allowing the whole output of the thermocouple to be normalized. In this way the thermocouple performance is optimized even at the very highest temperatures.

### *B. Application of self-validation to high temperature thermocouples*

Self-validation of high temperature thermocouples requires the application of high temperature stable references. The HTFPs described in earlier sections are ideal for this application. Miniature fixed points of Co-C, Pt-C, Ru-C and Ir-C have been produced; these are shown in Fig. 4.

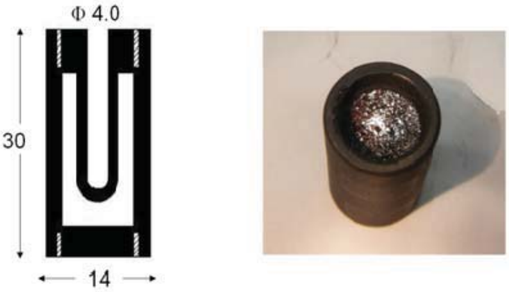

Figure 4: Cross-sectional diagram of a mini HTFP ingot used in self-validation studies of W-Re thermocouples [15].

These miniature HTFP ingots are then incorporated with the measurement junction of a metal-sheathed (usually tantalum) W-Re thermocouple (Fig. 5).

Figure 5: Incorporation of mini HTFP ingot with a metal sheathed tungsten rhenium (W-Re) thermocouple [15].

The test thermocouples are then placed in a furnace and raised in temperature to the melting point of the HTFP ingot. Each time the melting and freezing plateau was observed. For illustrative purposes see Fig. 6, but similar results have been obtained for all the HTFPs tested (up to the Ir-C point, 2292 °C) [18].

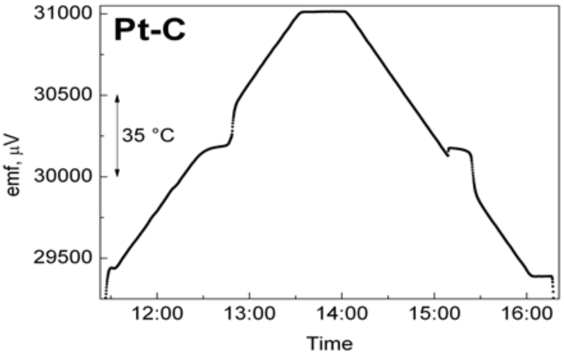

Figure 6: Typical Pt-C melt and freeze of the miniature HTFP (nominally 1738 °C), measured with a type C thermocouple [18].

It is clear that this transition can be used to normalize the thermocouple output and so maintain optimum control of a process. It has been shown [15, 18] that by implementing self-validation for type C thermocouples, instead of having to assign the manufacturing tolerance of 1% of temperature, the uncertainty could be about 2 °C – a potential factor of ten improvement in performance.

It should be noted that type C thermocouples generally operate in a vacuum or inert environment so there are no compatibility issues with the HTFP graphite crucibles, which are also compatible with the thermocouple tantalum sheathes.

In this section we have shown the possibility of improving high temperature thermometry in industry through proof of concept studies of self-validating W-Re thermocouples at high temperatures. However it is well known that there are a wide variety of unaddressed high temperature measurement problems in industry. Some of these are being tackled in a joint European Metrology Research Programme[1] (EMRP) project discussed briefly in the next section.

## VI. THE HITEMS PROJECT

HiTeMS, High Temperature Metrology for Industrial Applications, is a three-year, fifteen partner, research project part funded by the EMRP [19]. The objective of the research is to develop a suite of methods and techniques that will significantly improve the practice of industrial high temperature non-contact and contact thermometry, up to at least 2500 °C. Special emphasis is given to facilitating *in-situ* traceability, i.e. ensuring traceability to the International Temperature Scale of 1990 (ITS-90) directly within the industrial process. This is often lost when industrial thermometry is performed due to (for example) unknown sensor drift or (for radiation thermometers viewing through windows) unquantified transmission changes.

The following outstanding problems with high temperature measurement will be addressed by this research:

Non-contact thermometry:

[1] Information about the EMRP can be found at: http://www.euramet.org/index.php?id=publicity

- Emissivity and reflected radiation, with the target of achieving *in-situ* traceability

- Corrections for varying window/path transmission, to approximately 2500 ºC

- Real time traceable temperature measurement in laser materials processing

Contact thermometry:

- Lifetime assessment of base metal and drift measurements of base and noble metal thermocouples

- Self-validation and demonstrated *in-situ* validation for temperature sensors to at least 2000 ºC

- Facility for determination of reliable reference functions for high temperature non-standard thermocouples (demonstrated by determining a better reference function for the Ir-60%Rh/Ir thermocouple)

HiTeMS started in September 2011 and will conclude in Aug 2014. It is anticipated that by the end of the project many of the common problems encountered in industrial high temperature thermometry will have been addressed. More information about the project can be found at the HiTeMS website [20].

## VII. SUMMARY

An introduction to the international temperature scale of 1990 and temperature calibration has been given with special emphasis on traceability.

New high temperature fixed points were introduced and their significance in improving high temperature measurement described.

An overview of thermocouples has been given, how they work and their different types. This was followed by a description of inhomogeneity, the most common and least understood uncertainty, and the new thermocouple type based on pure thermoelements of Pt and Pd.

The use of the principle of self-validation in making step change improvements in high temperature thermometry was outlined.

Finally a brief description of the EMRP project HiTeMS was given and its chief objectives described.

In summary the developments reported here show that a step change improvement in the practice of high temperature and in particular thermocouple thermometry is underway.

## VIII. ACKNOWLEDGMENTS

The work described here was supported by the UK National Measurement Office, with additional support under a programme of, and funded by, the European Space Agency and the EMRP. The EMRP is jointly funded by the EMRP participating countries within EURAMET and the EU.

Thanks are given to Oijai Ongrai and Claire Elliott of NPL for providing some of the experimental results shown here, and Richard Rusby, of NPL, who gave valuable comments on this manuscript.

# An Integrated Backstepping and Sliding Mode Tracking Control Algorithm for Unmanned Underwater Vehicles

Bing Sun, Daqi Zhu, Weichong Li

Laboratory of Underwater Vehicles and Intelligent Systems
Shanghai Maritime University
Shanghai, China
email:zdq367@yahoo.com.cn

*Abstract*—**In this paper, an integrated backstepping and sliding mode tracking control algorithm is developed for three-dimensional tracking control of unmanned underwater vehicles (UUV). The proposed control strategy combines with a kinematic controller and dynamic controller together. The kinematic controller integrates a bio-inspired model with the basktepping method while the dynamic controller uses robust sliding mode control. Unlike the traditional backstepping method suffering from the speed jump problem, the application of bio-inspired model can generate smooth and continuous velocity signal even in the large initial errors. Therefore, a smooth control signal can be obtained by dynamic controller without thruster control saturation. The effectiveness and efficiency of the proposed control strategy are demonstrated through simulations and comparison studies.**

***Keywords-Unmanned underwater vehicles, tracking control, backstepping, bio-inspired model.***

## I. INTRODUCTION

Unmanned underwater vehicles (UUV) have been wildly used as a platform employed in risky missions such as oceanographic observations, bathymetric surveys, ocean floor analysis, military applications, recovery of lost man-made objects, etc [1]. This requires a more precise control behavior which has motivated an intensive research in the last decade. As a consequence, several different control approaches have been applied to the UUV motion control such as the adaptive control techniques [2-3], sliding-mode control [4-6], backstepping control algorithms [7-8], fuzzy-logic and neural network methods [9-12], etc.

The underwater vehicle dynamics is strongly coupled and highly nonlinear. In order to deal with the uncertain nonlinear parts in the underwater vehicle's dynamics, many researchers concentrated their interests on the applications of sliding mode control. Sliding mode method [4-5] is usually used for dynamic tracking control for the outstanding characteristic including insensitivity to parameter variations, and good rejection of disturbances. So sliding mode control is extraordinary suitable for robust tracking control of underwater vehicle. However, one major drawback of the sliding-mode approach is the high frequency of control action (chattering). To eliminate/reduce chattering, various methods have been proposed to reach a continuous robust control. For example, S. Serdar proposed a chattering-free sliding-mode control method with an adaptive estimate term [6].

The backstepping control algorithms [7-8] is the commonly used approach for tracking control. However, the disadvantage for backstepping method is quite obvious. The velocity control law is directly related to the state errors, so large velocities will be generated in big initial error condition and sharp speed jump occurs while sudden tracking error happens. It means that the required acceleration and forces/moments exceed their control constraint even infinite values at the velocity jump points, which is practically impossible.

To resolve the impractical speed jump problem of large initial velocities resulted from the backstepping technique, some fuzzy control methods [9-10] and neural network control algorithms [11-12] are proposed. The fuzzy rules based tracking control approaches can solve the problem of large initial vehicle velocities, but it is very difficult to formulate the fuzzy rules, which are usually obtained by trial and error based human knowledge. As neural networks are characterized by flexibility and an aptitude for dealing with non-linear problems, they are envisaged to be beneficial when used on underwater vehicles. For examples, a neural network adaptive controller is proposed by Li [11] for autonomous diving control of an UUV using adaptive backstepping method when the smooth unknown dynamics of a vehicle is approximated by a neural network. Anyhow, the existing neural networks based tracking control algorithms for underwater vehicle require either on-line learning or off-line training procedures which could be computational complicated.

This paper focuses on the problem of speed jump and the thruster control constraints for UUV, and the a kinematics/dynamics cascaded control system integrating backstepping technology and sliding mode control with bio-inspired neural dynamics model (bio-inspired model) [13-14] is presented for three-dimensional (3D) tracking control of OUTLAND1000 UUV. Due to the shunting characteristics of bio-inspired model, the output of the bio-inspired model is bounded in a finite interval and smooth without any sharp jumps when inputs have sudden changes. In addition, the novel tracking controller proposed can meet on-line navigation of an UUV because no learning procedures are needed in the bio-inspired neural dynamics model.

This paper is organized as follows: In the second section, the basic kinematics and dynamics of the UUV. In the third section, an integrating backstepping and sliding mode tracking control algorithm based on bio-inspired model is presented. In the fourth section thruster configuration and force allocation for OUTLAND1000 UUV are introduced. To illustrate effectiveness and efficiency of the proposed method, simulation examples are given in the fifth section. Finally, some concluding remarks are made.

## II. Background

In this section, two coordinate systems for UUV control are first briefly presented. Then the kinematic and dynamic model of UUV is provided. Finally the tracking control problem is briefly stated.

### A. Kinematic model

In a three-dimensional (3D) Cartesian workspace shown in Fig. 1, two coordinate frame systems are defined: the inertial frame system $\{O-XYZ\}$ and the body-fixed frame system $\{O_0-X_0Y_0Z_0\}$. The coordinate systems illustrated in Fig. 1 obey the right-hand rule and the Z-axis points to the downward.

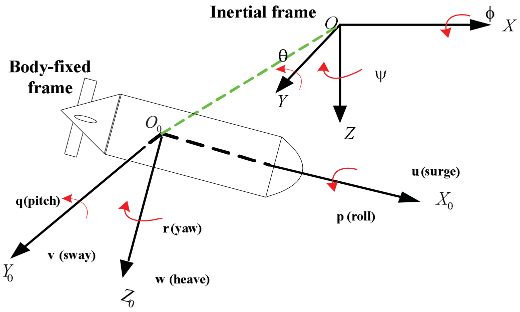

Fig. 1. Coordinate systems

The kinematic models are formulated as below. Let $\eta=[x \quad y \quad z \quad \phi \quad \theta \quad \psi]^T$ be the generalized coordinates representing the position $(x,y,z)$ and the orientation $(\phi,\theta,\psi)$ with respect to the inertial frame and $\boldsymbol{q}=[u \quad v \quad w \quad p \quad q \quad r]^T$ be the translational velocities $(u,v,w)$ and the rotational velocities $(p,q,r)$ with respect to the body frame attached at the vehicle. Then, the kinematic model relating the body-fixed frame to the inertial frame can be expressed in a compact vector form as follows[24]:

$$\dot{\eta}=J(\eta)\boldsymbol{q} \tag{1}$$

where $J\in R^{n\times n}$ is the spatial transformation matrix between the inertial frame and the UUV's body-fixed frame.

### B. Dynamic model

The dynamic equation of UUV can be presented as a compact vector form [15]:

$$\boldsymbol{M}\dot{\boldsymbol{q}}+\boldsymbol{C}(\boldsymbol{q})\boldsymbol{q}+\boldsymbol{D}(\boldsymbol{q})\boldsymbol{q}+\boldsymbol{g}(\eta)=\tau \tag{2}$$

where $\boldsymbol{M}\in R^{n\times n}$ -inertia matrix including the added mass effects ; $\boldsymbol{C}\in R^{n\times n}$ -the matrix of Coriolis and centrifugal terms (including added mass caused by hydrodynamic effect) ; $\boldsymbol{D}\in R^{n\times n}$ - the hydrodynamic damping matrix ; $\boldsymbol{g}\in R^{n}$ - gravity and buoyancy forces; $\tau\in R^{n}$ is the control forces and moments acting on the UUV centre of mass.

As mentioned earlier, the system dynamics are not exactly known. The system dynamics can be divided into two parts: estimated dynamics $\hat{\tau}$ and unknown dynamics $\tilde{\tau}$ :

$$\tau=\hat{\tau}+\tilde{\tau} \tag{3}$$

where $\hat{\tau}=\hat{\boldsymbol{M}}\dot{\boldsymbol{q}}+\hat{\boldsymbol{C}}\boldsymbol{q}+\hat{\boldsymbol{D}}\boldsymbol{q}+\hat{\boldsymbol{g}}$ , $\tilde{\tau}=\tilde{\boldsymbol{M}}\dot{\boldsymbol{q}}+\tilde{\boldsymbol{C}}\boldsymbol{q}+\tilde{\boldsymbol{D}}\boldsymbol{q}+\tilde{\boldsymbol{g}}$ , $\hat{\boldsymbol{M}},\hat{\boldsymbol{C}},\hat{\boldsymbol{D}},\hat{\boldsymbol{g}}$ are estimated terms, $\tilde{\boldsymbol{M}},\tilde{\boldsymbol{C}},\tilde{\boldsymbol{D}},\tilde{\boldsymbol{g}}$ are the unknown terms.

In this paper, the mainly research focuses on the model of OUTLAND1000 UUV. The thruster configuration and force allocation of OUTLAND1000 UUV will be described in detail in section 4. It has only four degrees of freedom (DOF) $(u,v,w,r)$ to conduct motion control, $p=q=0$ . So the simplified dynamic model in this paper's simulation is given as follows [16]:

$$(m-X_{\dot u})\dot u-mvr-X_u u-X_{uu}u|u|=\tau_X \tag{4}$$

$$(m-Y_{\dot v})\dot v-mur-Y_v v-Y_{vv}v|v|=\tau_Y \tag{5}$$

$$(m-Z_{\dot w})\dot w-Z_w w-Z_{ww}w|w|=\tau_Z \tag{6}$$

$$(I_z-N_{\dot r})\dot r+muv-mur-N_r r-N_{rr}r|r|=\tau_N \tag{7}$$

where $X_{\dot u},Y_{\dot v},Z_{\dot w},N_{\dot r}$ is the added mass effect, $X_u,Y_v,Z_w,N_r$ is the linear drag and $X_{uu},Y_{vv},Z_{ww},N_{rr}$ is the quadratic drag.

### C. Tracking control problem

The UUV is usually required to move at a low forward speed and a low rotational speed when it executes investigation tasks. This needs a precious tracking control. Consider that the UUV's major movement is in four degrees of freedom (DOF): surge, sway, heave, yaw, so in this paper, only the four DOF tracking control problem is represented. The controller design problem can be described as follows. The desired state of UUV is defined as

$$\eta_d=[x_d \quad y_d \quad z_d \quad \psi_d]^T \tag{8}$$

where $\eta_d=[x_d \quad y_d \quad z_d \quad \psi_d]^T$ is the desired state of UUV in the inertial frame, ( $x_d,y_d,z_d$ ) is coordinate of desired path in the inertial frame, $\psi_d$ is the counter-clockwise rotation angle of UUV along the Z-axis.

The desired forward and angular velocities can be deduced by

$$\begin{aligned} u_d &=\dot x_d\cos\psi_d+\dot y_d\sin\psi_d \\ v_d &=\dot x_d(-\sin\psi_d)+\dot y_d\cos\psi_d \\ w_d &=\dot z_d \\ r_d &=\dot\psi_d=\frac{\dot x_d\ddot y_d-\ddot x_d\dot y_d}{\dot x_d^2+\dot y_d^2} \end{aligned} \tag{9}$$

The actual state of UUV is represented by $\eta=[x \quad y \quad z \quad \psi]^{\mathrm{T}}$ , $\boldsymbol{q}=[u \quad v \quad w \quad r]^T$ . As the objective of the path tracking controllers is to make UUV follow the known path by controlling the velocity and angular velocities, so the tracking error $\boldsymbol{e}=\boldsymbol{\eta}_d-\boldsymbol{\eta}=[e_x \quad e_y \quad e_z \quad e_\psi]^T$ converges to zero. Here $\boldsymbol{e}$ is the tracking error in the inertial frame. A detailed model of tracking control problem is given in Fig. 2.

## III. CONTROL ALGORITHMS

The basic control architecture of the system is illustrated in Fig. 3. The design of the hybrid control strategy consists of two parts: (1). an outer loop virtual velocity controller by using position and orientation state errors; (2). an inner loop sliding-mode controller by using velocity state vector.

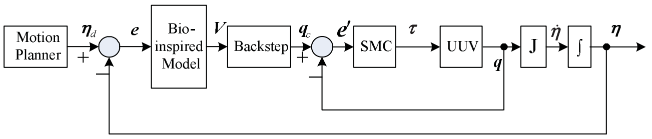

Fig. 3. The cascaded controller of UUV

### A. Virtual velocity controller

Backstepping method for nonholonomic mobile robot has been designed a lot for velocity tracking [12-13]. But the UUV in this study is a holonomic system, so the backstepping control law for the mobile robot is not fit for this control system. For this reason, a new backstepping control law is designed for UUV and makes it possible to follow a given reference posture with stability.

The virtual velocity controller based on the backstepping approach can be defined as:

$$\boldsymbol{q}_c=\begin{bmatrix}u_c\\ v_c\\ w_c\\ r_c\end{bmatrix}=\begin{bmatrix}k(e_x\cos\psi+e_y\sin\psi)+(u_d\cos e_\psi-v_d\sin e_\psi)\\ k(-e_x\sin\psi+e_y\cos\psi)+(u_d\sin e_\psi+v_d\cos e_\psi)\\ w_d+k_z e_z\\ r_d+k_\psi e_\psi\end{bmatrix} \quad (10)$$

where $k,k_z,k_\psi$ are constant coefficients, $\boldsymbol{q}_d=[u_d \quad v_d \quad w_d \quad r_d]^T$ is the desired velocity in the body-fixed frame, $u_d\cos e_\psi-v_d\sin e_\psi$ , $u_d\sin e_\psi+v_d\cos e_\psi$ represents the desired velocity frame transformed to the actual velocity frame seen in Fig. 2.

### B. Bio-inspired velocity controller

In-depth analysis of (10), the virtual speed can be found directly related to the tracking errors. In order to resolve the speed jump and control constraint problem, a bio-inspired model is added in the controller to design the virtual velocity. Bio-inspired neural dynamics model was first developed by Grossberg [17]. It can describe an on-line adaptive behavior of individuals. It was originally derived based on the membrane model proposed by Hodgkin and Huxley [18] for a patch of membrane using electrical elements. The dynamics of voltage across the membrane $V_m$ can be described in the membrane model using state equation technique as

$$C_m\frac{dV_m}{dt}=-(E_p+V_m)g_p+(E_{Na}-V_m)g_{Na}-(E_k+V_m)g_k \quad (11)$$

where $C_m$ is the membrane capacitance. The parameters $E_k$ , $E_{Na}$ and $E_p$ are the Nernst potentials for potassium ions, sodium ions, and passive leak current in the membrane, respectively. $g_k$ , $g_p$ and $g_{Na}$ are the conductance of potassium, sodium and the passive channels are functions of input signals that vary with time.

To simplify the equation, a shunting equation is obtained as

$$\dot{V}=-AV+(B-V)S(t)^+-(D+V)S(t)^- \quad (12)$$

where $V$ is the neural activity of the neuron. Parameters $A,B$ and $D$ are respectively the passive decay rate, the upper and lower bounds of the neural activity. The variables $S^+$ and $S^-$ represent the excitatory and inhibitory input, respectively. The shunting dynamic of an individual neuron can be modeled by this equation. The neutron dynamics are restricted to a bounded interval $[-D,B]$ and an automatic gain control. So we can infer the shunting equation to the following form

$$\dot{V}_i=-AV_i+(B-V_i)f(e_i)-(D+V_i)g(e_i) \quad (13)$$

where $f(e_i)=\max(e_i,0)$ , $g(e_i)=\max(-e_i,0)$ , $A,B,D$ are positive constants. For a system with appropriate chosen inputs, various desirable functional properties such as competitive, short memory, upper bound and lower bound can be derived from the model. The systems output $V$ is guaranteed to stay in a region $[-D,B]$ for any excitatory and inhibitory inputs.

So the proposed virtual velocity controller can be given as

$$\boldsymbol{q}_c=\begin{bmatrix}u_c\\ v_c\\ w_c\\ r_c\end{bmatrix}=\begin{bmatrix}k(V_x\cos\psi+V_y\sin\psi)+(u_d\cos e_\psi-v_d\sin e_\psi)\\ k(-V_x\sin\psi+V_y\cos\psi)+(u_d\sin e_\psi+v_d\cos e_\psi)\\ w_d+k_z V_z\\ r_d+k_\psi V_\psi\end{bmatrix} \quad (14)$$

where $k,k_z,k_\psi$ are the same parameters of (13). Due to the shunting characteristics of bio-inspired model, the output of the bio-inspired model is bounded in a finite interval and smooth without any sharp jumps when inputs have sudden changes. So the controller performance is significantly improved.

### C. The adaptive sliding-mode controller

After the velocity controller generates the virtual velocity of the underwater vehicles, a sliding-mode controller is used to generate the control forces and moments $\boldsymbol{\tau}=[\tau_X \quad \tau_Y \quad \tau_Z \quad \tau_N]^T$.

Then the control inputs $\boldsymbol{\tau}$ will be applied to the UUV dynamic model to produce the actual velocity in surge, sway, heave and yaw ($\boldsymbol{q}=[u \quad v \quad w \quad r]^T$) in the body-fixed frame respectively. So it will be easy to get the actual underwater vehicle's states ($\boldsymbol{\eta}=[x \quad y \quad z \quad \psi]^T$) in the inertial frame by $\dot{\boldsymbol{\eta}} = J\boldsymbol{q}$.

As a rule, sliding-mode control can be divided into two parts. First, define a sliding manifold $\boldsymbol{s}$. Second, find a control law to move toward the sliding manifold. The sliding manifold is defined as[8]:

$$\boldsymbol{s} = \dot{e}_c + 2\Lambda e_c + \Lambda^2 \int e_c \qquad (15)$$

where $\boldsymbol{e}_c = \boldsymbol{q}_c - \boldsymbol{q}$ is the velocity error between the virtual velocity and the actual velocity, $\Lambda$ represents a strictly positive constant, $\boldsymbol{s}$ is a $4\times1$ vector. Derivation of (15), then

$$\dot{\boldsymbol{s}} = \ddot{\boldsymbol{e}}_c + 2\Lambda\dot{\boldsymbol{e}}_c + \Lambda^2\boldsymbol{e}_c = \ddot{\boldsymbol{e}}_c + 2\Lambda(\dot{\boldsymbol{q}}_c - \dot{\boldsymbol{q}}) + \Lambda^2\boldsymbol{e}_c \qquad (16)$$

When the system is operating on the sliding surface, (11) equals zero, i.e.

$$\dot{\boldsymbol{s}} = \ddot{\boldsymbol{e}}_c + 2\Lambda\dot{\boldsymbol{e}}_c + \Lambda^2\boldsymbol{e}_c = \ddot{\boldsymbol{e}}_c + 2\Lambda(\dot{\boldsymbol{q}}_c - \dot{\boldsymbol{q}}) + \Lambda^2\boldsymbol{e}_c = 0 \qquad (17)$$

Substituting (2) into (17), then

$$\ddot{\boldsymbol{e}}_c + 2\Lambda(\dot{\boldsymbol{q}}_c - \boldsymbol{M}^{-1}(\boldsymbol{\tau} - \boldsymbol{Cq} - \boldsymbol{Dq} - \boldsymbol{g})) + \Lambda^2\boldsymbol{e} = 0 \qquad (18)$$

So the equivalent control law can be concluded as

$$\boldsymbol{\tau}_{eq} = \hat{\boldsymbol{M}}(\dot{\boldsymbol{q}}_c + \frac{\ddot{\boldsymbol{e}}_c}{2\Lambda} + \frac{\Lambda}{2}\boldsymbol{e}_c) + \hat{\boldsymbol{C}}\boldsymbol{q} + \hat{\boldsymbol{D}}\boldsymbol{q} + \hat{\boldsymbol{g}} \qquad (19)$$

where $\hat{\boldsymbol{M}}, \hat{\boldsymbol{C}}, \hat{\boldsymbol{D}}, \hat{\boldsymbol{g}}$ are estimated terms. Considering the difficulty of computing $\ddot{e}_c$ in (19), a feedback control input of acceleration error is introduced

$$\ddot{\boldsymbol{e}}_c = -k\dot{\boldsymbol{e}}_c \qquad (20)$$

where $k$ is a constant scalar representing the strictly positive constant that determines the rate of acceleration error.

The conventional sliding-mode can be designed as

$$\boldsymbol{\tau} = \boldsymbol{\tau}_{eq} + k\,\mathrm{sgn}(\boldsymbol{s}) \qquad (21)$$

To eliminate chattering problem caused by the discontinuous term, an adaptive term [8] is added in the control law to replace the switching term

$$\boldsymbol{\tau}_{ad} = \tilde{\boldsymbol{\tau}}_{est} + (K + \frac{\hat{\boldsymbol{C}}}{2\Lambda})\boldsymbol{s} \qquad (22)$$

where $\tilde{\boldsymbol{\tau}}_{est}$ is an adaptive term that estimates the lumped uncertainty vector defined in (3), K is also a constant scalar representing the strictly positive constant related to the convergence rate of the controller. The estimation of the lumped uncertainty vector is proposed to follow:

$$\dot{\tilde{\boldsymbol{\tau}}}_{est} = \Gamma\boldsymbol{s} \qquad (23)$$

where $\Gamma$ represent the strictly positive constant that determines the rate of adaption.

The total control law can be defined as

$$\boldsymbol{\tau} = \boldsymbol{\tau}_{eq} + \boldsymbol{\tau}_{ad} = \boldsymbol{\tau}_{eq} + \tilde{\boldsymbol{\tau}}_{est} + (K + \frac{\hat{C}}{2\Lambda})\boldsymbol{s} \qquad (24)$$

## IV. Formulation of The Control Allocation Problem

The OUTLAND1000 is used to demonstrate the performance of the proposed bio-inspired cascaded tracking control approach. It has four fixed direction thrusters; three horizontal thrusters denoted as $HT^i, i \in [1,3]$, and one vertical thruster denoted as $VT^1$. The OUTLAND1000 and the thruster's configuration enables direct control of surge, yaw and heave, as indicated in Fig. 4, 5.

In this paper the four degree motion control is discussed. Each thruster exerts thrust (force) **F** and torque **Q**. The position vector ${}^i\boldsymbol{r} = [{}^ir_x \quad {}^ir_y \quad {}^ir_z]^T$ determines the position of the point of attack of the force **F.** The orientation of the thruster is defined by the unit vector ${}^i\boldsymbol{e} = [{}^ie_x \quad {}^ie_y \quad {}^ie_z]^T$. The force **F** also generates the moment **Q =r×F.** The vector of forces and moments can be written as [19]:

$$F_i = k_1 n_i^2 = k u_i^2, n_i = k_2 u_i, Q_i = r_i \times k u_i^2, i = 1,2,3,4 \qquad (25)$$

where $\lambda = k_1 k_2^2$ is the thruster motor control parameter, $u_i$ is the control voltage of $ith$ thruster, $n_i$ is the rotational speed of $ith$ thruster.

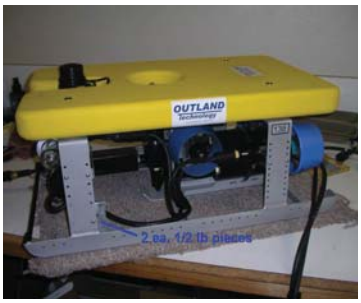

Fig. 4 OUTLAND1000

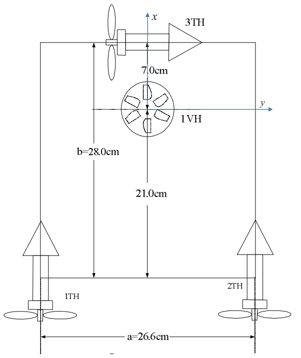

Fig. 5 Configuration of the thrusters

The total vector of propulsion forces and moments $\boldsymbol{\tau}$ in the horizontal plane are considered:

$$\tau = \begin{bmatrix} \tau_X \\ \tau_Y \\ \tau_Z \\ \tau_N \end{bmatrix} = \begin{bmatrix} \lambda & \lambda & 0 & 0 \\ 0 & 0 & \lambda & 0 \\ 0 & 0 & 0 & \lambda \\ a\lambda/2 & -a\lambda/2 & (b-21)\lambda & 0 \end{bmatrix} \begin{bmatrix} u_1^2 \\ u_2^2 \\ u_3^2 \\ u_4^2 \end{bmatrix} = B \cdot u \qquad (26)$$

where $\boldsymbol{\tau}$ are represented as the motions of surge, sway, heave and yaw respectively, and $a\lambda/2 = 13.3\lambda$ , $(b-21)\lambda = 7\lambda$ (from Fig. 5), Each component of the control vector is limited by constraint:

$$-u_m \le u_i \le u_m, -n_m \le n_i \le n_m, \; i = 1,2,3,4 \qquad (27)$$

where $u_m$ is the thruster maximum control variable, $n_m$ is the thruster maximum rotational speed . From (25) and (26):

$$\tau_{Xm} = 2F_m = 2\lambda u_m^2 \Rightarrow \lambda = 2\tau_{Ym} / u_m^2 \qquad (28)$$

$$\tau_{Ym} = F_m = \lambda u_m^2 \Rightarrow \lambda = \tau_{Ym} / u_m^2 \qquad (29)$$

$$\tau_{Zm} = F_m = \lambda u_m^2 \Rightarrow \lambda = \tau_{Ym} / u_m^2 \qquad (30)$$

$$\tau_{Nm} = a\lambda u_m^2 / 2 + (b-21)\lambda u_m^2 = 20.3\lambda u_m^2 \Rightarrow 20.3\lambda = \tau_{Nm} / u_m^2 \qquad (31)$$

Finally, the general constrained control allocation problem for the OUTLAND1000 can be formulated as: For given normalized $\overline{\tau}$ , find $\overline{u}$ feasibility such that

$$\overline{\tau} = \overline{B} \cdot \overline{u} \tag{32}$$

where $-1 \le \overline{u} = [\frac{u_1}{u_m} \quad \frac{u_2}{u_m} \quad \frac{u_3}{u_m} \quad \frac{u_4}{u_m}]^T \le 1$, $-1 \le \overline{\tau} \le 1$,

$$\overline{\tau} = [\frac{\tau_X}{\tau_{Xm}} \quad \frac{\tau_Y}{\tau_{Ym}} \quad \frac{\tau_Z}{\tau_{Zm}} \quad \frac{\tau_N}{\tau_{Nm}}]^T, \ \overline{B} = \begin{bmatrix} 1/2 & 1/2 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0.655 & -0.655 & 0.345 & 0 \end{bmatrix}.$$

## V. SIMULATION

In this paper, the two methods were simulated for tracking control problem: the proposed backstepping method and the bio-inspired method. The backstepping method given in (10) was used as a case study to illustrate the performance of the proposed control strategies. From the simulation results, the proposed controller can reach a robust control while the speed jump and thruster saturation problem can be solved successfully.

The hydrodynamic parameter of OUTLAND1000 UUV is given in Table I by estimation through the comparison of the similar UUV model [16]. To reflect uncertainties of the vehicle dynamics, 20% model inaccuracies were incorporated into the controller's dynamic model. It means that in the following simulations, the parameters in Table I will be set as the actual value, while the estimated value is 80% of the actual value. The parameter setting of the cascaded controller is shown in Table II.

Table I. Hydrodynamic Parameters of OUTLAND1000 UUV

| | | |
|---|---|---|
| $X_{\dot{u}} = 34$ | $X_u$=6 | $X_{uu} = 18$ |
| $Y_{\dot{v}} = 75$ | $Y_v = 10$ | $Y_{vv} = 4$ |
| $Z_{\dot{w}} = 33$ | $Z_w = 7$ | $Z_{ww} = 4$ |
| $N_{\dot{r}} = 62$ | $N_r = 14$ | $N_r = 14$ |

A typical case to track a spiral line is studied. The UUV starts at Posture (0, 0, 1, 0), while the desired initial robot posture is (0, -2, 0, 0). Thus the initial posture error is (0, -2, -1, 0). Time varies from 0 to 20s. The desired state of UUV is $x_d(t) = 2\sin(0.5t)$ , $y_d(t) = -2\cos(0.5t)$ , $z_d(t) = 0.1t$ , $\psi_d(t) = 0.5t$ . The parameter setting of the hybrid controller is shown in Table II.

Table II. Controller Parameters

| $k_c$ | Γ | K | Λ | $k$ | $k_z$ | $k_\psi$ | A | B | D |
|---|---|---|---|---|---|---|---|---|---|
| 10 | 5 | 100 | 3 | 2 | 2 | 5 | 2 | 1 | 1 |

Fig. 6 ~ Fig. 8 shows the simulation results of the spiral line tracking. The red solid lines indicate the basktepping method results, and the blue solid lines are the bio-inspired method results. Fig. 6 gives the desired trajectory and tracking control results of backstepping method and bio-inspired method on the same condition. Fig. 7 shows the virtual velocity $\boldsymbol{q}_c$ by the backstepping method and bio-inspired method. The normalized thruster control variable $\overline{\boldsymbol{u}}$ of trajectory tracking is shown in Fig. 8. Table III is the maximum normalized control variable of each thruster.

In the simulation results of trajectory tracking in Fig. 6, it seems that for both two methods, the UUV can drive to reach and stay on the trajectory in quick response. In Fig. 7, for the virtual velocity controller based on the backstepping approach (non-biological inspired), this virtual velocity $q_c$ occurs the sharp speed jumps when tracking errors change suddenly at initial time. For example the virtual sway speed of the backstepping method jumps to -4m/s, but the bio-inspired method is limited in the range of -0.5m/s~0 m/s in Fig. 7.

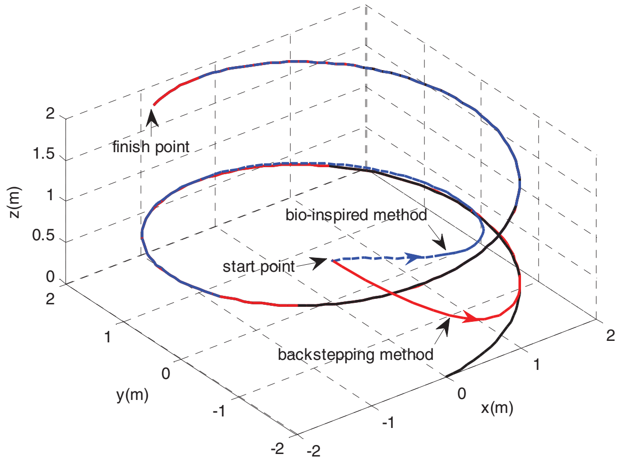

Fig. 6. Systems trajectories using bio-inspired model and the backstepping method

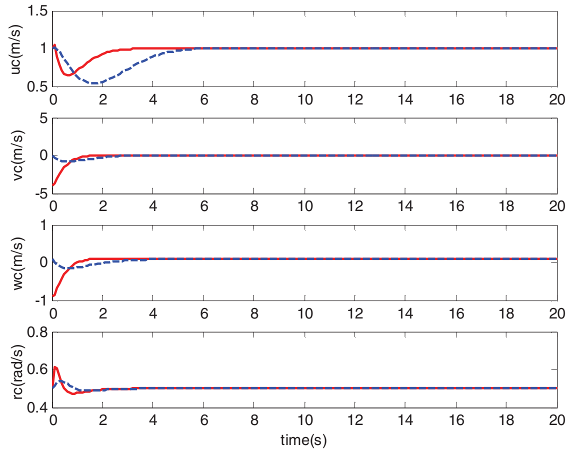

Fig. 7. Virtual velocity using bio-inspired model (dotted line) and the backstepping method (solid line)

In order to catch up the virtual velocities, the UUV accelerates both linear and angular velocities. So the UUV needs to generate quite large forces/moments to track the virtual velocity $q_c$ . It means that the required acceleration and forces/moments may exceed their control constraint values at the velocity jump points. In order to achieve such large speed, it can be seen that the maximum normalized thruster control variable of $\overline{u}_3$ is -5.6880 and the other maximum normalized thruster control variable are also greater than the limitation output ( $-1 \le \bar{\boldsymbol{u}} \le 1$ ) which is practically impossible. In addition, the control variable needs more time to adjust the overshoot process. By contrast, for the bio-inspired tracking control method, no any control value exceeds their maximum control values, and all control forces limited in the thruster control saturation point. This proves the efficiency of the proposed cascaded tracking method.

Table III. Maximum normalized thruster control variable

| Algorithm | $\bar{u}_1$ | $\bar{u}_2$ | $\bar{u}_3$ | $\bar{u}_4$ |
|---|---|---|---|---|
| Backstepping method | 2.4953 | -1.8335 | -5.6880 | -2.3782 |
| Bio-inspired method | 0.9055 | -0.6122 | -0.5290 | -0.4728 |

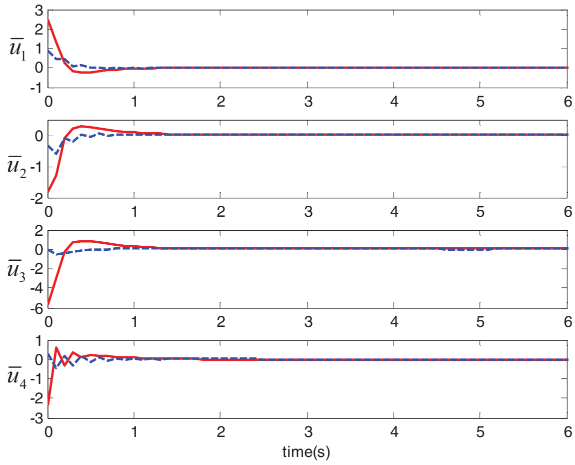

Fig. 8. Thruster forces using bio-inspired model (dotted line) and the backstepping method (solid line)

## VI. Conclusion

Background information about tracking control of unmanned underwater vehicles is firstly established in the paper. Then an integrated backstepping and sliding mode tracking control algorithm is proposed for three-dimensional tracking control problem. In the control system, there exist two closed loop systems: inner loop ensures the velocity tracking and the outer loop ensures the position and orientation tracking. In the traditional backstepping method, it always suffers from the sharp speed jump problem which will cause thruster saturation. Because of the smooth and bounded response properties, the proposed velocity controller uses the bio-inspired model to eliminate or inhibit the sharp speed jumps. From the simulation results, it is clearly to see bio-inspired method reduces the thrust output obviously without significant performance loss while the conventional backstepping method may cause thruster saturation.

In the dynamic controller, the sliding mode control method uses an adaptive term to compensate the nonlinear uncertainties part and the disturbance of the underwater vehicles dynamics. Simulation results showed that the designed controller performs well with stability and robustness. On the other hand, ocean currents should be added to the outside interference. This warrants further research.

**Abstract — This paper investigates several general friction models and applies different friction models to accurately simulate the propulsion of a capsule driven by an internally oscillating mass. The six published friction models are reviewed and are validated using the simulation studies. The simulation results are verified with a physical prototype in an experimentation test. The most accurate friction model can be chosen for a given application.**

***Keywords-Pendulum-driven cart, friction models, friction measurement experiment***

## I. INTRODUCTION

Friction is the resistance to motion that exists when a solid object is moved tangentially with respect to the surface of another that it touches, or when an attempt is made to produce such motion [1]. This is a common physical nonlinear phenomenon and exists in almost every kind of mechanical system and makes an effect on the system which cannot be ignored. Friction can lead to tracking errors, limit cycles and unsteady stick-slip movements [2]. If we do not minimize the friction force effectively, it may cause both economic losses and industrial losses. Friction is also a quite important factor to some processes, such as walking, starting and stopping a car, skating and so on.

Nowadays many focused researches are conducted on the 'Capsule Robot' for medical purposes, because the capsule robot can go into the human body to do work such as treatment, inspection, image acquisition and so on without hurting the patient [3], [4], [5]. A new tracking control issue via the pendulum-driven cart system was solved by the closed-loop control strategy [6]. The six-step optimization motion control approach was also improved by the pendulum-driven cart-pole system [7]. In [6] and [7], the velocity of the cart changed to negative value at some moment, so the displacement decreased. In the pendulum-driven cart system, there was no opposite force, the cart should not go backwards, and this paper is to do research on this problem. However, a simple friction model was used in [3]-[7]. The friction plays an active role in the capsule robot movement. This paper aims to investigate the realistic friction models which can be used in analysis and control of an active driving capsule robot.

The structure of the paper is as follows: in section II, the review of previous work on the pendulum-driven cart pole-system is presented. In section III, investigation on friction phenomena and friction models are shown. A simulation study is carried out in section IV along with the implementation of the different friction models mentioned above. The experiment on measurement of friction parameters is described and compared with the experimental results and the simulation results, where the most suitable friction model for this system is selected. In section V, the conclusions are presented.

## II. MODELLING OF THE PENDULUM-DRIVEN CART SYSTEM

Fig.1 shows the pendulum-driven cart system, the inverted pendulum is fixed on the cart. The cart has a relative smooth surface which makes it move horizontally on the ground. There is a torque motor mounted on the cart which generates the torque to swing the inverted pendulum. $M$ is the mass of the cart, m is the mass of the ball of the pendulum, $l$ is the length of the pendulum, $\mu$ is the friction coefficient between the ground and the cart, $\theta$ is the pendulum angle from the vertical direction, $x$ is the displacement of the cart, and $\tau$ is the torque from the torque motor.

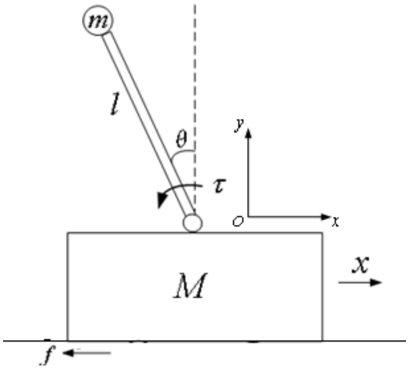

Figure 1. Pendulum-driven cart system

The Coulomb model of friction used in [6] is

$$F_f = -\mu N \operatorname{sgn}(\dot{x}),\ N = Mg + F_y \tag{1}$$

where $\mu$ is the friction coefficient between the cart and the surface, $N$ is the normal force, $F_y$ is the resultant force in the vertical direction.

The dynamic model of the system is described by

This work has been supported by the European Erasmus-Mundus Sustainable eTourism project 2010-2359, the EPSRC UK-Japan Network on Human Adaptive Mechatronics Project (EP/E025250/1) and EU Erasmus Mundus Project-ELINK (EM ECW-ref.149674-EM-1- 2008-1-UK-ERAMUNDUS).

$$(M+m)\ddot{x} - ml\ddot{\theta}(\mu \sin\theta \operatorname{sgn}\dot{x} + \cos\theta) + \\ ml\dot{\theta}^2(\sin\theta - \mu\cos\theta \operatorname{sgn}\dot{x}) + \mu(M+m)g \operatorname{sgn}\dot{x} = 0 \tag{2}$$

The improved friction model used in [7] is

$$F_f = -\mu N \operatorname{sgn}(\dot{x}),\ N = Mg + F_y \\ \mu = \begin{cases} sign(F_x)\mu_k & (\dot{x} = 0) \\ sign(\dot{x})\mu_k & (\dot{x} \neq 0 \end{cases} \tag{3}$$

where $\mu_k$ is the friction coefficient, $F_y$ is the resultant force in the vertical direction. The following dynamic model can be obtained

$$(M+m)\ddot{x} - ml\ddot{\theta}(\mu\sin\theta + \cos\theta) + ml\dot{\theta}^2 \\ (\sin\theta - \mu\cos\theta) + \mu(M+m)g\operatorname{sgn}\dot{x} = 0 \tag{4}$$

Based on the friction model (2) and the dynamic model (4), the simulation was carried out using Matlab/Simulink and the sample time is 0.01 second. When the inverted pendulum swings, the reaction force from the pendulum to the cart drives the cart to move in the horizontal direction, the displacement of the cart is shown in Fig. 2.

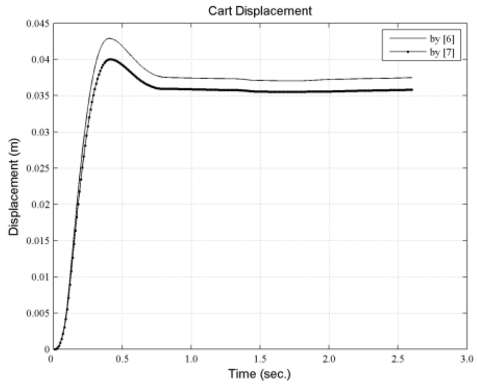

Figure 2. Cart displacements as found by [6]and [7]

From Fig. 2, there is decrease in the displacement curves, which means that the velocities of the cart change to negative values at the point that the displacement values decrease, which is not consistent with the reality situation, based on research of the reasons, improvement of the friction model can get the better result.

From the system configuration, the motor swings the pendulum to cause a lateral force on the cart to enable motion, which can be considered to be a spring. Assuming the cart to be a steel block on a smooth aluminium surface, the system can be simplified as shown in Fig. 5.

## III. FRICTION MODELS

Friction is the key factor to determine the progress of the pendulum-driven cart and the accuracy between the simulation and the physical system. In this paper, general friction phenomena and friction models have been investigated and the friction models have been applied to the dynamic model of the pendulum-driven cart system in Matlab\ Simulink [6], [7] and physical experiment has been carried out to prove the real friction model of the system via comparison of the simulation study and the experiment results.

Friction is the tangential reaction force between two surfaces in contact [8], is dependent on the physical characteristics of the contact surfaces, and displacement and the velocity of the contact body. There are many typical phenomena of friction, for instance, the Stribeck affect, hysteresis, spring-like characteristics for static friction, and varying break-away force [2]. Based on these friction phenomena, there are many friction models. The classical friction models are Coulomb friction model, Coulomb plus viscous friction model and Coulomb plus viscous plus static friction model [9].

Based on the experiment results, the Dahl friction model, LuGre friction model and so on [9], [10], [11] were proposed. In this paper, the Coulomb friction model, the Coulomb plus viscous friction model, the Coulomb plus viscous plus static friction model, the Stribeck friction model, the LuGre friction mode and the Dahl friction model are studied and implemented into the dynamic model of the pendulum-driven cart-pole system.

### *A. Modelling idea and evaluation criteria*

The conventional hypothesis to model the friction is that the direction of the friction force should be opposite to the direction of the relative velocity between the two contact surfaces. In [6], [7], the velocity of the cart changes to negative and the cart retreats at the end of the motion. The reason for this is that at the moment when the velocity of the cart changes to zero, friction changes its direction to the opposite at once. However in the simulation study, it cannot be achieved exactly even if the sample time is very small, to save the computing time and get the more exact result, modelling the friction force under the new hypothesis that the friction tries to stop the mass block [12]. This paper switches the dynamic and static friction model when the relative velocity between the steel mass block and the aluminium surface changes to zero. The reason for switching is that when a body is moving, the friction involved is the dynamic friction, when the velocity of the body changes to zero, the body stops, at this time, the friction involved is the static friction. Consequently, the friction model in this paper is dynamic model when the velocity of the block is not equal to zero, and uses the static model when the velocity of the block changes to zero.

To select the most accurate friction model for the mass block system, evaluation criteria used in this paper are that the velocity will not change to negative and the displacement of the mass block will not decrease, that is, the mass block will stop with the effect of friction and there is no reverse motion in the system, which is consistent with the physical reality.

### *B. Friction phenomena*

#### *1) Stick-slip motion*

Stick-slip motion is one of the typical friction behaviours in system. The reason for stick-slip motion is the friction is greater when the body keeps still than in motion, experiment [2] shows that the mass is still at first, and when there is a linearly increasing force generated by the spring, the mass moves to a very small displacement firstly and then starts to slide when the applied force reaches the break-away force, decrease the spring force and the mass slows down and stops, the friction force increases because the static friction is greater than the dynamic friction. In [18], the model for stick-slip friction is always the function of velocity. Outside the small region around velocity is zero, the stick-slip friction is an arbitrary function of velocity, and inside the region, friction is determined by other forces in the system.

*2) Stribeck effect*

The Stribeck effect is to describe the friction behaviour when the relative velocity between the two contact surfaces is very small. The Stribeck friction force is function of steady-state velocity, when the relative velocity is within very low range, the friction force will decrease as the relative velocity increases. The relationship of the Stribeck effect and the relative velocity is shown in Fig. 3.

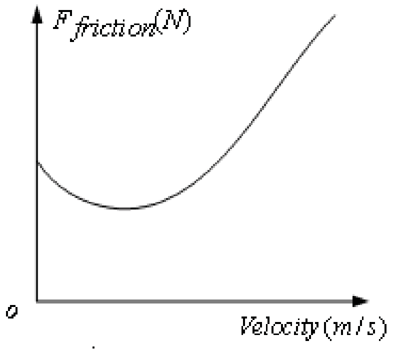

Figure 3. Stribeck effect

*3) Pre-sliding displacement*

When the applied force is smaller than the maximum static friction, the two contact bodies keep still, but from a micro point of view, there is a very tiny displacement on the asperities on the contact surfaces, this is called pre-sliding displacement, which is also known as the Dahl effect [9], [10]. During the pre-sliding stage of the contact bodies, the deflection of the asperities of the surfaces has the spring-like characteristic, and the friction force is the function of the displacement and is independent with the relative velocity between the contact surfaces. The graph of the Dahl effect and the displacement is shown as Fig. 4.

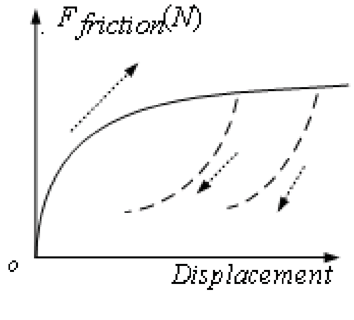

Figure 4. Pre-sliding displacement behaviour as found by [13]

*C. Friction models*

*1) Stribeck model*

The Stribeck model describes the friction phenomenon that the friction force does not decrease discontinuously when the contact surfaces starts to slip. The friction force is dependent on the velocity, when the relative velocity between the contact surfaces is very low, the friction force has a negative slope.

$$F = \begin{cases} F(v) & (\dot{x} \neq 0) \\ F_e = F_x & (\dot{x} = 0 \, \& \, |F_e| \prec |F_s|) \\ F_s \operatorname{sgn}(F_e) & (otherwise) \end{cases} \tag{5}$$

$$F_v = F_c + (F_s - F_c)e^{-\frac{\dot{x}}{\dot{x}_s}} + \mu\dot{x}$$

where $F_y$ is the Stribeck friction force, $F_s$ is the static friction force, $\dot{x}_s$ is called the Stribeck velocity, which means the low velocity as shown in Fig. 3[8], $F_c$ is the Coulomb friction force, $F_x$ is the resultant force in the horizontal direction.

*2) Dahl friction model*

The applied force is performed by the spring-like characteristics. There is a kind of viscous between the contact surfaces, if the applied force is larger than the defined range, and the viscous effect will be damaged.

$$\frac{dz}{dt} = \dot{x} \text{-} \sigma_0 \frac{|\dot{x}|}{F_c} Z$$

$$F_f = \begin{cases} F_d = \sigma_0 Z \operatorname{sgn}(\dot{x}) & (\dot{x} \neq 0) \\ F_x & (\dot{x} = 0) \end{cases} \tag{6}$$

where $F_d$ is the Dahl friction force, $F_c$ is the Coulomb friction force, $\sigma_0$ is the stiffness coefficient, and $Z$ is the bristle deflection. When the velocity changes to zero, the friction form changes to the resultant force of the horizontal direction, that is $F_x$.

*3) Coulomb friction model*

The Coulomb friction model was discovered by Leonardo da Vinci (1452-1519) and is commonly used in engineering [14]. The Coulomb friction is opposite to the motion direction, proportion to the normal pressure, and independent with displacement, but dependent on the direction of velocity.

$$F_f = \begin{cases} F_c = \mu N \operatorname{sgn}(\dot{x}) & (\dot{x} \neq 0) \\ F_x & (\dot{x} = 0) \end{cases} \tag{7}$$

where $\mu$ is the friction coefficient, $N$ is the normal force, $\dot{x}$ is the velocity and $F_x$ is the horizontal resultant force.

*4) Viscous friction model*

With the development of fluid dynamic technology, affect of viscosity lubrication and viscosity on force has been studied, and velocity has been considered as an important factor of friction, the viscous friction model has been proposed as *Fv* in (8) [15], where $\dot{x}$ is the sliding speed, and $\mu_v$ is the viscous coefficient. When the velocity changes to zero, the friction model switches to $F_x$ as shown in (8).

$$F_f = \begin{cases} F_V = \mu_V \dot{x} \operatorname{sgn}(\dot{x}) & (\dot{x} \neq 0) \\ F_x & (\dot{x} = 0) \end{cases} \tag{8}$$

where *Fv* is the viscous friction, is the viscous friction coefficient, $\mu_v$ is the resultant force in the horizontal direction, $\dot{x}$ is the velocity.

*5) LuGre friction model*

The LuGre friction models the average deflection force of elastic springs [16]. If the applied tangential force is large enough to damage the spring-like characteristic, the bristle starts to slip. The LuGre friction models the Stribeck effect and supposes that the contact surfaces are pushed apart by the lubricant.

$$\begin{gathered} \frac{dz}{dt} = \dot{x} - \frac{\sigma_1 |\dot{x}|}{F_V} Z \\ F_V = F_C + (F_S - F_C) e^{-(\frac{\dot{x}}{v_S})\alpha} \\ F_f = \begin{cases} F_V = (\sigma_1 Z + \sigma_2 \frac{dz}{dt} + \sigma_3 \dot{x}) \operatorname{sgn}(\dot{x}) & (\dot{x} \neq 0) \\ F_x & (\dot{x} = 0) \end{cases} \end{gathered} \tag{9}$$

where the state *Z* represents the average bristle deflection, which means the difference between the relative position of the bristle and the position where the bond was formed [8], $\sigma_1$ is the stiffness, $\sigma_2$ is the micro damping and $\sigma_3$ is the viscous friction coefficient, $F_v$ represents the Stribeck effect, $F_c$ is the Coulomb friction force and $F_s$ is the static friction force.

*6) Coulomb+viscous friction model*

Based on the development of fluid mechanics, it is found that there is viscosity between the contact surfaces, the viscous friction force is proportional to the velocity.

$$F_f = \begin{cases} F_c \operatorname{sgn}(\dot{x}) + \mu \dot{x} \operatorname{sgn}(\dot{x}) & (\dot{x} \neq 0) \\ F_x & (\dot{x} = 0) \end{cases} \tag{10}$$

where $F_c$ is the Coulomb friction, $\dot{x}$ is the velocity, $\mu$ is the viscous friction coefficient and $F_x$ is the resultant force in the horizontal direction.

## IV. SIMULATION STUDY OF THE SPRING-BLOCK SYSTEM

To get the real values of the parameters, for instance, the dynamic friction coefficient, the static friction coefficient, the maximum static friction force and so on, in this paper, a physical experiment was carried out to complete this work.

For the system as shown in Fig. 5, the steel block stands on the aluminium flat, compasses the spring one end of which is fixed to the left wall. When the spring is released, the steel block will move forward and will stop at one point because of the friction of the contact surfaces. Applying different friction models in simulation, different values of the mass block displacements can be obtained. The model under which the displacement value is closest to the experiment result can be chosen as the most accurate model.

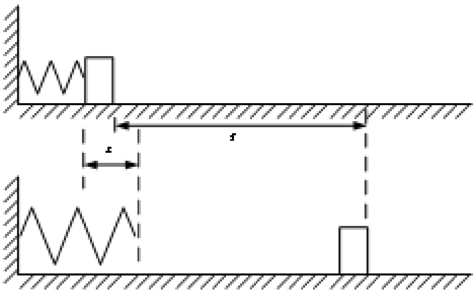

Figure 5. Spring-steel block system for experiment and simulation study

From the energy equation (11), the displacement of the system is unique for the determinant parameters. As a result, the value of displacement can be chosen as the key factor to select the friction model.

$$\frac{1}{2} kx^2 = \mu mgs \tag{11}$$

Both in the simulation study and in the experiment, the applied force is *F*=10N, the applied time is 0.1s.

TABLE I. STEEL BLOCK PARAMETERS

| Parameter | Value |
|---|---|
| *M* | 1kg |
| *K* | 100N/m |
| $\mu_d$ | 0.25[17] |
| $\mu_s$ | 0.35[17] |

Parameters used simulation study, the same with the real parameters used in experiment

### *A. Physical experiment to find the most accurate friction model*

As shown in Fig. 5, the spring is attached to the left wall with a compression length *x*. There are also a steel mass block and an aluminium platform. When the spring is released, the steel mass block will go to the right direction and will stop at a distance *s*. Values of parameters applied in the experiment and the simulation study are the same. In Fig. 5, *m* is the mass of the steel block, *k* the spring constant, and *F=Kx* the external applied force to the system. The task of the experiment is to measure the displacement of the block when the spring releases. Parameter values used in the experiment are as shown in Table I. Through the experiment, the displacement of the mass block is 0.20*m*.

### *B. Apply friction models to the spring-mass block system in simulink*

*1) Coulomb friction model result*

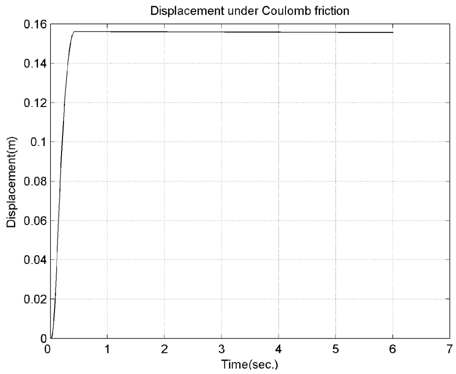

Figure 6. Displacement under Coulomb friction model

Figure 6. shows that the velocity of the mass block under the Coulomb friction model is always positive and the displacement keeps at 0.16$m$ when the mass block goes to still, without reverse motion.

*2) Dahl friction model result*

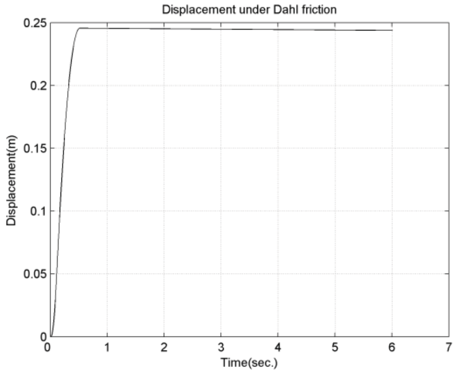

Figure 7. Displacement under Dahl friction model

Figure 7. illustrates that the relative velocity between the steel mass block and aluminium flat does not turn to negative, and the displacement is 0.25$m$ when the steel block stops without the inverse motion.

*3) Stribeck friction model result*

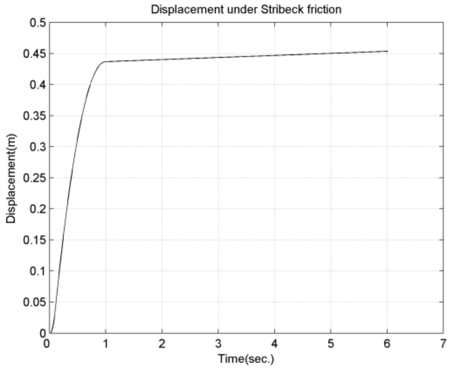

Figure 8. Displacement under Stribeck friction model

From Fig. 8, the velocity of the steel block under the Stribeck friction model does not change to zero exactly and the displacement is about 0.45$m$ when the simulation time reaches about 10$s$, the final result is not consistent with the physical reality.

*4) LuGre friction model result*

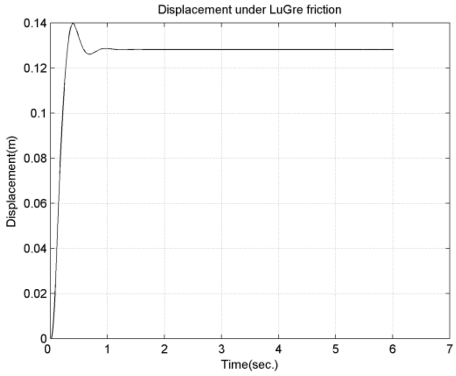

Figure 9. Displacement under LuGre friction model

Figure 9. demonstrates that the velocity of the steel block under the LuGre friction model firstly changes to negative and then returns to zero. And the displacement decreases before it keeps still. The final displacement is 0.13$m$.

*5) Coulomb plus viscous friction model result*

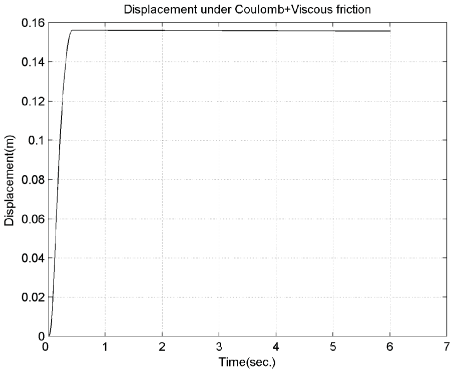

Figure 10. Displacement under Coulomb+Viscous friction model

From Fig. 10, the velocity does not change to negative and the displacement of the steel mass block stops at 0.16$m$ without inverse motion.

The research results from the simulation study are summarized in table II.

TABLE II. RESEARCH RESULTS

| **Friction model** | **Velocity*** | **Displacement** | **Relative error**** |
|---|---|---|---|
| Coulomb | Yes | 0.16$m$ | 20% |
| Dahl | Yes | 0.25$m$ | 25% |
| LuGre | No | 0.13$m$ | 35% |
| Stribeck | Yes | 0.45$m$ | 125% |
| Coulomb+Viscous | Yes | 0.16$m$ | 20% |

*velocity is always positive or not; **relative error is between the simulation result and the experiment result.

From Table II, the LuGre friction model falls into disuse firstly because of negative velocity. Displacement of mass block reaches different values under different friction models. The minimal relative error is 20% under the improved Coulomb friction model as shown in (7) and improved Coulomb plus viscous friction model as shown in (10). According to the selection criterion proposed previous, the most accurate friction model should be the improved Coulomb friction model or the Coulomb plus viscous friction model.

Friction property depends mostly on the contact surfaces. Because the spring-steel block and the pendulum-driven cart share the same physical condition, the selected friction model can be applied to the pendulum-driven cart system in the future research.

## V. CONCLUSIONS

Applying the selected friction model (take Coulomb plus viscous friction model for instance) to the pendulum-driven cart-pole system as shown in Fig. 1, the displacement and velocity of the cart under the Coulomb plus Viscous friction model are shown in Fig. 11.

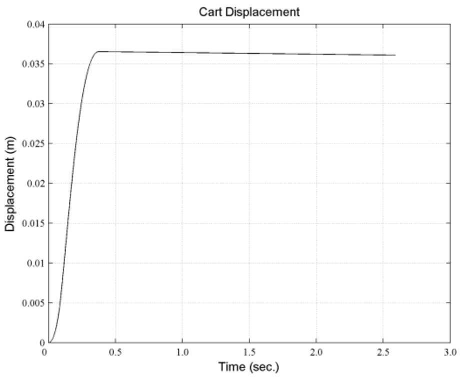

Figure 11. Cart displacement under Coulomb+viscous friction model

From Fig. 11, the cart velocity under the Coulomb plus viscous friction model does not change to negative. The cart displacement under the Coulomb plus viscous friction model does not decrease any more. At the same time, the improved friction model can also makes the cart drives to the same displacement with the previous friction models, without any inverse motion, which is consistent with the physical phenomena.

This paper has completed the following tasks

- Studied the friction phenomena and investigated switching between static and dynamic friction models.
- Proposed two selection criterions of the friction models.
- Simulated the spring-steel block system.
- Did the physical experiment.
- Got the most suitable friction model for the spring-steel mass block system as shown in Fig. 5 and the pendulum-driven cart system as shown in Fig. 1.

In conclusion, the selected friction model considers the switching between dynamic and static friction, and makes the pendulum-driven cart system move in the positive direction without any inverse motion.

# A theoretical approach to the passive control of spiral vortex breakdown

Ubaid A. Qadri and Matthew P. Juniper

University of Cambridge
Cambridge, UK CB2 1PZ
Email:uaq20@cam.ac.uk

***Abstract*—Previous numerical simulations have shown that vortex breakdown starts with the formation of a steady axisymmetric bubble and that an unsteady spiralling mode then develops on top of this. We study how this spiral mode of vortex breakdown might be suppressed or promoted. We use a Lagrangian approach to identify regions of the flow which are sensitive to small open-loop steady and unsteady (harmonic) forces. We find these regions to be upstream of the vortex breakdown bubble. We investigate passive control using a small axisymmetric control ring. In this case, the steady and unsteady control forces are caused by the drag force on the control ring. We find a narrow region upstream of the bubble where the control ring will stabilise the flow and we verify this using numerical simulations.**

***Index Terms*—flow control, vortex breakdown, passive control, adjoint, sensitivity analysis**

## I. Introduction

Vortex breakdown has been observed in many practical flows, such as the flow over the leading edge of delta wings at high angles of attack, the injection of fuel and air into combustion chambers, and the intense rotating flow found in a tornado. In all these cases, when the fluid rotates with sufficient azimuthal velocity (swirl), a stagnation point and a recirculation bubble form within it. The transition from the flow without a breakdown bubble to the flow with a breakdown bubble is labelled *axisymmetric* vortex breakdown. In many cases, a spiral structure is seen to emanate and grow downstream of the breakdown bubble. This is labelled *spiral* vortex breakdown.

Vortex breakdown was first observed in the flow over gothic and delta wings at high angles of attack in 1957 [1]. Since then, several different forms of vortex breakdown have been observed in a variety of experimental settings such as tubes, nozzles, and combustion chambers. Investigators often observed the axisymmetric and spiral modes of breakdown to occur almost simultaneously. This led to disagreements over the nature of vortex breakdown. Recent numerical studies of vortex breakdown in an unconfined domain [2], [3], however, have confirmed that the basic form of vortex breakdown is axisymmetric and that the spiral mode is caused by the self-sustained growth of helical perturbations on top of the breakdown bubble. This is a global instability.

The importance of the vortex breakdown phenomenon means that there is a need to understand and control it. In the past, various open-loop control strategies have been attempted [4]. These include active flow control using blowing and suction, and passive flow control using mechanical devices in the flow. However, their success has always been limited due to insufficient knowledge of the physical mechanisms that are at work. To this end, numerical sensitivity analyses have been successful in predicting how one might control vortex shedding off cylinders and other blunt bodies at moderate Reynolds numbers [5]–[8]. These sensitivity analyses use adjoints to calculate the receptivity of the flow to external forcing and the sensitivity of the flow to internal feedback. They can provide information about the effect of steady and harmonic forces on the unstable mode. Hence they have been used to predict where a control device should be placed to either suppress or promote vortex shedding.

In this paper, we carry out a similar analysis around the axisymmetric vortex breakdown state and predict how the spiral mode of vortex breakdown might be suppressed or promoted. In Section II, we consider the stability of the axisymmetric breakdown state and show that spiral vortex breakdown is caused by a linear global instability. In Section III, we use adjoints to evaluate the effect of a small control force on the growth rate of the unstable mode and identify the regions of the flow that are most sensitive to a control force. In Section IV, we apply these results to the simple case of passive control using a small axisymmetric control ring. Finally, in Section V, we discuss how these techniques can be applied in practice.

This study is at $Re = 200$ and the primary motivation is scientific. There are important industrial motivations, however. Vortex breakdown occurs in wingtip vortices behind aircraft, in vacuum cleaners, and in gas turbine combustion chambers. In the case of combustion chambers, hydrodynamic instabilities in the flow can lock into acoustic resonances within the combustion chamber, causing high amplitude thermoacoustic instabilities, which can be catastropic. This fundamental study of spiral vortex breakdown will reveal the regions of the flow where control would be most effective. This could help designers devise effective control strategies.

## II. The flow configuration and the global stability analysis

We study the motion of a viscous fluid in a cylindrical domain with length $X_{max}$ and radius $R_{max}$, using cylindrical coordinates $(x, r, \theta)$. The flow has density $\rho$, pressure $p$, temperature $T$, and velocity $\mathbf{u} = (u_x, u_r, u_\theta)^T$. We describe the motion of the flow using the Navier–Stokes equations in the low Mach number limit. This allows for density variations in the flow but excludes acoustic waves. These equations can be expressed in terms of the momentum $\mathbf{m} = \rho\mathbf{u}$, temperature and pressure as

$$\frac{\partial \mathbf{q}}{\partial t} = \mathcal{N}\mathbf{q}, \tag{1}$$

where $\mathbf{q} \equiv (m_x,\, m_r,\, m_\theta,\, T, p)^T$ is the state vector and $\mathcal{N}$ is a nonlinear differential operator representing the action of the equations on the state vector. The density, $\rho$, is not included in the state vector because it can be derived from the temperature, $T$.

Along $x = X_{max}$ and $r = R_{max}$, we choose boundary conditions so that we model flow into a semi-infinite domain in the downstream and radial directions. At the inlet to the domain, we impose velocity profiles that have been used to study vortex breakdown numerically in the past [9]. This Grabowski profile, shown in Figure 1, has uniform density and temperature. The ratio of the azimuthal to axial velocities at $r = 1$ defines the swirl parameter, $Sw$. The Reynolds number is defined in terms of the nominal vortex core radius and uniform axial velocity. In this study, we keep $Re = 200$.

We obtain a steady axisymmetric laminar baseflow, $\bar{\mathbf{q}}$, or equilibrium point of the equations (1) such that

$$\mathcal{N}\bar{\mathbf{q}} = 0, \tag{2}$$

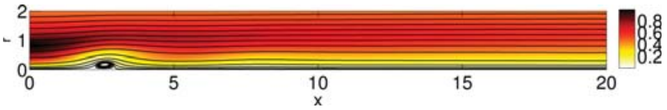

Fig. 2. Steady baseflow at $Sw = 0.915$ and $Re = 200$. The domain extends radially from $-8 \leq r \leq 8$ but only a portion is shown here. There is a small axisymmetric breakdown bubble around $x = 2.5$.

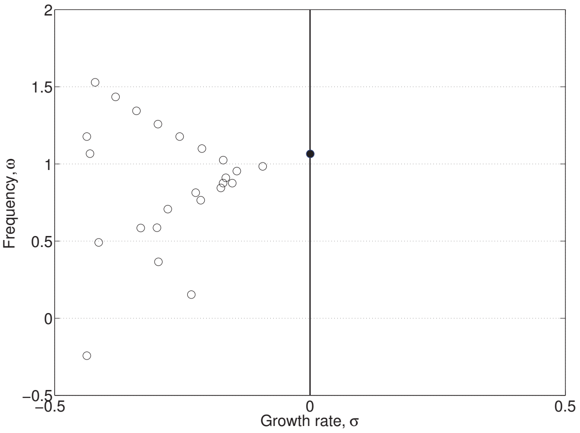

Fig. 3. Spectrum of the linear operator $\mathbf{L}$ for $m = -1$ for the baseflow in Figure 2, showing the 25 least stable eigenvalues. One mode, coloured black, is just unstable.

Figure 2 shows the steady baseflow at $Sw = 0.915$. There is a breakdown bubble around $x = 2.5$. The evolution of small perturbations $\mathbf{q}'$ around this field is governed by

$$\frac{\partial \mathbf{q}'}{\partial t} = \mathbf{L}\mathbf{q}', \tag{3}$$

where $\mathbf{L}$ represents the Navier–Stokes equations linearized about the base-flow $\bar{\mathbf{q}}$. We decompose the perturbations into Fourier modes in time and the azimuthal direction

$$\mathbf{q}'(x, r, \theta, t) = \hat{\mathbf{q}}(x, r)e^{\mathrm{i}m\theta + \lambda t}, \tag{4}$$

where $m$ (without a subscript) is the azimuthal wavenumber, and $\lambda \equiv \sigma + \mathrm{i}\omega$ contains the growth rate, $\sigma$, and frequency, $\omega$. We study the linear dynamics of the flow by analyzing the eigenvalues of $\mathbf{L}$. These are given by solving the matrix eigenvalue problem

$$\lambda\hat{\mathbf{q}} = \mathbf{L}_m\hat{\mathbf{q}}, \tag{5}$$

where $\mathbf{L}_m$ is the linear operator for the azimuthal wavenumber $m$. Each of these eigenvalues has a corresponding two-dimensional eigenfunction, $\hat{\mathbf{q}}(x, r)$. We label each eigenvalue/eigenfunction pair a *direct global mode*. If $\sigma > 0$, the mode is linearly globally unstable. In this linear analysis, the flow tends to the form of the global mode with highest $\sigma$ in the long-time limit and therefore this mode determines the system's overall stability.

Figure 3 shows the eigenvalue spectrum for $m = -1$ at $Sw = 0.915$, for which there is one unstable global mode. All

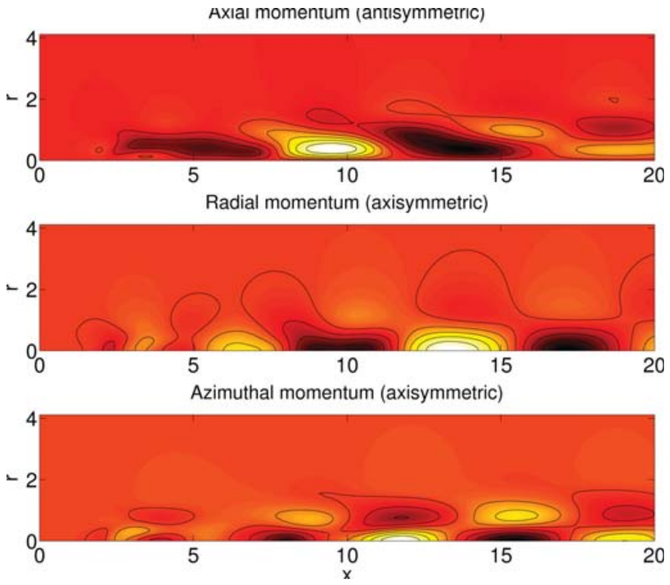

Fig. 4. Spatial structure of the most unstable eigenmode for $m = -1$, showing the real part of the axial, radial and azimuthal momentum in the top half of the domain.

other azimuthal wavenumbers are stable. The spatial structure of the unstable global mode is shown in Figure 4 using the real part of the axial, radial and azimuthal momentum. The imaginary part of the global mode is $1/4$ wavelength out of phase because this mode grows and advects downstream.

## III. Sensitivity to a control force

We now consider open-loop control of the unstable eigenvalue. Depending on the application, engineers might want either to suppress the unstable mode (to delay transition, for instance) or to promote it (to increase mixing, for instance).

To begin with, we evaluate the effect of a small control force on the unstable eigenvalue. We model the control force by adding mass, momentum and energy source terms to the right-hand side of equation (1):

$$\frac{\partial \mathbf{q}}{\partial t} = \mathcal{N}\mathbf{q} + \mathbf{F}. \qquad (6)$$

Here, the forcing terms have been grouped together as $\mathbf{F}$. The control force has a steady component ($\bar{\mathbf{F}}$) that acts on the base flow ($\bar{\mathbf{q}}$) and a linearized perturbation ($\mathbf{f}'$) that acts on the linear operator ($\mathbf{L}$) . We model the effects of these two components separately [10].

### *A. The sensitivity to steady forcing*

The eigenvalue of the global mode, $\lambda = \sigma + \mathrm{i}\omega$, is a function of the base flow fields ($\bar{\mathbf{q}}$) and these are, in turn, functions of the steady components of the forcing terms ($\bar{\mathbf{F}}$). The eigenvalue can, thus, be considered to be a function of the steady component of the forcing terms, $\lambda = f(\bar{\mathbf{F}})$. We wish to find the gradient of the functional $\lambda(\bar{\mathbf{F}})$ [8, Fig.9] for the unstable flow in §II. We investigate the variation of the eigenvalue, $\delta\lambda_{\bar{\mathbf{F}}}$, with respect to small variations of the steady forces, $\delta\bar{\mathbf{F}}$. The change in the eigenvalue is given by

$$\delta\lambda_{\bar{\mathbf{F}}} = \langle \nabla_{\bar{\mathbf{F}}}\lambda, \delta\bar{\mathbf{F}} \rangle, \qquad (7)$$

where $\nabla_{\bar{\mathbf{F}}}\lambda$ is a complex function that we call the *sensitivity of the eigenvalue to steady forcing*. The notation $\langle \mathbf{a}, \mathbf{b} \rangle$ denotes an inner product over a volume $V$,

$$\langle \mathbf{a}, \mathbf{b} \rangle = \frac{1}{V}\int_V \mathbf{a}^H \mathbf{b}\, dV, \qquad (8)$$

where $\mathbf{a}^H$ denotes the Hermitian (*i.e.* complex conjugate transpose) of $\mathbf{a}$.

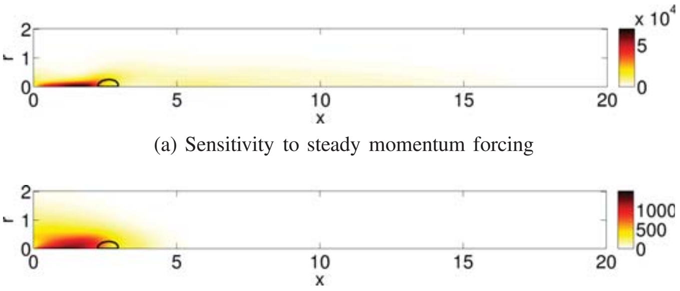
We calculate the sensitivity function by formulating a Lagrangian problem for $\lambda$. The nonlinear and linearised Navier–Stokes equations act as constraints in this problem,

$$\mathcal{L} = \lambda - \langle \bar{\mathbf{q}}^+, \mathcal{N}\bar{\mathbf{q}} - \bar{\mathbf{F}} \rangle - \langle \hat{\mathbf{q}}^+, \lambda\hat{\mathbf{q}} - \mathbf{L}_m\hat{\mathbf{q}} \rangle \qquad (9)$$

The Lagrange multipliers, $\bar{\mathbf{q}}^+$ and $\hat{\mathbf{q}}^+$, are the adjoint base flow and adjoint global mode fields respectively. We are interested in the functional derivative of $\mathcal{L}$ with respect to $\bar{\mathbf{F}}$. To find this, we first set the functional derivatives of $\mathcal{L}$ with respect to all other variables to zero. This leads to a set of equations that defines an eigenvalue problem for the adjoint global mode, a set of equations for the adjoint base flow fields and the normalization condition $\langle \hat{\mathbf{m}}^+, \hat{\mathbf{m}} \rangle + \langle \hat{T}^+, \hat{T} \rangle = 1$. The analysis then shows that the sensitivity of the eigenvalue to the steady forcing terms is given by the relevant adjoint baseflow field. For example, the sensitivity to momentum forcing is given by the adjoint baseflow momentum, $\bar{\mathbf{m}}^+$.

The adjoint base flow fields are complex valued. The real part represents the sensitivity of the growth rate, $\sigma$ while the imaginary part represents the sensitivity of the frequency $\omega$ to small changes in the steady forcing. They provide information about the most sensitive regions for control based on the physical mechanisms that cause the instability.

The adjoint base flow equations contain terms from the steady base flow, the direct global mode and the adjoint global mode. These need to be calculated before the adjoint base flow equations can be solved. The procedure for obtaining the sensitivity to steady forcing involves the following steps:
1. Obtain a steady base flow (Equation 2 and Figure 2).
2. Obtain the direct global mode by solving the direct eigenvalue problem (Equation 5 and Figure 4).
3. Obtain the adjoint global mode by solving the adjoint eigenvalue problem.
4. Normalize the adjoint global mode.
5. Solve the adjoint base flow equations to obtain the sensitivity of that global mode to steady forcing.



(a) Sensitivity to steady momentum forcing

(b) Sensitivity to unsteady momentum forcing

Fig. 5. Sensitivity to steady and unsteady forcing for the marginally unstable mode. Darker regions are more sensitive. The thick black line indicates the vortex breakdown bubble. The quantities plotted are (a) The adjoint baseflow momentum $||\bar{\mathbf{m}}^{+}||$ and (b) the adjoint global mode momentum $||\hat{\mathbf{m}}^{+}||$

### B. *Sensitivity to unsteady forcing*

The change in the eigenvalue due to a small linearized force ($\delta\mathbf{f}'$) that acts on the linear operator $\mathbf{L}$ is given by

$$\delta\lambda_{\mathbf{f}'} = \langle \nabla_{\mathbf{f}'}\lambda, \delta\mathbf{f}' \rangle, \tag{10}$$

where $\nabla_{\mathbf{f}'}\lambda$ is labelled the *sensitivity of the eigenvalue to harmonic forcing*.

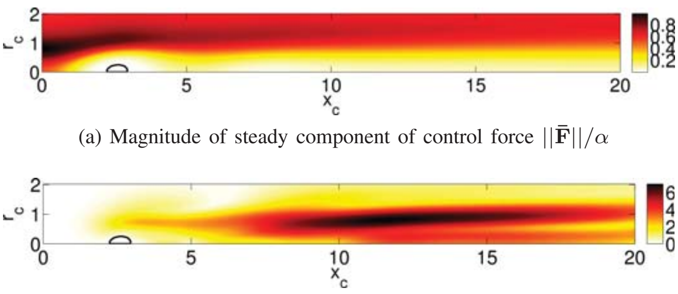
As for the steady forcing terms, the sensitivity of the eigenvalue to harmonic forcing is given by the relevant adjoint global mode fields. The change in the eigenvalue is, thus, simply obtained by projecting the linearized force onto the adjoint global mode fields. The largest change is obtained when the forcing frequency is equal to the frequency of the linear global mode [8, §4.1].

### C. *Results of sensitivity analysis*

Figures 5a and 5b show the sensitivity of the marginally unstable eigenvalue to steady and harmonic forcing respectively. We notice that, for both types of forcing, the flow is most sensitive just upstream of the breakdown bubble. This shows where a control force will have the greatest effect. The scales in the plot indicate that the sensitivity to steady forcing is almost an order of magnitude greater than the sensitivity to harmonic forcing.

## IV. Passive control using a small control ring

In this section, we extend the results from the previous section to the specific case of a thin axisymmetric control ring that is placed in the flow. The force on the flow is equal and opposite to the drag force that the control ring experiences. In a cylindrical co-ordinate system, this force can be modelled by the force on a small circular cylinder. As a simple model, the steady and unsteady components of the force due to a cylinder placed at $(x_c, r_c)$ are given by



(a) Magnitude of steady component of control force $||\bar{\mathbf{F}}||/\alpha$

(b) Magnitude of unsteady component of control force $||\hat{\mathbf{f}}||/\alpha$

Fig. 6. Magnitude of the steady and unsteady force from a control ring placed in the flow. Darker regions have higher magnitude. The thick black line indicates the vortex breakdown bubble.

$$\begin{aligned}
\bar{\mathbf{F}}(x,r) &= -\alpha||\bar{\mathbf{u}}||\bar{\mathbf{u}}\,\delta(x-x_c, r-r_c), && (11)\\
\mathbf{f}'(x,r,t) &= \hat{\mathbf{f}}(x,r)e^{\lambda t}, && (12)\\
\hat{\mathbf{f}}(x,r) &= -\alpha\left(\frac{\bar{\mathbf{u}}\cdot\hat{\mathbf{u}}}{||\bar{\mathbf{u}}||}\bar{\mathbf{u}} + ||\bar{\mathbf{u}}||\hat{\mathbf{u}}\right)\delta(x-x_c, r-r_c) && (13)
\end{aligned}$$

where $\alpha$ is a measure of the magnitude of the force.

Figures 6a and 6b show the magnitude of the steady and unsteady force as a function of the location of the control ring. The steady component is largest near the inlet because the baseflow velocities are high there, whereas the unsteady component is largest further downstream because the amplitude of the global mode is maximum there. We also notice that the unsteady component of the force is about an order of magnitude greater than the steady component. However, we know from equations (7) and (10) that the effect of the control ring on the unstable eigenvalue depends on the overlap of figures 5 and 6. We substitute the expressions in equations (11) and (13) into equations (7) and (10). The total change in the eigenvalue is given by the sum of the contributions from the steady and unsteady components

$$\delta\lambda_{total} = \delta\lambda_{\bar{\mathbf{F}}} + \delta\lambda_{\mathbf{f}'}. \tag{14}$$

In Figure 7, we plot the change in the eigenvalue as a function of the location of the control ring showing the total change as well as the contributions from the steady and unsteady components of the force on the same color scale. These figures identify the locations where passive control using the control ring would be most effective. There is a narrow region upstream of the bubble where the control ring will stabilise the flow and a much larger region downstream of the bubble where the control ring will destabilise the flow. These figures also show that the contribution from the steady component is significantly larger than the contribution from the unsteady component.

## V. Dynamics of the controlled system

We now verify whether the behaviour predicted by our linear sensitivity analysis actually occurs. We model the

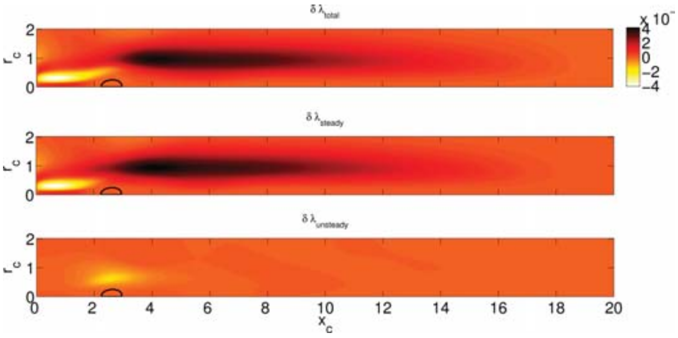


Fig. 7. The change in the eigenvalue as a function of the location of the control ring, from top (a) Total change, (b) Contribution from the steady component of the force and (c) Contribution from the unsteady component of the force. The figures have the same color scale. Light regions indicate regions of stabilisation, whereas dark regions indicate regions of destabilisation. The thick black line indicates the vortex breakdown bubble.

presence of a small control ring at $(x_c, r_c) = (0.66, 0.33)$. This corresponds to the centre of the region of stabilisation in Figure 7(a).

We choose a value of $\alpha = 0.1$ and add the forcing term in equation (11) to our nonlinear equations. We obtain a new steady baseflow and study the linear dynamics of the controlled system. Figure 8 compares the spectrum of the controlled system with that of the uncontrolled system. We notice that the unstable eigenvalue has been stabilised. Our linear sensitivity analysis predicts the eigenvalue of the system with a control ring at $(x_c, r_c) = (0.66, 0.33)$ to be $-0.021 + 2.120\text{i}$ which agrees well with the value obtained from the stability analysis of the controlled system, $-0.018 + 2.119\text{i}$.

The dynamics of the controlled and uncontrolled system can also be seen in Figure 9. We superpose small amplitude random-noise perturbations on the steady baseflows for the controlled and uncontrolled systems and monitor the energy of these perturbations over time. In the uncontrolled system, following some initial transient phase, these perturbations grow linearly. In the controlled system, these perturbations decay linearly.

## VI. Applications and further work

In the previous section, we demonstrated that this approach to the control of spiral vortex breakdown works in theory. We now consider some of the practical issues related to this approach.

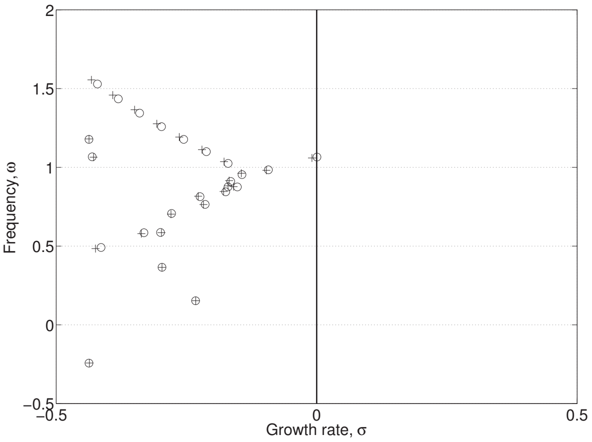

Fig. 8. Spectrum of the linear operator $\mathbf{L}$ for $m = -1$ for the uncontrolled (o) and controlled (+) baseflows, showing the 25 least stable eigenvalues. The marginally unstable eigenvalue in the uncontrolled flow is stable in the controlled flow.

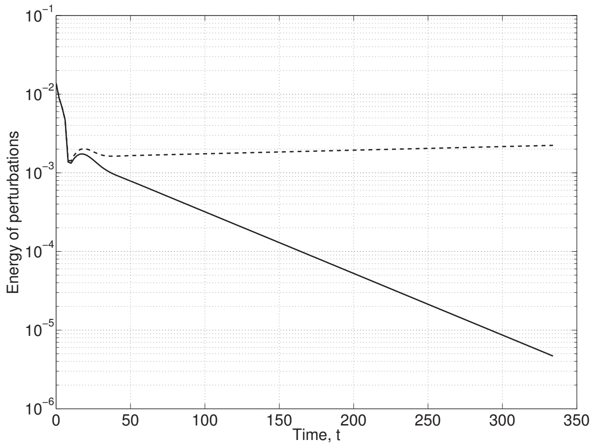

Fig. 9. The evolution of the energy of perturbations for $m = -1$ on top of the baseflows for the uncontrolled (dashed) and controlled (solid) system.

Practical engineering applications feature flows at much higher Reynolds numbers than that considered in this paper. In such cases, obtaining a steady baseflow would be very difficult and it might be easier and more relevant to carry out a sensitivity analysis around the mean flow. This would not be mathematically rigorous but could still provide valuable practical information for designers.

The control ring concept that we have used here is a simple model for a control device. An example of something similar that could be used in practice is a hot wire that forms an axisymmetric ring centred on the axis. The sensitivity of the location of the hot wire to the temperature and velocity can be obtained from the relevant adjoint fields, (namely, the adjoint temperature $\bar{T}^+$ and the adjoint momentum $\bar{\mathbf{m}}^+$. We have chosen to demonstrate this technique for vortex breakdown in an open domain. However, it can just as easily be applied to the control of vortex breakdown in a closed vessel (such as a combustion chamber). In this case, the adjoint pressure $\bar{p}^+$ can be used to obtain the sensitivity to mass injection. This would offer insight into how active control techniques such as blowing or suction could be used to control spiral vortex breakdown.

The tools that have been developed here are now being applied to study swirling flows with variable density and combustion. The overall aim of this project is to develop the capability of producing sensitivity maps of real fuel injectors in combustion chambers. These sensitivity maps would give information about where the design should be changed to promote or suppress certain flow behaviours, taking into account the physical mechanisms that act in the flow.

## VII. Conclusions

In this paper, we have considered a theoretical approach to the control of spiral vortex breakdown. We have shown that spiral vortex breakdown is caused by an unstable eigenmode that grows on top of the steady axisymmetric vortex breakdown bubble. We have used a Lagrangian approach to identify regions where the flow is most sensitive to small steady and unsteady (harmonic) forces. We have found that the regions upstream of the vortex breakdown bubble are most sensitive to steady and unsteady forces.

We then considered passive control using a small control ring placed in the flow. We have identified regions where this control device should be placed to stabilise or destabilise the flow. We have found that there is a narrow region upstream of the bubble where the control ring will stabilise the flow. We have verified this using numerical simulations.

The results from this study have shown that a linear sensitivity analysis can provide useful information for control, based on the underlying physics of the flow. This technique can be easily extended to control spiral vortex breakdown in more complicated geometries.

***Abstract*—Stochastic adaptive control of a manipulator with a passive joint which has neither an actuator nor a holding brake is investigated. Aiming at shaping the controlled manipulators dynamics to be of minimized motion tracking errors and joint accelerations, we employ the linear quadratic regulation (LQR) optimization technique to obtain an optimal reference model. Adaptive neural network (NN) control has been developed to ensure the reference model can be matched in finite time, in the presence of various uncertainties and stochastic noise. In addition, due to the stochastic noise, we transform the system equation to the Ito stochastic differential equation (SDE) form and then use the Ito formula to deal with the stochastic terms of the systems. Simulation studies show the effectiveness of the planned trajectory and the feedback control laws.**

*Key Words* – Stochastic NN control, optimization, LQR, model reference control

## I. Introduction

Underactuated robots have received considerable research attention in the last two decades ([1]-[7]). In contrast to conventional robot for which each joint has one actuator and its degree of freedom equals the number of actuators, an underactuated robot has passive joints equipped with no actuators. The underactuation structure make possible for the robots to reduce the weight, energy consumption, and cost of manipulators, which can be applied to the tasks involving an impact, e.g., hitting or hammering an object, will be useful since the impact causes no damage to the joint actuators. It can also contribute to fault tolerance of fully-actuated manipulators in case some of the joint actuators fail.

Though the passive joints are not actuated but they can be controlled by using the dynamic coupling with the active joints, i.e., these passive joints can be indirectly driven by other active joints. The zero torque at the passive joints results in a second-order nonholonomic constraint. This method allows the control of more joints than actuators. In robotics, nonholonomic constraints formulated as nonintegrable differential equations containing time-derivatives of generalized coordinates (velocity, acceleration etc.) are mainly studied. Such constraints include the following: 1) Kinematic constraints which geometrically restrict the direction of mobility; 2) Dynamic constraints due to dynamic balance at passive degrees of freedom where no force or torque is applied. Wheeled vehicles [1], rolling contact between objects [2], trailers [3], [4], and manipulators with nonholonomic gears [5] are mechanical systems which have constraints of the former type. Constraints on space robots [6], [7] belong to the latter. These systems commonly have fewer control inputs than the number of generalized coordinates. Therefore, it is necessary to combine the limited number of inputs skillfully in order to control all the coordinates. So how to efficiently control this kind of nonholonomic systems becomes an interesting research area.

In this paper we consider a $n$-joints under-actuated system with passive last joint and use the LQR optimization approach to derive a reference model for the first $n-1$ joints subsystems, which guarantees motion tracking and achieves the minimized moving accelerations. High order neural networks (HONNs) have been employed to design the adaptive control in order to make the controlled dynamics to match the reference model dynamics in finite time. Instead of leaving the unactuated joint dynamics uncontrolled, a reference trajectory for the last joint is designed to indirectly affect the movements such that the desired motion can be achieved. HONNs also have been employed to construct a reference trajectory generator of the last joint.

## II. Stochastic finite-time attractiveness

Consider the following stochastic nonlinear system with the Ito SDE form

$$dx = f(x)dt + g(x)dw \tag{1}$$

where $x \in \mathbf{R}^n$ is the state, $w$ is an independent $r$-dimensional standard Wiener process defined on the complete probability space $(\Omega, \mathscr{F}, \mathbf{P})$, the Borel measurable functions $f : \mathbf{R}^n \to \mathbf{R}^n$ and $g : \mathbf{R}^n \to \mathbf{R}^{n\times r}$ are locally Lipschitz continuous with $f(0) = 0$ and $g(0) = 0$. Without loss of generality, we use 0 and $x_0$ to denote the initial time and the initial state of the system. The solution of system (1) with the initial state $x_0$ is denoted by $x(t;x_0)$.

The following two definitions come from [8], which will be used to express our system stability.

*Definition 1:* For system (1), define $T(x_0,w) = \inf\{T \geq 0 : x(t;x_0) = 0, \forall t \geq T\}$, which is called the stochastic settling time function.

*Definition 2:* The equilibrium $x = 0$ of system (1) is globally stochastically finite-time attractive, if for $x_0 \in \mathbf{R}^n$, the following conditions hold.

(i) Stochastic settling time function $T_0(x_0,w)$ exists with probability one.

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

(ii) Provided that $T_0(x_0,w)$ exists, then $E[T_0(x_0,w)] < \infty$.

For a given $V(x) \in \mathbf{C}^2$, the infinitesimal generator $\mathscr{L}$ with regard to (1) is defined by

$$\mathscr{L}V(x) = \frac{\partial V}{\partial x} f(x) + \frac{1}{2} Tr\left\{ g^T(x) \frac{\partial^2 V}{\partial x^2} g(x) \right\}. \tag{2}$$

We now state the stochastic Lyapunov lemma for stochastic finite-time attractiveness, which is a combination of Corollary 1 in [8], Theorem 3.1 in [9] and Revision of Corollary 1 in [10], and the proof is omitted here for simplicity.

*Lemma 1:* Assume that system (1) admits a unique solution. If there exists a $\mathbf{C}^2$ function $V : \mathbf{R}^n \to \mathbf{R}_+$ and class $\mathbf{K}_\infty$ function $\alpha_1, \alpha_2$, positive numbers $c > 0$ and $0 < \gamma < 1$, such that for $\forall x \in \mathbf{R}^n$ and $t \geq 0$,

$$\begin{aligned} &\alpha_1(\|x\|) \leq V(x) \leq \alpha_2(\|x\|), \\ &\mathscr{L}V(x) \leq -c(V(x))^\gamma, \end{aligned}$$

then the equilibrium $x = 0$ of system (1) is stochastically finite-time attractive, and $E[T_0(x_0,w)] \leq \frac{(V(x_0))^{1-\gamma}}{c(1-\gamma)}$, which implies $T_0(x_0,w) < +\infty$ a.s.

## III. Dynamics of Under-actuated Robot Manipulator

Partition of generalized coordinate vector $q$ as $q = [q_a^T,\ q_b^T]^T$ with $q_a = [q_1, q_2, \ldots, q_{n-1}]^T$ and $q_b = q_n$ such that

$$q_a = I_0 q, \quad I_0 = [I_{[n-1,n-1]}, 0_{[n-1,1]}] \in R^{(n-1)\times n} \tag{3}$$

and $\tau_a = [\tau_1, \tau_2, \ldots, \tau_{n-1}]^T$. The dynamics model of robot manipulator with passive last joint is described as follows:

$$\begin{aligned} &\begin{bmatrix} M_a & M_{ab} \\ M_{ba} & M_b \end{bmatrix} \begin{bmatrix} \ddot{q}_a \\ \ddot{q}_b \end{bmatrix} + \begin{bmatrix} C_a & C_{ab} \\ C_{ba} & C_b \end{bmatrix} \begin{bmatrix} \dot{q}_a \\ \dot{q}_b \end{bmatrix} \\ &\qquad + \begin{bmatrix} g_a \\ g_b \end{bmatrix} + \begin{bmatrix} \dot{w}_a \\ \dot{w}_b \end{bmatrix} = \begin{bmatrix} \tau_a \\ 0 \end{bmatrix} \end{aligned} \tag{4}$$

Define

$$M = \begin{bmatrix} M_a & M_{ab} \\ M_{ba} & M_b \end{bmatrix}, g = \begin{bmatrix} g_a \\ g_b \end{bmatrix},$$
$$C = \begin{bmatrix} C_a & C_{ab} \\ C_{ba} & C_b \end{bmatrix}, \dot{w} = \begin{bmatrix} \dot{w}_a \\ \dot{w}_b \end{bmatrix}$$

Then (4) can be written in a compact form as

$$M\ddot{q} + C\dot{q} + g + \dot{w} = I_0^T \tau_a \tag{5}$$

where $w$ is an $n$-dimensional independent standard Wiener process. The following property are well known for the Lagrange-Euler formulation of robotic dynamics:

*Property 1:* The matrix $M$ is symmetric and positive definite.

Therefore, the blocks $M_a$ and $M_b$ are also invertable and the inverse of matrix $M$ exist and is

$$M^{-1} = \begin{bmatrix} S_b^{-1} & -M_a^{-1} M_{ab} S_a^{-1} \\ M_b^{-1} M_{ba} S_b^{-1} & S_a^{-1} \end{bmatrix} \tag{6}$$

where $S_a$ and $S_b$ are Schur complements of $M_a$ and $M_b$, respectively, defined as $S_a = M_b - M_{ba} M_a^{-1} M_{ab}, S_b = M_a - M_{ab} M_b^{-1} M_{ba}$. Multiplying $I_0 M^{-1}$ on both sides of (5) gives us

$$\ddot{q}_a + I_0 M^{-1} C\dot{q} + I_0 M^{-1} g + I_0 M^{-1} \dot{w} = I_0 M^{-1} I_0^T \tau_a = S_b^{-1} \tau_a \tag{7}$$

Then, multiplying $S_b$ on both sides of the above equation, we have

$$S_b \ddot{q}_a + S_b I_0 M^{-1} C\dot{q} + S_b I_0 M^{-1} g + S_b I_0 M^{-1} \dot{w}_a = \tau_a \tag{8}$$

Define $\mathscr{M} \triangleq S_b \in \mathbf{R}^{(n-1)\times(n-1)}$, $\mathscr{C} \triangleq S_b I_0 M^{-1} C = [\mathscr{C}_a, \mathscr{C}_b] \in \mathbf{R}^{(n-1)\times n}$ with $\mathscr{C}_a \in \mathbf{R}^{(n-1)\times(n-1)}$, $\mathscr{C}_b \in \mathbf{R}^{(n-1)\times 1}$, and $\mathscr{G} = S_b I_0 M^{-1} g, \mathscr{S} = S_b I_0 M^{-1}$, then, we have $q_a$-subsystems as follows

$$\Sigma_{q_a} : \mathscr{M}\ddot{q}_a + \mathscr{C}_a \dot{q}_a + \mathscr{C}_b \dot{q}_b = \tau_a - \mathscr{G} - \mathscr{S}\dot{w}_a \tag{9}$$

At the same time, we obtain the $q_b$-subsystem as follows:

$$\Sigma_{q_b} : M_b \ddot{q}_b + C_b \dot{q}_b + g_b + \dot{w}_b + M_{ba} \ddot{q}_a + C_{ba} \dot{q}_a = 0 \tag{10}$$

*Remark 1:* It should be mentioned that due to the unknown system parameters in the above dynamics formulation, the dynamics matrices $\mathscr{M}, \mathscr{S}$ are actually unknown for control design.However, we still can estimate their regions. So we assume there exist the positive constants $\underline{m}$ and $\bar{m}$ such that $\underline{m} \leq |\mathscr{M}^{-1}| \leq \bar{m}$. But it should be mentioned that these bounds are only used in the stability analysis, and their exact values need not to be known in our controller design.

## IV. Control of subsystem $\Sigma_a$

### A. Subsystem dynamics and optimal reference model

For convenience, defining $\bar{q}_a = [q_a^T,\ \dot{q}_a^T]^T$, $\bar{q}_b = [q_b,\ \dot{q}_b]^T$, and $\bar{q} = [q_a^T,\ q_b,\ \dot{q}_a^T,\ \dot{q}_b]^T$, we rewrite (9) as

$$\dot{\bar{q}}_a = A_a \bar{q}_a + A_b \bar{q}_b + B\mathscr{M}^{-1}(\tau_a - \mathscr{G}) - B\mathscr{M}^{-1}\mathscr{S}\dot{w}_a \tag{11}$$

where

$$\begin{aligned} A_a &= \begin{bmatrix} 0_{[n-1,n-1]} & I_{[n-1,n-1]} \\ 0_{[n-1,n-1]} & -\mathscr{M}^{-1}\mathscr{C}_a \end{bmatrix} = \begin{bmatrix} \mathbf{0} & \mathbf{I} \\ A_{a1} & A_{a2} \end{bmatrix} \\ A_b &= \begin{bmatrix} 0_{[n-1,1]} & 0_{[n-1,1]} \\ 0_{[n-1,1]} & -\mathscr{M}^{-1}\mathscr{C}_b \end{bmatrix} = \begin{bmatrix} \mathbf{0} & \mathbf{0} \\ A_{b1} & A_{b2} \end{bmatrix} \\ B &= \begin{bmatrix} 0_{[n-1,n-1]}, I_{[n-1,n-1]} \end{bmatrix}^T \end{aligned} \tag{12}$$

For clarity, here and hereafter, the argument $\bar{q}$ of $A_a, A_b, \mathscr{M}, \mathscr{S}$ and $\mathscr{G}$ is omitted.

The control objective is to control the subsystem dynamics (11) to follow a given reference model

$$\dot{\bar{q}}_m = A_m \bar{q}_m + B M_d^{-1} r_m \tag{13}$$

where $\bar{q}_m \in R^{2(n-1)\times 2(n-1)}$ is the desired response of the system,

$$\begin{aligned} A_m &= \begin{bmatrix} 0_{[n-1,n-1]} & I_{[n-1,n-1]} \\ A_{m1}(\bar{q}_m) & A_{m2}(\bar{q}_m) \end{bmatrix} \\ &= \begin{bmatrix} 0_{[n-1,n-1]} & I_{[n-1,n-1]} \\ -M_d^{-1} K_d & -M_d^{-1} C_d \end{bmatrix} \in \mathbf{R}^{2(n-1)\times 2(n-1)} \\ r_m &= -F_\eta(q_d, \dot{q}_d), \quad \bar{q}_m = [q_m^T, \dot{q}_m^T]^T \end{aligned} \tag{14}$$

In order to choose the optimal values of the reference model parameters, we introduce the following performance index:

$$P_I = \int_{t_0}^{t_f} (e_m^T Q e_m + \ddot{q}_m^T M_d \ddot{q}_m) dt. \tag{15}$$

where $Q = \begin{bmatrix} q_1 & 0 \\ & \ddots \\ 0 & q_{n-1} \end{bmatrix}$, which minimizes both the motion tracking error $e_m = q_m - q_d$ and the joints' angular accelerations. In order to apply the LQR optimization technique[11], we rewrite the reference model (13) as

$$\dot{\bar{q}}_m = A_d \bar{q}_m + Bu \tag{16}$$

with

$$\begin{aligned} A_d &= \begin{bmatrix} 0_{[n-1,n-1]} & I_{[n-1,n-1]} \\ 0_{[n-1,n-1]} & 0_{[n-1,n-1]} \end{bmatrix}, \\ u &= -M_d^{-1}[K_d,\ C_d]\bar{q}_m - M_d^{-1} F_\eta(q_d, \dot{q}_d) \end{aligned} \tag{17}$$

Noting that $u = \ddot{q}_m$ and introducing $\bar{Q}$ defined as

$$\bar{Q} = \begin{bmatrix} Q & 0_{[n-1,n-1]} \\ 0_{[n-1,n-1]} & 0_{[n-1,n-1]} \end{bmatrix} \tag{18}$$

we can then rewrite the performance index (15) as

$$P_{\bar{I}} = \int_{t_0}^{t_f} \left( (\bar{q}_m - \bar{q}_d)^T \bar{Q} (\bar{q}_m - \bar{q}_d) + u^T M_d u \right) dt, \tag{19}$$

where $\bar{q}_d = [q_d^T,\ \dot{q}_d^T]^T$. If we regard $u$ as the control input to system (16), then the minimization of (19) subject to dynamics constraint (16) becomes a typical LQR control design problem, where the solution of $u$ that minimizes (19) is

$$u = -M_d^{-1} B^T P \bar{q}_m - M_d^{-1} B^T s \tag{20}$$

where $P$ is the solution of the following differential equation

$$-\dot{P} = PA_d + A_d^T P - PBM_d^{-1} B^T P + \bar{Q}, \quad P(t_f) = 0_{[2(n-1),2(n-1)]}$$

and $s$ is the solution of the following differential equation

$$-\dot{s} = (A_d - BM_d^{-1} B^T P)^T s + \bar{Q}\bar{q}_d, \quad s(t_f) = 0_{[2(n-1)]} \tag{21}$$

Comparing equations (17) and (20), we can see that the matrices $K_d$ and $C_d$ can be calculated in the following manner:

$$[K_d, C_d] = B^T P, \quad F_\eta = B^T s \tag{22}$$

### *B. NN control and model matching*

According to $\mathscr{M}$'s nonsingularity and from the state feedback control for linear systems, we conclude that there exist $K(\bar{q}) \in \mathbf{R}^{(n-1)\times 2(n-1)}, L(\bar{q}) \in \mathbf{R}^{(n-1)\times 2}, T(\bar{q}) \in \mathbf{R}^{(n-1)\times(n-1)}, G(\bar{q}) \in \mathbf{R}^{(n-1)\times 1}$ such that for the control law chosen by

$$\tau_a = G(\bar{q}) + K(\bar{q})\bar{q}_a + L(\bar{q})\bar{q}_b + T(\bar{q}) r_m, \tag{23}$$

the closed-loop system is the same as the reference model (13). By substituting the control law (23) into the system equation (11), the closed-loop system is given by

$$\begin{aligned} d\bar{q}_a = &\{[A_a + B\mathscr{M}^{-1}K(\bar{q})]\bar{q}_a + [A_b + B\mathscr{M}^{-1}L(\bar{q})]\bar{q}_b \\ &+ B\mathscr{M}^{-1}T(\bar{q})r_m + B\mathscr{M}^{-1}[G(\bar{q}) - \mathscr{G}]\}dt \\ &- B\mathscr{M}^{-1}\mathscr{S} dw_a \end{aligned} \tag{24}$$

Comparing it to match the reference model (13), we obtain

$$\begin{aligned} A_a + B\mathscr{M}^{-1}K(\bar{q}) = A_m, \qquad & \mathscr{M}^{-1}T(\bar{q}) = M_d^{-1} \\ A_b + B\mathscr{M}^{-1}L(\bar{q}) = 0_{[2(n-1),2]}, \quad & G(\bar{q}) - \mathscr{G} = 0_{[n-1]} \end{aligned} \tag{25}$$

Then we have

$$K(\bar{q}) = \mathscr{M}([A_{m1}\ A_{m2}] - [A_{a1}\ \ A_{a2}]),\ G(\bar{q}) = \mathscr{G}, \tag{26}$$

$$L(\bar{q}) = -\mathscr{M}[A_{b1}\ A_{b2}],\ T(\bar{q}) = \mathscr{M}M_d^{-1} \tag{27}$$

Unfortunately, according to Remark 1, the dynamic matrices $A_a, A_b, \mathscr{M}, \mathscr{G}$ are not available during practical implementation, and then the exact values of the desired gains $K(\bar{q}), L(\bar{q}), T(\bar{q})$ and $G(\bar{q})$ are also unknown.

We can employ the HONNs [12] to approximate the controller gains as follows

$$K(\bar{q}) = K^*(\bar{q}) + \varepsilon_K,\ L(\bar{q}) = L^*(\bar{q}) + \varepsilon_L \tag{28}$$

$$T(\bar{q}) = T^*(\bar{q}) + \varepsilon_T,\ G(\bar{q}) = G^*(\bar{q}) + \varepsilon_G \tag{29}$$

with

$$K^*(\bar{q}) = [W_K^{\langle T \rangle} \langle\cdot\rangle S_K(\bar{q})], T^*(\bar{q}) = [W_T^{\langle T \rangle} \langle\cdot\rangle S_T(\bar{q})] \tag{30}$$

$$L^*(\bar{q}) = [W_L^{\langle T \rangle} \langle\cdot\rangle S_L(\bar{q})], G^*(\bar{q}) = [W_G^{\langle T \rangle} \langle\cdot\rangle S_G(\bar{q})] \tag{31}$$

where $\langle\rangle$ expresses matrix block-wise operator, defined in [12]. $W_{Ki,j}, W_{Li,k}, W_{Ti,s}, W_{Gi} \in \mathbf{R}^{l\times 1}$ are the NN ideal weights for $K_{i,j}(\bar{q}), L_{i,k}(\bar{q}), T_{i,s}(\bar{q}), G_i(\bar{q})$, respectively $(i = 1, \cdots, n-1; j = 1, \cdots, 2(n-1); k = 1, 2; s = 1, \cdots, n-1)$, $l$ is the number of the neurons. $S_K(\bar{q}), S_L(\bar{q}), S_T(\bar{q}), S_G(\bar{q})$ are the outputs of the bounded basis functions, and $\varepsilon_K, \varepsilon_L, \varepsilon_T, \varepsilon_G$ are the NN approximation errors. For a fixed number of nodes, we know that $\|\varepsilon_K\|, \|\varepsilon_L\|, \|\varepsilon_T\|, \|\varepsilon_G\|$ are bounded, $W_K, W_L, W_T, W_G$ are unknown constant parameters.

Consider the following NN based control law

$$\begin{aligned} \tau_a &= \hat{K}(\bar{q})\bar{q}_a + \hat{L}(\bar{q})\bar{q}_b + \hat{T}(\bar{q})r_m + \hat{G}(\bar{q}) + \tau_r \\ &= [\hat{W}_K^{\langle T \rangle} \langle\cdot\rangle S_K(\bar{q})]\bar{q}_a + [\hat{W}_L^{\langle T \rangle} \langle\cdot\rangle S_L(\bar{q})]\bar{q}_b \\ &\quad + [W_T^{\langle T \rangle} \langle\cdot\rangle S_T(\bar{q})]r_m + [W_G^{\langle T \rangle} \langle\cdot\rangle S_G(\bar{q})] + \tau_r \end{aligned} \tag{32}$$

where $\tau_r$ is a robust control term for closed-loop stability which will be defined later to compensate for the approximation errors of the NNs and to suppress the disturbaces.

Define

$$\begin{aligned} &e = \bar{q}_a - \bar{q}_{am}, \quad \tilde{W}_K = \hat{W}_K - W_K, \\ &\tilde{W}_L = \hat{W}_L - W_L,\ \tilde{W}_T = \hat{W}_T - W_T,\ \tilde{W}_G = \hat{W}_G - W_G \end{aligned} \tag{33}$$

Substituting the control law (32) into the subsystem dynamics (11), using (33), applying the NN approximations (28)-(29), and recalling (25), we obtain the following error equation

$$\begin{aligned} de = &\Big\{ A_m e + B\mathscr{M}^{-1}(\tau_r - \varepsilon_K \bar{q}_a - \varepsilon_L \bar{q}_b - \varepsilon_T r_m - \varepsilon_G) \qquad (34) \\ &+ B\mathscr{M}^{-1}[\tilde{W}_K^{\langle T \rangle} \langle\cdot\rangle S_K(\bar{q})]\bar{q}_a + B\mathscr{M}^{-1}[\tilde{W}_L^{\langle T \rangle} \langle\cdot\rangle S_L(\bar{q})]\bar{q}_b \\ &+ B\mathscr{M}^{-1}[\tilde{W}_T^{\langle T \rangle} \langle\cdot\rangle S_T(\bar{q})]r_m + B\mathscr{M}^{-1}[\tilde{W}_G^{\langle T \rangle} \langle\cdot\rangle S_G(\bar{q})] \Big\} dt \\ &- B\mathscr{M}^{-1}\mathscr{S} dw_a \end{aligned}$$

For stable $A_m$ of the reference model, let $P_m$ be the symmetric positive definite solution of the Lyapunov equation

$$P_m A_m + A_m^T P_m = -Q_m \tag{35}$$

where $Q_m$ is symmetric positive definite.

The following theorem states the stability of the adaptive NN control.

*Theorem 1:* For the system (11), consider the NN based control laws (32). If the updating laws of the weights of the adaptive NNs are given by

$$\begin{aligned}(\dot{\hat{W}}_{Ki}^{\langle T\rangle})^T &= -\Gamma_{Ki}\langle\cdot\rangle S_{Ki}(\bar{q})\bar{q}_a(e^TP_me)e^TP_m(B)_i\\ (\dot{\hat{W}}_{Ti}^{\langle T\rangle})^T &= -\Gamma_{Ti}\langle\cdot\rangle S_{Ti}(\bar{q})r_m(e^TP_me)e^TP_m(B)_i\\ (\dot{\hat{W}}_{Li}^{\langle T\rangle})^T &= -\Gamma_{Li}\langle\cdot\rangle S_{Li}(\bar{q})\bar{q}_b(e^TP_me)e^TP_m(B)_i\\ \dot{\hat{W}}_{Gi} &= -\Gamma_{Gi}S_{Gi}(\bar{q})\bar{q}_b(e^TP_me)e^TP_m(B)_i\end{aligned} \tag{36}$$

and

$$\begin{aligned}\tau_r &= -k_r(e^TP_me)\,\mathrm{sgn}(B^TP_me)-k_2e-k_3(\|B\|\|P_m\|\|e\|)^2\\ k_r &= k_1+k_{r1}+k_{r2}\end{aligned} \tag{37}$$

where $(B)_i$ stands for the $i-$th column of $B$, $k_1,k_2$ are the positive constants, $k_3 \geq 6\bar{m}\bar{\mathscr{S}}^2, k_{r1} \geq \|\varepsilon_K\bar{q}_a+\varepsilon_L\bar{q}_b+\varepsilon_Tr_m+\varepsilon_G\|, k_{r2} \geq \|[\tilde{W}_K^{\langle T\rangle}\langle\cdot\rangle S_K(\bar{q})]\|\|\bar{q}_a\|+\|[\tilde{W}_L^{\langle T\rangle}\langle\cdot\rangle S_L(\bar{q})]\|\|\bar{q}_b\|+\|[\tilde{W}_T^{\langle T\rangle}\langle\cdot\rangle S_T(\bar{q})]\|\|r_m\|+\|[\tilde{W}_G^{\langle T\rangle}\langle\cdot\rangle S_G(\bar{q})]\|$, $\Gamma_{Ki}\in\mathbf{R}^{(2(n-1)\cdot l)\times(2(n-1)\cdot l)}$, $\Gamma_{Ti}\in\mathbf{R}^{((n-1)\cdot l)\times((n-1)\cdot l)}$, $\Gamma_{Li}\in\mathbf{R}^{(2l)\times(2l)}$,$\Gamma_{Gi}\in\mathbf{R}^{l\times l}$ are the symmetric positive definite matrices, then the adaptive NN controller ensures that the closed-loop system are stochastically finite-time attractive, and for each bounded initial condition, and the parameter estimates $\hat{W}_K,\hat{W}_L,\hat{W}_T,\hat{W}_G$ satisfy

$$\begin{aligned}&\mathbf{P}\{\lim_{t\to\infty}\|\hat{W}_K\|,\lim_{t\to\infty}\|\hat{W}_L\|,\lim_{t\to\infty}\|\hat{W}_T\|\text{and}\\ &\lim_{t\to\infty}\|\hat{W}_G\| \text{ exist and are finite}\}=1.\end{aligned} \tag{38}$$

*Remark 2:* In $\tau_r$, we introduced a positive constant $k_2$, which is only used in the practical controller design to improve the controller's smoothness and doesn't affect our stability proof.

*Proof:* Choose the following Lyapunov function

$$V_1 = U_1+U_2,\ U_1=\frac{1}{2\bar{m}}(e^TP_me)^2,$$

$$\begin{aligned}U_2 = &\sum_{i=1}^{n-1}\tilde{W}_{Ki}^{\langle T\rangle}\Gamma_{Ki}^{-1}(\tilde{W}_{Ki}^{\langle T\rangle})^T+\sum_{i=1}^{n-1}\tilde{W}_{Li}^{\langle T\rangle}\Gamma_{Ki}^{-1}(\tilde{W}_{Li}^{\langle T\rangle})^T\\ &+\sum_{i=1}^{n-1}\tilde{W}_{Ti}^{\langle T\rangle}\Gamma_{Ti}^{-1}(\tilde{W}_{Ti}^{\langle T\rangle})^T+\sum_{i=1}^{n-1}\tilde{W}_{Gi}^{T}\Gamma_{Gi}^{-1}\tilde{W}_{Gi}.\end{aligned} \tag{39}$$

Bearing in mind $\underline{m} \leq |\mathscr{M}^{-1}| \leq \bar{m}$ and applying the Ito formula to $V_1$ yield

$$\begin{aligned}\mathscr{L}V_1 \leq\ & 2(e^TP_me)e^TP_mB(\tau_r-\varepsilon_K\bar{q}_a-\varepsilon_L\bar{q}_b-\varepsilon_Tr_m\\ &-\varepsilon_G)+6\bar{m}\bar{\mathscr{S}}(\|B\|\|P_m\|\|e\|)^2\\ &+2\sum_{i=1}^{n-1}[\tilde{W}_{Ki}^{\langle T\rangle}\langle\cdot\rangle S_{Ki}(\bar{q})]\bar{q}_a(e^TP_me)e^TP_m(B)_i\\ &+2\sum_{i=1}^{n-1}[\tilde{W}_{Ti}^{\langle T\rangle}\langle\cdot\rangle S_{Ti}(\bar{q})]r_m(e^TP_me)e^TP_m(B)_i\\ &+2\sum_{i=1}^{n-1}[\tilde{W}_{Li}^{\langle T\rangle}\langle\cdot\rangle S_{Li}(\bar{q})]\bar{q}_b(e^TP_me)e^TP_m(B)_i\\ &+2\sum_{i=1}^{n-1}\tilde{W}_{Gi}^{T}S_{Gi}(\bar{q})(e^TP_me)e^TP_m(B)_i\\ &+2\sum_{i=1}^{n-1}\tilde{W}_{Ki}^{\langle T\rangle}\Gamma_{Ki}^{-1}(\dot{\tilde{W}}_{Ki}^{\langle T\rangle})^T+2\sum_{i=1}^{n-1}\tilde{W}_{Ti}^{\langle T\rangle}\Gamma_{Ti}^{-1}(\dot{\tilde{W}}_{Ti}^{\langle T\rangle})^T\\ &+2\sum_{i=1}^{n-1}\tilde{W}_{Li}^{\langle T\rangle}\Gamma_{Li}^{-1}(\dot{\tilde{W}}_{Li}^{\langle T\rangle})^T+2\sum_{i=1}^{n-1}\tilde{W}_{Gi}^{T}\Gamma_{Ti}^{-1}\dot{\tilde{W}}_{Gi}\end{aligned} \tag{40}$$

Substituting the adaptive laws (36) to (40), and further substituting $\tau_r$ from (37), leads to

$$\begin{aligned}\mathscr{L}V_1 =\ & -2(k_1+k_{r2})(e^TP_me)e^TP_mB\,\mathrm{sgn}(B^TP_me)\\ &-2k_2(e^TP_me)e^TP_mBe\\ \leq\ & -k_0\|e\|^3<0,\|e\|\neq 0,\end{aligned} \tag{41}$$

with $k_0 = 2k_1\|P_m\|^2\|B\| > 0$. According to Theorem 1 [14], expression (41) means both $U_1$ and $U_2$ are bounded in probability and consequently $\|e\|,\|\tilde{W}_K\|,\|\tilde{W}_T\|$, $\|\tilde{W}_L\|,\|\tilde{W}_G\|$ are bounded in probability, i.e., $\mathbf{P}\{\lim_{t\to\infty}\|\hat{W}_K\|$, $\lim_{t\to\infty}\|\hat{W}_L\|$, $\lim_{t\to\infty}\|\hat{W}_T\|$, and $\lim_{t\to\infty}\|\hat{W}_G\|$ exist and are finite$\}=1$.

On the other hand, according to (40), (41) and (37), we have

$$\begin{aligned}\mathscr{L}U_1 \leq\ & -\frac{1}{\bar{m}}(e^TP_me)(e^TQ_me)-k_0\|e\|^3\leq -k_0\|e\|^3\\ =\ & = -k_0\left(\frac{1}{\|P_m\|^2}(\|e\|\|P_m\|\|e\|)^2\right)^{\frac{3}{4}}\\ \leq\ & -k_0\left(\frac{1}{\|P_m\|^2}\right)^{\frac{3}{4}}\left((e^TP_me)^2\right)^{\frac{3}{4}}=-c(U_1)^{\frac{3}{4}}\end{aligned} \tag{42}$$

where $c = k_0\left(\frac{2\bar{m}}{\|P_m\|^2}\right)^{\frac{3}{4}}$. Thus, by Lemma 1, the closed-loop system (34) achieves the finite-time attractiveness, i.e., the matching error $e$ will reach the origin in finite time with probability one. This completes the proof. ■

## V. Reference trajectory generator for $q_b$ subsystem

For the motion of the passive joint, however, to our best knowledge, there has been very little study to discuss the automatic control of its movement until now. In this work, we attempt to set up a framework to design the reference trajectory for manipulating the last joint to track the desired trajectory. As above discussed, after finite time, $q_a$ will exactly track $q_{ad}$, such that the dynamics (10) becomes as follows:

$$\begin{aligned}\ddot{q}_b =\ & -M_b^{-1}C_b\dot{q}_b-M_b^{-1}g_b-M_b^{-1}\dot{w}_b-M_b^{-1}M_{ba}\ddot{q}_{ad}\\ &-M_b^{-1}C_{ba}\dot{q}_{ad}\end{aligned} \tag{43}$$

Let $\varphi = [\varphi_1, \varphi_2]^T = [q_b, \dot{q}_b]^T$, $\phi = [\phi_1^T, \phi_2^T]^T = [q_{ad}^T, \dot{q}_{ad}^T]^T$ and $v = \ddot{q}_{ad}$. Then, equation (43) can be rewritten as

$$\dot{\varphi}_1 = \varphi_2, \dot{\varphi}_2 = f(\varphi, \phi, v) - M_b^{-1}\dot{w}_b \tag{44}$$

with $f(\varphi, \phi, v) = -M_b^{-1}M_{ba}v - M_b^{-1}(C_b\varphi_2 + g_b + C_{ba}\phi_2)$ and $\dot{\phi}_1 = \phi_2, \dot{\phi}_2 = v$.

Consider the desired forward position and forward velocity of the manipulator as $q_{bd}$ and $\dot{q}_{bd}$, respectively. Then, our design objective is to construct a $v$ (subsequently $\phi_1$ and $\phi_2$) such that $\varphi_1$ and $\varphi_2$ of system (44) follow $\varphi_{1m}$ and $\varphi_{2m}$ generated from the following reference model

$$\dot{\varphi}_{1m} = \varphi_{2m}, \dot{\varphi}_{2m} = f_m(q_{bd}, \dot{q}_{bd}, \varphi_m) \tag{45}$$

where $\varphi_m = [\varphi_{1m}, \varphi_{2m}]^T$ and $f_m(q_{bd}, \dot{q}_{bd}, \varphi_m) = -k_1(\varphi_{1m} - q_{bd}) - k_2(\varphi_{2m} - \dot{q}_{bd}) + \ddot{q}_{bd}$. It can be easily checked that the reference model (45) ensures that $\varphi_{1m} \to q_{bd}$ and $\varphi_{2m} \to \dot{q}_{bd}$. According to implicit function theorem based neural network design [13], there must exist a function $f_v : v^* = f_v(q_{bd}, \dot{q}_{bd}, \varphi, \phi)$ such that $f(\varphi, \phi, v^*) = f_m(q_{bd}, \dot{q}_{bd}, \varphi)$, i.e., there exists the ideal HONNs weight vectors such that

$$v^* = [W_v^{*\langle T\rangle}\langle\cdot\rangle S_v(z)] + \varepsilon_v, \quad z = [q_{bd}, \dot{q}_{bd}, \varphi^T, \phi^T]^T \tag{46}$$

where $\varepsilon_v \in \mathbf{R}^{(n-1)\times 1}$ is the neural network approximation error vector. Let us employ HONNs to approximate $v^*$ as follows:

$$\hat{v} = \hat{W}_v^{\langle T\rangle}\langle\cdot\rangle S_v(z) \tag{47}$$

with $\hat{W}_v^{\langle T\rangle} = [\hat{W}_{v1}^T, \hat{W}_{v2}^T, \cdots, \hat{W}_{v(n-1)}^T]$, where $\hat{W}_{vi}^T \in \mathbf{R}^{l\times 1}(i = 1, 2, \cdots, n-1)$ are the neural network weight vectors. Substituting $\hat{v}$ into (44) and using $f(\phi, \varphi, v^*) = f_m(q_{bd}, \dot{q}_{bd}, \varphi)$, we have

$$\begin{aligned} \dot{\varphi}_1 &= \varphi_2 & (48)\\ \dot{\varphi}_2 &= f_m(q_{bd}, \dot{q}_{bd}, \varphi) - M_b^{-1}(\dot{w}_b + M_{ba}([\tilde{W}_v^{\langle T\rangle}\langle\cdot\rangle S_v(z)] - \varepsilon_v)) \end{aligned}$$

where $\tilde{W} = \hat{W} - W^*$. Define $\tilde{\varphi}_1 = \varphi_1 - \varphi_{1m}$ and $\tilde{\varphi}_2 = \varphi_2 - \varphi_{2m}$ such that $\tilde{\varphi} = \hat{\varphi} - \varphi$. Then, the comparison between (45) and (48) yields

$$\begin{aligned} \dot{\tilde{\varphi}}_1 &= \tilde{\varphi}_2 & (49)\\ \dot{\tilde{\varphi}}_2 &= -k_1\tilde{\varphi}_1 - k_2\tilde{\varphi}_2 - M_b^{-1}(\dot{w}_b + M_{ba}([\tilde{W}_v^{\langle T\rangle}\langle\cdot\rangle S_v(z)] - \varepsilon_v)) \end{aligned}$$

*Theorem 2:* Consider the following weight adaptation law for HONN employed in (47)

$$\dot{\hat{W}}_{vi} = \Gamma_{vi}S_{vi}(z)\tilde{\varphi}^T P_W[0 \quad 1]^T - \sigma\Gamma_{vi}\hat{W}_{vi} \tag{50}$$

where $\Gamma_{vi} \in \mathbf{R}^{l\times l}$ and $\sigma$ are suitably chosen as a symmetric positive definite matrix and a positive scalar, respectively. Then, the tracking errors $\tilde{\varphi}_1$ and $\tilde{\varphi}_2$ in (49) will be eventually bounded into a small neighborhood around zero.

*Proof:* Let us rewrite the error dynamics (49) as the form of Ito SDE

$$\begin{aligned} d\tilde{\varphi} &= \left[A_W\tilde{\varphi} - [0 \ 1]^T M_b^{-1}\sum_{i=1}^{n-1} M_{bai}(\tilde{W}_{vi}^T S_{vi}(z) - \varepsilon_{vi})\right]dt\\ &\quad -[0 \ 1]^T M_b^{-1}dw_b \end{aligned} \tag{51}$$

where $M_{bai}$ represents the $i$-th element of vector $M_{ba}$, $A_W = \begin{bmatrix} 0 & 1 \\ -k_1 & -k_2 \end{bmatrix}$ satisfies the Lyapunov equation $A_W^T P_W + P_W A_W = -Q_W$, i.e., for any symmetric positive definite matrix $Q_W$, there exists a symmetric positive definite $P_W$ satisfying the above equation.

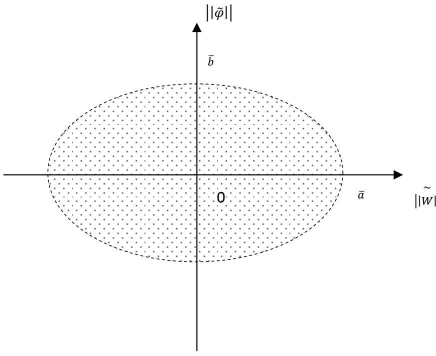

Fig. 1. Bounding set of $\|\tilde{W}_v^{\langle T\rangle}\|$ and $\|\tilde{\varphi}\|$.

Considering the following Lyapunov function

$$V_2(t) = \tilde{\varphi}^T P_W\tilde{\varphi} + M_b^{-1}\sum_{i=1}^{n-1} M_{bai}\tilde{W}_{vi}^T\Gamma_{vi}^{-1}\tilde{W}_{vi}^T \tag{52}$$

and the closed-loop dynamics (51) with the update law (50), we obtain

$$\begin{aligned} \mathscr{L}V_2(t) \leq\ & -\lambda_{Q_W}\|\tilde{\varphi}\|^2 - 2\sigma M_b^{-1}|M_{ba}|\|\tilde{W}_v^{\langle T\rangle}\|^2 + \varepsilon^2\|\tilde{\varphi}\|^2\\ & +\varepsilon^2\|\tilde{W}_v^{\langle T\rangle}\|^2 + \frac{1}{\varepsilon^2}\varepsilon_0^2 M_b^{-1}|M_{ba}|^2\|P_W[0 \ 1]^T\|^2\\ & +\frac{1}{\varepsilon^2}\sigma^2 M_b^{-1}|M_{ba}|^2\|W_v^{*\langle T\rangle}\|^2 + Tr(P_W)(M_b^{-1})^2 \end{aligned}$$

where $|\varepsilon_v| \leq \varepsilon_0$, $\lambda_{Q_W}$ is the minimum eigenvalue of $Q_W$, $\varepsilon$ is any given positive constant and we can choose it sufficiently small. Furthermore, we can choose the suitable $Q_W$ and $\sigma$ making $\lambda_{Q_W} \geq \varepsilon^2, 2\sigma M_b^{-1}|M_{ba}| \geq \varepsilon^2$, and it follows that $\dot{V}_2(t) \leq 0$ in the complementary set of a set $S_b$ defined as

$$S_b \triangleq \left\{(\tilde{\varphi}, \tilde{W}) \left| \frac{\|\tilde{W}_v^{\langle T\rangle}\|^2}{\bar{a}^2} + \frac{\|\tilde{\varphi}\|^2}{\bar{b}^2} - 1 \leq 0 \right.\right\}$$

with $\bar{a} = \dfrac{\bar{c}}{\sqrt{\lambda_{Q_W} - \varepsilon^2}}, \bar{b} = \dfrac{\bar{c}}{\sqrt{2\sigma M_b^{-1}|M_{ba}| - \varepsilon^2}}$, $\bar{c} = \sqrt{\frac{1}{\varepsilon^2}M_b^{-1}|M_{ba}|^2(\varepsilon_0^2\|P_W[0 \ 1]^T\|^2 + \sigma^2\|W_v^{*\langle T\rangle}\|^2) + Tr(P_W)(M_b^{-1})^2}$. Obviously, the set $S_b$ defined above is compact. Hence, by Theorem 1 in [14], it follows that all the solutions of (51) are bounded in probability. The set $S_b$ is shown in Fig. 1 and consists of the closed region bounded by the closed oval arc defined by $\frac{\|\tilde{W}_v^{\langle T\rangle}\|^2}{\bar{a}^2} + \frac{\|\tilde{\varphi}\|^2}{\bar{b}^2} = 1$. Thus, the proof is completed. ■

## VI. Simulation Studies

In this section, the developed trajectory generator and controller will be applied to the cart-pendulum system as shown in Fig. 2 [15]. Let $q_1 = x$ and $q_2 = \theta$, then the dynamics can be described as a fully control subsystem of $q_1$:

$$\Sigma_a : \ddot{q}_1 = \frac{4ml\dot{q}_2^2\sin q_2 - 3mg\sin q_2\cos q_2 + 4F}{4(M+m) - 3m\cos^2 q_2} \tag{53}$$

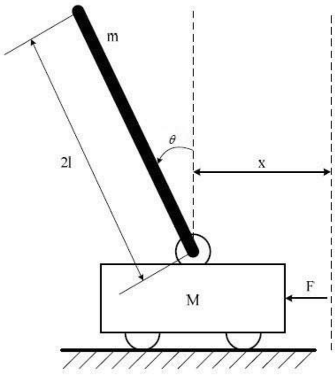

Fig. 2. The cart-pendulum system

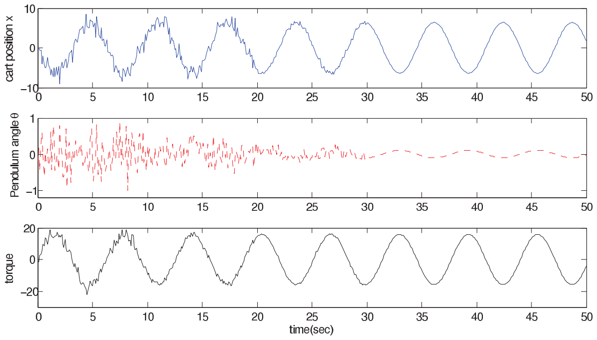

Fig. 3. The simulation results

and an uncontrolled subsystem of $q_2$

$$\Sigma_b : \ddot{q}_2 = \frac{3(M+m)g\sin q_2 - 3m\dot{q}_2^2\sin q_2\cos q_2}{4(M+m)l - 3ml\cos^2 q_2} + \frac{3mg\sin q_2\cos q_2}{4(M+m) - 3m\cos^2 q_2} - \frac{3}{4}\cos q_2\ddot{q}_1 \quad (54)$$

where the mass of cart is 2.4kg; the mass of pendulum is 0.23kg; the length of the pendulum (2l) is 0.36m, $w_1, w_2$ are indepent standard Weiner progresses. The control objective is to make $q_2$ to track $\frac{\pi}{30}\sin(t)$.

The simulation results are shown in Fig. 3. As clearly shown by the simulation results, in the presence of unknown system parameters and external disturbances, the proposed adaptive NN controller is able to guarantee the pendulum's exact tracking of the given trajectory.

## VII. Conclusion

In this paper, adaptive NN control has been designed on the stochastic under-actuated systems for dynamic balance and motion tracking of desired trajectories. The dynamics of the the actuated subsystem has been shaped to follow a reference model, which is derived by using the LQR optimization technique to minimize both the motion tracking error and the transient acceleration. The unactuated subsystem is discussed by suitably generating a reference trajectory. Simulation results have demonstrated the efficiency of the proposed method.

# Wireless Event-driven Networked Predictive Control Over Internet

Wenshan Hu, Hong Zhou, and Qijun Deng

*Abstract*—**In networked control systems, the network uncertainties can degrade the control performance and even result in instability, especially for the Internet-based control system with wireless communication in which the transmission delay could be many times of the sampling period of control systems. NPC (Networked Predictive Control) is an active method to compensate for the effects of network uncertainty. However, control systems need to make long time prediction due to the long transmission distance. Without an accurate mathematical model, the control performance can not be guaranteed. In order to address this problem, a new NPC scheme designed for wireless NPC with long time delay is introduced in this paper. It uses the information of the previous prediction errors to correct the future predictions. A correction algorithm is designed to reduce the predictive errors. To validate the new control schemes, both simulations and experiments have been conducted. The results show that even with "not so" accurate mathematical models, the new schemes can still maintain good control performance in Internet-based NPC with wireless communication.**

## I. Introduction

In the last decade, network technology has been developed rapidly. More and more network technologies have been applied to control systems [1-8]. With the emergence of high speed network technology, a cluster of devices can be linked together economically to form distributed networks. Due to the use of network, especially Internet, the complexity and costs of distributed control systems are reduced greatly and the maintenance of the systems becomes much easier [9-10]. Control systems with devices from different locations can be integrated together using the existing Internet infrastructure which provides a cheap solution for remote data transmission and data exchanges. Internet based control systems allow remote monitoring and adjustment of plants over the Internet around world.

Recently, wireless networked control systems become a popular research area in control theory and industrial applications. Without requiring network cables, devices can be connected into networks using wireless communication, which is promising for remote industrial controls and factory automations. For example, distributed power generation and microgrids [11-12] play more and more important roles in new energy research area. In these systems, unlike big power stations in conventional grids, small and medium size power generation units are located diversely. Wireless wide area networks (WWAN) such as WiMAX, CDMA, GPRS allow rapid development, flexible installation, fully mobile operation which are ideally suitable for these distributed industrial applications.

The technologies of the Internet of Things are developed rapidly in recent years. The research of NCSs is a key part in Internet of Things. In the future Internet of Things, diversely located objects and devices are connected to Internet using both wired and wireless communication. Information such as control commands and measurement data is transmitted through networks.

In wireless networks, the random time delay and data dropouts induced by the data transmission and traffic congestion are even worse than wired ones. These network uncertainties disturb the control performance and even result in instability. Therefore, a wireless networked predictive control systems are studied in this paper. The networked predictive control consists of the control prediction generator and network delay compensator [13-18]. The control predictive generator provides a sequence of future control predictions and the network delay pick up the appropriate control signal from the sequence to eliminate the effects of network transmission delay. Because of the long time delay in wireless networks, the model based prediction may not be accurate due to the model uncertainties. To tackle this problem, NPC is modified and the prediction errors are corrected using the previous predictive errors in this paper.

## II. Design of Wireless Wide Area NPC

### A. Structure of Wireless Wide Area NPC

Fig. 1 is the structure of the proposed Internet-based NPC with wireless communication. It can be separated into two sides: the controller side and the plant side. Both sides are connected to the Internet using wireless connections.

Most of the control calculations are implemented on the controller side. It could be a powerful mainframe computer which has the capability to serve many control loops. The tasks on the plant side are simple. This part can be achieved using a low-cost solution with limited computing capability such as MCU or ARM embedded control board. The diagram of this kind of system is shown in Fig. 2.

Manuscript received September 15, 2011. This work was supported by the National Science Foundation of China under Grant 61004030.

Wenshan Hu Hong Zhou and Qijun Deng are with Department of Automation, School of Mechanical and Power Engineering, Wuhan University, Wuhan, 430072, China (e-mail: wenshan.hu@whu.edu.cn)

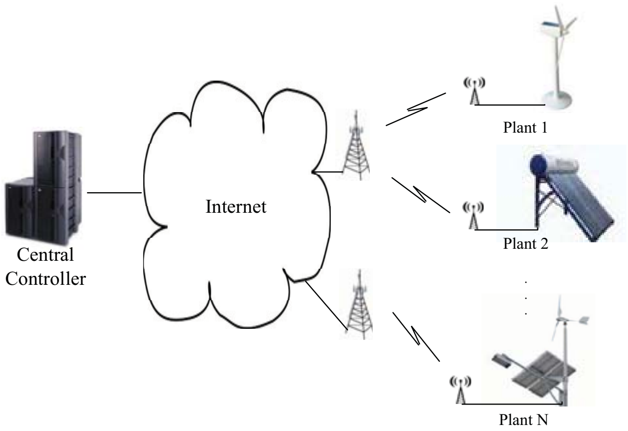

Fig. 2. Diagram of wireless wide area networked control systems

### B. Plant Model and Local Control

It is considered that the dynamic process can be described by the autoregressive moving average model as

$$A(z^{-1})y(t) = B(z^{-1})u(t) \tag{1}$$

where $u(t)$ and $y(t)$ are the open loop input and output of the plant. $A(z^{-1}) \in \Re[z^{-1}, n_a]$ with $a_0 = 1$ and $B(z^{-1}) \in \Re[z^{-1}, n_b]$ with $b_0 = 0$ are the system polynomials.

For the local control without network transmission delay and data dropout, a controller is designed as

$$C(z^{-1})u(t) = D(z^{-1})e(t) \tag{2}$$

where polynomial $C(z^{-1}) \in \Re[z^{-1}, n_c]$ and $c_0 = 0$ and $D(z^{-1}) \in \Re[z^{-1}, n_d]$ and

$$e(t) = r(t) - y(t) \tag{3}$$

where $r(t)$ is the reference input and $y(t)$ is the system output.

### C. Start of a Control Cycle

In this method, a control cycle is initiated by the plant side rather than controller side, which is similar to the method in [14-15]. At each sampling period, the previous plant output sequence $y(t)$, previous control sequence $u(t)$, previous prediction error sequence $e_y(t)$ and a timestamp $t$ which indicates the current plant side time are packed together and sent out in a single packet to the controller side, which initiates a control cycle. The three sequences in the packet are

$$\begin{bmatrix} y(t-1) \\ y(t-2) \\ \vdots \\ y(t-n_l) \end{bmatrix}, \begin{bmatrix} u(t-1) \\ u(t-2) \\ \vdots \\ u(t-n_l) \end{bmatrix}, \begin{bmatrix} e_y(t) \\ e_y(t-1) \end{bmatrix} \tag{4}$$

where $n_l$=max($n_a$, $n_b$, $n_c$, $n_d$).

### D. Design of Controller

The controller is event driven rather than time driven. It is only when the plant side receives the data from the feedback channel does the controller generates control predictions. Without receiving new data from the plant side, it is in an "idle state."

It is assumed that at a time instance, the controller receives a packet from the plant side. Inside the packet, the sequence of plant outputs $y$ (including $y(t), y(t-1), \cdots, y(t-n_a)$ ), previous control sequence $u$ (including $u(t), u(t-1), \cdots, u(t-n_a)$ ) and a time stamp which indicates the time at which the packet is packed and sent out. Because the controller is event-driven and the time delay compensation is based on the round trip time delay measurement, it is noted that variable $t$ indicates the plant side time instance at which the packet is packed and sent out. It has nothing to do with the time instance at which the controller receives the packet. Using the round trip delay prediction, the future control sequence can be generated using the algorithm described below without knowing any information about the controller time at all.

For the sake of simplicity of analysis, it is assumed that the maximum time delay is bounded within $N$ steps. The following defines the operation on the predictions:

$$x(t+i\,|\,t) = q^{-1}x(t+i+1\,|\,t) \quad \text{for } i = 0,1,\cdots \tag{5}$$

$$x(t-1) = q^{-1}x(t\,|\,t) \tag{6}$$

$$x(t-i-1) = q^{-1}x(t-i) \quad \text{for } i = 1,2,\cdots \tag{7}$$

where represents $x(.)$, $y(.)$ or $u(.)$, and $x(t+i|t)$ denotes the $i$-th step-ahead prediction of $x(t)$ based on the previous data up to time $t$.

Based on the data up to plant side time $t$, and the mathematical model of the plant, the one-step plant output prediction with model uncertainty correction can be calculated as

$$y(t+1\,|\,t) = (1 - A(q^{-1}))y(t+1\,|\,t) + B(q^{-1})u(t+1) + c_m \tag{8}$$

where $c_m$ is the correction factor, and $m$ is a counter on the controller side. $c_m$ is calculated using the information of previous prediction errors. The initial value of $m$ is 1 and each time the controller process a packet from the plant side, $m$ is increased by 1. The details of the calculation of $c_m$ are introduced in Section *2.E*.

The corresponding one-step prediction for control signal is

$$\begin{aligned} u(t+1\mid t) &= (1-C(q^{-1}))u(t+1\mid t) \\ &\quad + D(q^{-1})(r(t+1)-y(t+1\mid t)) \end{aligned} \tag{9}$$

Using the same method recursively, the future plant output predictions can be obtained based on the data calculated at the previous step.

$$y(t+k\mid t) = (1-A(q^{-1}))y(t+k\mid t) + B(q^{-1})u(t+k) + c_m \tag{10}$$

where $k$=1,2,…,$N$. The future control predictions are

$$\begin{aligned} u(t+k\mid t) &= (1-C(q^{-1}))u(t+k\mid t) \\ &\quad + D(q^{-1})(r(t+k)-y(t+k\mid t)) \end{aligned} \tag{11}$$

where $k$=1,2,…,$N$.

After $N$-step calculations, the future control sequence $U(t|t)$ and future plant output $Y(t|t)$ are obtained, where

$$U(t\mid t) = [u(t+1\mid t), u(t+2\mid t), \cdots, u(t+N\mid t)]^T \tag{12}$$

$$Y(t\mid t) = [y(t+1\mid t), y(t+2\mid t), \cdots, y(t+N\mid t)]^T \tag{13}$$

They are packed together with the timestamp $t$ and sent back to the plant side.

### *E. Calculation of Model Uncertainty Correction Factor*

In conventional NPC, if the mathematical model of the plant is not accurate enough, the control performance would be degraded greatly. It normally results in big static errors in some practical applications. Because the prediction is not accurate due to the model uncertainty, the controller "thought" the plant "had" reached the target position, so it stops the adjustment of the control signals. However, the plant doesn't follow the controller's prediction. Therefore, the static errors can not be corrected.

In order to cope with this problem, a model uncertainty correction algorithm is introduced in this paper. Based on the history prediction error sequence obtained from the plant side, the controller estimates the correction values for the future prediction. The estimation method is similar to the idea of PI control. Different from the PI control algorithm, the target of the method is to minimize the prediction errors rather than the control residuals. Therefore, the input is the prediction error rather than residual. The transfer function between prediction error $e_y(t)$ and the correction factor $c(t)$ is

$$c(t) = (k_p + k_i \frac{Tz^{-1}}{1-z^{-1}})e(t) = \frac{k_p - (k_p - k_i T)z^{-1}}{1-z^{-1}} e_y(t) \tag{14}$$

where the proportional gain $k_p$ and integral gain $k_i$ are the two parameters of the algorithm. Written in the incremental form, (14) is described as

$$\Delta c(t) = (1-z^{-1})c(t) = (k_p - (k_p - k_i T)z^{-1})e_y(t) \tag{15}$$

where $\Delta c(t)$ is the increase of $c(t)$.

With $\Delta c(t)$ calculated by using (15), the correction factor can be obtained,

$$c(t) = c(t-1) + \Delta c(t) \tag{16}$$

However, due to the stochastic nature of the Internet, the time delay is random. Therefore, the previous correction value $c(t\text{-}1)$ may not be available on the controller side. In order to simplify the analysis, the correction factor on the controller side $c_m$ is used to replace $c(t)$. Equation (16) can be rewritten as

$$c_m = c_{m-1} + \Delta c(t) \tag{17}$$

Combine with (16), the model uncertainty correction factor is obtained as

$$c_m = c_{m-1} + k_p e_y(t) - (k_p - k_i T)e_y(t-1) \tag{18}$$

With the previous correction factor $c_{m\text{-}1}$ and previous prediction errors $e_y(t)$ and $e_y(t\text{-}1)$ available, it is straightforward to calculate the current correction factor $c_m$.

If the transmission delay between the plant side and the controller is constant and there is no data dropout, $c_m$ is equal to the corresponding $c(t)$. However, in real network environment, the packet with plant side timestamp $t$ may arrive earlier than the packet with timestamp $t$-1. In that case, $c_m$ is not $c(t)$ but it is close to $c(t)$.

### *F. Design of Plant Side*

The plant side receives the packet from the controller, in which the timestamp $t$ the control sequence $U(t|t)$ and plant output sequence $Y(t|t)$ are packed. To calculate the RTT delay, the timestamp $t$ is picked up and compared with the current plant side time $t_c$

$$t_d = t_c - t \tag{19}$$

where $t_d$ is the RTT delay.

According to the time delay measurement $t_d$, the $t_d$-th value in the sequence $U(t|t)$ is picked up and applied to the plant actuator.

$$u(t+t_d) = u(t+t_d \mid t) \tag{20}$$

Similarly, the $t_d$-th value in sequence $Y(t|t)$ is also picked up as the predicted plant output.

$$\hat{y}(t+t_d) = y(t+t_d \mid t) \tag{21}$$

The predicted plant output $\hat{y}(t+t_d)$ is then compared the real plant output $y(t+t_d)$. The prediction error $e_y(t+t_d)$ is obtained as

$$e_y(t+t_d) = y(t+t_d) - \hat{y}(t+t_d) \tag{22}$$

The history data of the plant output $y$, control signal $u$ and prediction error $e_y$ are buffered as below

$$\begin{bmatrix} y(t_c-1) \\ y(t_c-2) \\ \vdots \\ y(t_c-n_b) \end{bmatrix}, \begin{bmatrix} u(t_c-1) \\ u(t_c-2) \\ \vdots \\ u(t_c-n_b) \end{bmatrix}, \begin{bmatrix} e_y(t_c) \\ e_y(t_c-1) \end{bmatrix} \qquad (23)$$

These data are packed with the current time stamp $t_c$ and sent out the controller side, which initiates another control cycle.

## III. Simulation Results

In order to validate the proposed method, a speed control system for a cooling fan is considered. The control system is designed to drive a fan to the target speed. The mathematical model is identified as

$$G(z^{-1}) = \frac{B(z^{-1})}{A(z^{-1})} = \frac{0.4662z^{-1} - 0.2843z^{-2}}{1 - 1.396z^{-1} + 0.4681z^{-2}} \qquad (24)$$

where the input is the PWM duty cycle (ranged from 0 to 1) applied to the fan motor and the output is the voltage reading from the speed sensor (ranged is from 0v to 3v). The power supply voltage is 12v and the sampling time is 0.1s.

The following Proportional-integral Controller is designed when the network transmission delay and data dropout is not considered.

$$G_c(z^{-1}) = \frac{D(z^{-1})}{C(z^{-1})} = \frac{0.33 - 0.23z^{-1}}{1 - z^{-1}} \qquad (25)$$

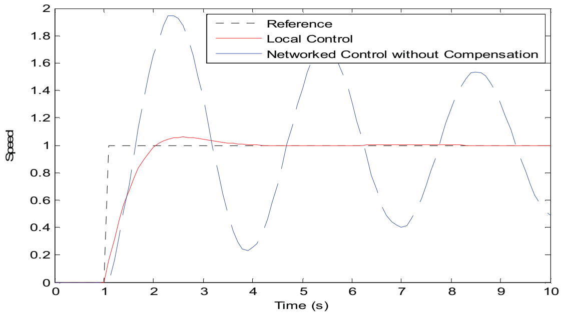

Fig. 3. Simulation of networked control without compensation

The unit step response of local control without communication delay and the networked control without any network uncertainty compensation are shown in Fig. 3. It indicates that the performance of local control is quite good. However, in the networked environment, the round trip time delay varies from 4 to 6 steps (0.4s to 0.6s), the control performance degrades greatly with huge overshoot and very long settling time, which is unacceptable in practical applications.

In order to compensate for the effects of the network uncertainty, the NPC methods proposed in this paper has been adopted. Fig. 4. shows the simulation results. For comparison, two simulations have been conducted. One is the conventional NPC, the other is the NPC with model uncertainty correction designed for NCS on WWANs. Because the mathematical model in simulation is perfectly accurate, the NPC methods can fully compensate for the effects of the network uncertainty. Therefore, there is no model prediction error at all. The results of local control and NPC with and without model uncertainty are exactly the same.

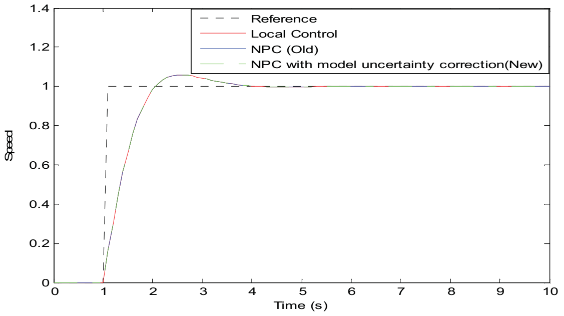

Fig. 4. Simulation of long –distance WNPC without model uncertainties

The mathematical model can not always reflect the dynamical behaviors of the real plant in practical applications. If the power supply voltage of the cooling fan changes from 12v to 10v, correspondingly, the mathematical model (24) will be change to

$$G(z^{-1}) = \frac{B(z^{-1})}{A(z^{-1})} = \frac{0.3885z^{-1} - 0.2369z^{-2}}{1 - 1.396z^{-1} + 0.4681z^{-2}} \qquad (26)$$

If the NPC algorithm still uses the old mathematical model to calculate the predictive control sequence, the prediction errors will be inevitable, which results in big static error shown in Fig. 5. The target output should be 1 for the unit step response, but the real output finally settles down at 0.84. The control performance has been degraded greatly. It shows the prediction errors can result in big static error if the model is not accurate.

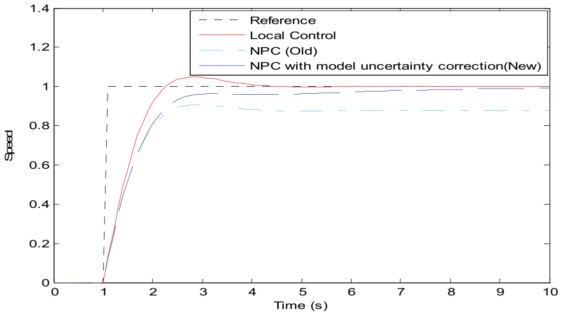

Fig. 5. Simulation of long-distance WNPC with model uncertainties

To cope with this problem, the model uncertainty compensation method proposed in this paper is applied. The previous prediction errors are used to correct the future predictions, and the "PI" correction algorithm tries decreasing the prediction errors as the control process going on. In this case, the both parameters $k_p$ and $k_i$ are 0.1. With the prediction becoming more accuracy, the plant output is quickly approaching the target, as shown in Fig. 5. The control performance has been improved significantly comparing with the conventional NPC.

## IV. Experimental Results

### A. *Test Rig*

A networked cooling fan speed control test rig has been setup to validate the effectiveness of the proposed control algorithm. The whole system consists of three parts: a PC based remote controller on the controller side and a networked module made by Chinese Academy of Sciences (CAS) and a cooling fan on the plant side. The PC and the networked module are connected via Internet and long-distance wireless network. The picture of the test rig is shown in Fig. 6. It can be seen that the cooling fan is placed on the left hand side and the networked module is on the right hand side.

The PC controller with the IP address 202.114.106.29 is located in the campus of Wuhan University. The networked module is connected to the GPRS wireless network provided by China Mobile. The PC controller works as the server side and the networked module works as the client side, so the communication channel between them can be established. The communication protocol adopted in the experiments is UDP. The diagram of the whole wireless networked control system is shown in Fig. 7.

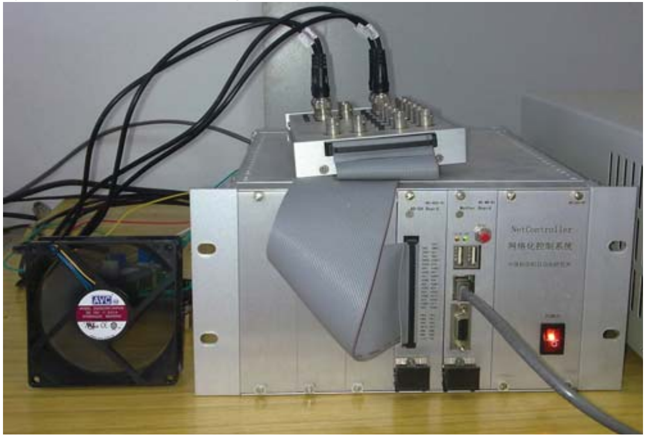

Fig. 6. Cooling fan control test rig

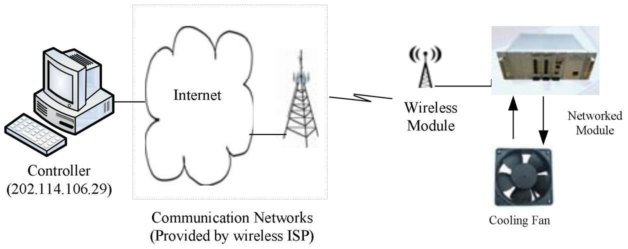

Fig. 7. Experimental diagram

### B. *Experimental Results*

The round trip time delays are measured during the experiments, which are shown in Fig. 8. It can be seen the round trip time delay varies from 4 to 7 steps (0.4 to 0.7s).

Fig 9. shows the experimental results of local control without network and networked control without time delay compensation. The target speed jumps from 1000RPM to 2200 RPM at 1s. It can be seen that in local control, the control performance is good, but network uncertainty degrades the control performance greatly.

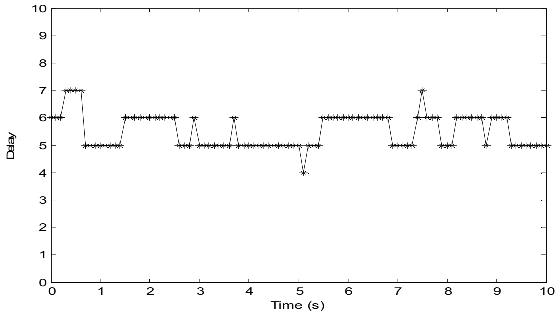

Fig. 8. Round trip time delay measurement

In order to compensate for the network uncertainty, NPC algorithm is adopted. The experiments of both the conventional NPC and NPC with model uncertainty correction proposed in this paper have been conducted. Because the mathematical model identified is quite accurate, both the old and new methods are able to maintain good control performance in the networked environment, which is shown in Fig. 10.

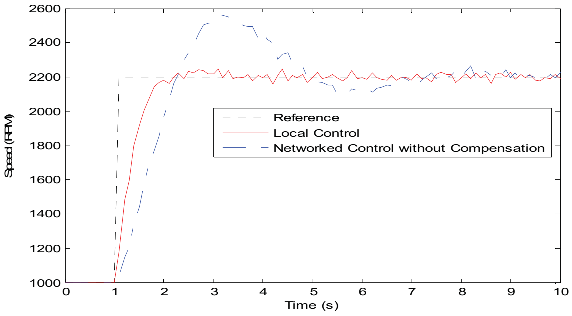

Fig. 9. Results of local control and networked control without delay compensation

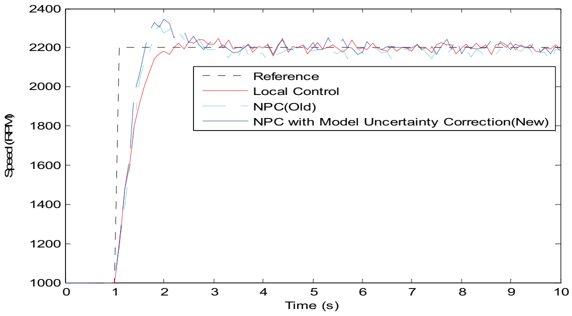

Fig. 10. Results of networked predictive control

When the working condition of the cooling fan is changed, the old method no longer works properly. For example, if the power supply voltage decreases from 12V to 10V, the old method results in a big static error, which is similar to the simulation results. As shown in Fig. 11, the static error is around 200RPM which is not acceptable in practical applications. However, if the new method proposed in this paper has been adopted, the result is very close to the local control even with a not so accurate mathematical model. Same with the simulations, both parameters $k_p$ and $k_i$ for the model correction algorithm are 0.1. The results prove that the proposed methods can compensate for the effects of both network uncertainties and model uncertainties in the NPC system effectively.

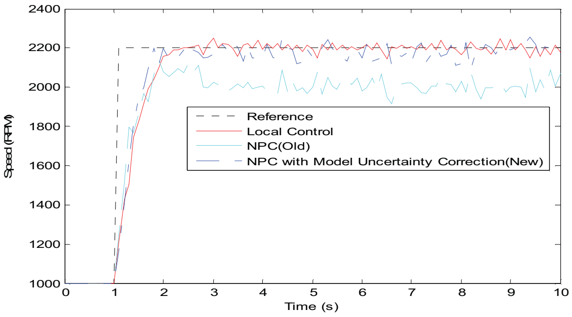

Fig. 11. Results of networked predictive control with 10v power supply

## V. Conclusions

In this paper, a new wireless Internet-based NPC with model uncertainty compensation has been introduced. It is designed for the networked control systems on with wireless communication. In these systems, because of the long transmission delay, the control systems have to cope with the cases that the time delay is many times of the sampling period. The NPC method is able to cope with that situation very well, but it requires very accurate mathematical models. With imperfect models, the control performances would be affected. In this paper, based on the NPC, a model uncertainty correction algorithm is designed to tackle this problem. In order to validate the proposed method, both simulations and experiments have been conducts. The results show that even not so accurate models, the new NPC scheme can still maintain good control performance in WWAN based networked control systems.

***Abstract*—The uncontrolled use of limited resources in conjunction with unpredictable nature of traffic load injection in Wireless Local Area Networks (WLANs) may lead to congestion, and cannot guarantee strict Quality of Service (QoS) required by real-time service. Rate control is an important mechanism for the provisioning of QoS in the IEEE 802.11e WLANs. In this paper, a bio-inspired rate control scheme is proposed based on the extended Lotka-Volterra model, which considers the effects of arrival traffic on the system stability according to the limited network resources and competitions with others traffic flows, and ensures that the network works in unsaturated case and rapidly converge to a global stable equilibrium point (EP). Moreover, all traffic flows are of peaceful coexistence and QoS differentiation. Extensive simulations are conducted to illustrate the performance of the proposed rate control scheme.**

***Index Terms*—Rate control, QoS Differentiation, Bio-inspired model, 802.11e EDCA**

## I. Introduction

WLANs based on the IEEE 802.11 Distributed Coordination Function (DCF) have been widely used in recent years due to their simple deployment and low cost. Since the current DCF can only support best effort traffic, whilst the growing popularity of real-time services and multimedia based applications, it has recently become more critical to tailor IEEE 802.11 Medium Access Control (MAC) protocol to meet the stringent requirements of such services. The IEEE 802.11e Enhanced Distributed Channel Access (EDCA) is proposed to support prioritized QoS[1]. It provides priority-based medium access mechanism with different Arbitration Inter Frame Space (AIFS), initial and maximum Contention Window (CW) size, and the limit of consecutive Transmission Opportunity (TXOP).

Meanwhile, considerable effort was devoted to theoretical analysis of the performance of the 802.11 EDCA [2-5]. However, it cannot guarantee strict QoS required by real-time services such as voice and video without proper network rate control mechanisms. It has been proven that the QoS requirements of the real-time traffic can be satisfied if the input traffic is properly regulated[6]. Meanwhile, it is found that in unsaturated case the 802.11e EDCA achieves the maximum throughput and small delay because of the low collision probability[7,8]. To keep the network operating in unsaturated case, it is crucial to regulate total input traffic. In [6], Chen integrated two admission control schemes and a rate control scheme relying on the average delay estimate and the channel busyness ratio. Lee proposed a bandwidth control scheme by combing the IEEE 802.11e EDCA protocol to overcome the guaranteed bandwidth issue in multi-rate environments [9]. Antoniou proposed a Lotka-Volterra-based congestion control (LVCC) scheme to regulate the input flows without considering the QoS differentiation [10]. Yaghmaee [11] and Chen [12] proposed a priority-based rate control algorithm for service differentiation.

The transmission rate of the traffic can be controlled based on two criteria. First, the injected traffic should not break off the original transmitting traffic, and all the traffic would be co-existing and served. Second, the regulated traffic should be able to promptly access the whole bandwidth in order to utilize the channel efficiently. One may argue that this can be easily achieved if the channel access parameters such as AIFS and CW are set much larger than those for the real-time traffic. However, this approach is problematic in that it will unnecessarily impede the best effort traffic from accessing the channel even when there is no heavy real-time traffic in the network, leading to channel under-utilization and unreasonably large delay for the best effort traffic.

In this paper, to guarantee the strict QoS differentiation and maximize the utility of limited network sources, a bio-inspired rate control scheme is proposed to optimize the transmission rate of each data flow. The stability of the proposed control scheme is analyzed under different network conditions.

TABLE I
RECOMMENDED IEEE 802.11E EDCA PARAMETER SETTING

| Prio_ | AC | Designation | AIFS | CWmin | CWmax | TXOP |
|---|---|---|---|---|---|---|
| 3 | AC(3) | Voice | 2 | 7 | 15 | 0.003 |
| 2 | AC(2) | Video | 2 | 15 | 31 | 0.006 |
| 1 | AC(1) | Best effort | 3 | 31 | 1023 | 0 |
| 0 | AC(0) | Background | 7 | 31 | 1023 | 0 |

The remainder of this paper is organized as follows: Section 2 introduces the protocol of IEEE 802.11e EDCA. The extended Lotka-Volterra model is introduced in Section 3. In Section 4, we introduce the bio-inspired rate control scheme. Section 5 presents the performance of bio-inspired rate control scheme. The paper is concluded in Section 6.

## II. IEEE 802.11E EDCA PROTOCOL

Since the demands of multimedia applications over WLANs increase tremendously in recent years, which requires the wireless network paradigm to be rethought in the view of need for mechanisms to deliver multimedia content with a certain level of quality of service (QoS). The IEEE 802.11 Task Group E has developed a new standard known as the IEEE 802.11e to provide the QoS support.

According to the IEEE 802.11e standard, the EDCA mechanism extends the DCF mechanism of traditional IEEE 802.11 protocol to enhance the QoS support in the MAC-layer by introducing four access categories $AC[n]$ $(n = 0, 1, 2, 3)$ to serve different types of traffic, which includes AC_VO (for voice traffic), AC_VI (for video traffic), AC_BE (for best effort traffic) and AC_BK (for background traffic). To simplify the notations, we rename four ACs as $AC[3]$, $AC[2]$, $AC[1]$ and $AC[0]$ from the highest priority to the lowest priority in the rest of this paper. Each queue $AC[n]$ transmits packets with an independent channel access parameters including: Minimal Contention Window Size ($CW_{\min}[n]$), Maximal Contention Window Size ($CW_{\max}[n]$), Arbitration Inter-Frame Space Number ($AIFS[n]$), and the limit of consecutive Transmission Opportunity ($TXOP[n]$). The recommended value of each parameter is shown in Table I.

To achieve service differentiation among four ACs, instead of using fixed DCF Interframe Space (DIFS) as in IEEE 802.11 DCF mechanism, EDCA assigns $CW_{\min}$, $CW_{\max}$, $AIFS$ and $TXOP$ with different values to manipulate the successful transmission probability of different types of frames. If one AC has a smaller value of $AIFS$ or $CW_{\min}$ or $CW_{\max}$, then this AC has more chances to access the wireless medium and transmit the waiting or arriving frames. For $AC[i]$ and $AC[j]$ $(0 \leq i < j \leq 3)$, then $CW_{min}[i] \geq CW_{min}[j]$, $CW_{max}[i] \geq CW_{max}[j]$, and $AIFS_i \geq AIFS_j$. Note that in the above inequalities, at least one must be strictly "not equal to" as shown in Table I. Each queue within a station is treated as an individual virtual station, and the backoff procedure of each AC is the same as that of DCF. When a collision occurs among different ACs within the same station, the AC with a higher priority is granted the opportunity to transmit, while the AC with a lower priority is kept waiting, i.e., suffers from a virtual collision.

## III. EXTENDED LOTKA-VOLTERRA MODEL

In order to achieve the better performance and QoS differentiation for IEEE 802.11e EDCA WLANs. We use the bio-inspired model to regulate the input data flows. The nature of the world shows that the dynamics of many biological systems and laws governing them are based on a surprisingly small number of simple generic rules which yield collaborative and effective patterns for resource management, task allocation and social differentiation without the need of any externally controlling entity[13]. For example, population dynamics has traditionally been the dominant branch of mathematical biology which studies how populations of species change in time and space as well as the process that cause these changes.

Population dynamics can be modeled with a simple balance equation that describes how the overall population size of species changes over time as a result of species interaction with each other as well as with non-living parts of their surroundings (i.e. resources). Proposed by Lotka and Volterra, the well-known Lotka-Volterra models concerning ecological population modeling have been extensively investigated in the literature[10,14]. When two or more species live in proximity and share the same basic requirements, they usually compete for resources, food, habit, or territory. A deterministic, competitive Lotka-Volterra system with $n$ species is given by [10,14]

$$\frac{dx_i}{dt} = x_i \left[ r_i - \sum_{j=1}^{n} a_{ij} x_j \right], \quad i = 1, 2, ..., n \tag{1}$$

where $x_i$ represents the population size of species $i$ at time $t$, the constant $r_i$ is the growth rate of species $i$, $n$ is the number of species in an ecosystem, and $a_{ij}$ represents the effect of inter-specific (if $i \neq j$) or intra-specific (if $i = j$) competition. The quotient $r_i / a_{ii}$ is the carrying capacity of the $i$th species in absence of other species. In a vector form, we can rewrite (1) as

$$dx/dt = diag\left(x_1, x_2, ..., x_n\right)\left[B - Ax)\right]$$

where $x = (x_1, x_2, ..., x_n)^{\mathrm{T}}$ is an $n$-dimensional species state vector, $B = (r_1, r_2, ..., r_n)^{\mathrm{T}}$ is the set of growth rate of each species, $A = (a_{ij})_{n \times n}$ is an $n \times n$ matrix, known as the community matrix, and superscript $^{\mathrm{T}}$ denotes the transpose operation.

In this paper, we borrow the idea of population dynamics to analyze the optimal sending rate of each traffic flow under changing network conditions. A WLANs can be considered as analogous to an ecosystem. An ecosystem comprises of multiple species that live together and interact with resources and competitors to meet their needs for survival and coexist. Similarly, a WLANs involves a number of wireless stations. Each station has a limited buffer size to store packets and is able to initiate a traffic flow. Traffic flows can be seen as species that compete with each other for available network resources while traversing the access point to the user. The number of bytes per traffic flow corresponds to the population size of each species. Moreover, the species of an ecosystem have different positions in its biological chain, i.e. some species are much stronger and powerful than others, they will consume more resources from the surrounding environment. This phenomenon can also been seen in WLANs, that the traffic flows with a higher priority are much more important than those with a lower priority, and bandwidth of the network will be priorly allocated to the traffic flows with the highest priority, which means that the packets of the flow with the highest priority have more opportunities to be transmitted. In analogy with ecosystems, the goal of the WLANs is expected to be the coexistence of all traffic flows and achieve QoS differentiation.

## IV. Proposed Bio-inspired rate control scheme

According to the above extended Lotka-Volterra competitive model, there are five correspondences between a WLANs and an ecosystem, i.e. 1) the traffic flows $n$ initiated by each node play the role of competing species; 2) the number of bytes $x_i$ sent by a traffic flow within a given period refers to the population size of a species; 3) the transmission rate of each traffic flow is affected by inter-actions among competing flows as well as the available bandwidth, named inter-specific or intra-specific coefficient $a_{ij}$; 4) the growth rate $r_i$ of each flow refers to the growth rate of each species; 5) the limited bandwidth $N$ of a WLANs can be seen as the resource in the ecosystem.

### A. Considering the QoS Differentiation

The transmission rate evolution of each flow will be driven by variations in available bandwidth of source/relay nodes and by the injection of unpredictable traffic load along the network path towards the user. Each station is expected to initiate a traffic flow when triggered by a specific event or a periodic sensing task. In order to analyze the difference of competition from inter-specific or intra-specific data flows, we redefine the inter-specific competition coefficient of different flows as $a_{ij}$ and the intra-specific competition coefficient of the same type flows as $\beta_i$. To support the service differentiation between the above four ACs in the IEEE 802.11e EDCA as described in Section II, we give two assumptions as follows:

1. The effect of inter-specific competition coming from flow $j$ to flow $i$ can be neglected if the priority of $AC[j]$ is lower than that of $AC[i]$, i.e. The higher priority $AC[i]$ will be granted to transmit frames when colliding with $AC[j]$. However, according to the access procedure of IEEE 802.11e EDCA protocol as shown in Fig.1, (where Short Interframe Space (SIFS) is the small time interval between the data frame and its acknowledgement; PCF Interframe Space (PIFS) is one of the interframe space used in IEEE 802.11 based WLANs.) the $AIFS$ values of $AC[2]$ and $AC[3]$ are identical as listed in Table I, so in this paper, we consider the competition from $AC[2]$ to $AC[3]$. Then the inter-specific competition coefficients are

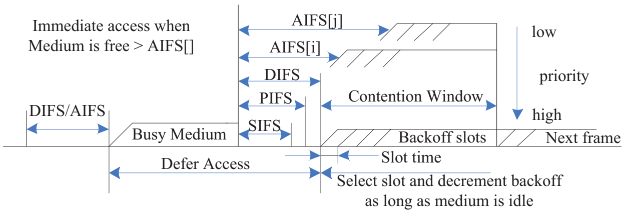

Fig. 1. IEEE 802.11e EDCA access procedure

$$\begin{cases} a_{ij} > 0, \ 0 \leq i < j \leq 3 \\ a_{32} > 0, \quad i = 3, j = 2 \\ a_{ij} = 0, \quad otherwise \end{cases}$$

2. The effect of intra-specific competition of any traffic flow $i$ with its number increasing or decreasing is a constant, i.e. the coefficient $a_{ii} = a_{jj} = \beta$.

Then the proposed bio-inspired rate control scheme based on the extended Lotka-Volterra model for WLANs with considering the QoS differentiation can be written as:

$$\begin{cases} \dot{x}_3(t) = r_3 x_3 \left[ \left(1 - \frac{\beta x_3}{N_3}\right) - a_{32} \frac{x_2}{N_2} \right] \\ \dot{x}_2(t) = r_2 x_2 \left[ \left(1 - \frac{\beta x_2}{N_2}\right) - a_{23} \frac{x_3}{N_3} \right] \\ \dot{x}_1(t) = r_1 x_1 \left[ \left(1 - \frac{\beta x_1}{N_1}\right) - a_{13} \frac{x_3}{N_3} - a_{12} \frac{x_2}{N_2} \right] \\ \dot{x}_0(t) = r_0 x_0 \left[ \left(1 - \frac{\beta x_0}{N_0}\right) - a_{03} \frac{x_3}{N_3} - a_{02} \frac{x_2}{N_2} - a_{01} \frac{x_1}{N_1} \right] \end{cases} \tag{2}$$

where $x_3$, $x_2$, $x_1$ and $x_0$ means the transmission rate of priority queue $AC[3]$, $AC[2]$, $AC[1]$ and $AC[0]$, respectively.

### B. Stability Analysis

The proposed Bio-inspired competitive rate control scheme is adaptive to bursty traffic flows. For example, the transmission rate will reach to the optimal maximal value when other data flows are removed; However, while some higher priority flows are injected into the network unpredictably, the transmission rates of the former flows are reduced smoothly according to the competitions and available bandwidth. So the real-time transmission rate is very important to show the validation of the proposed control scheme and its performance. Based on the nonlinear ordinary differential Equation (2), the real-time transmission rate can be derived:

$$x_3(t) = \frac{N_3 w_3 x_3(0)}{\beta N_2 x_3(0) + [N_3 w_3 - \beta N_2 x_3(0)] e^{-\frac{w_3 r_3}{N_2} t}}$$

$$x_2(t) = \frac{N_2 w_2 x_2(0)}{\beta N_3 x_2(0) + [N_2 w_2 - \beta N_3 x_2(0)] e^{-\frac{w_2 r_2}{N_3} t}}$$

$$x_1(t) = \frac{N_1 (N_2 N_3 - w_1) x_1(0)}{N_2 N_3 \beta x_1(0) + \varphi_1 e^{-\frac{N_2 N_3 - w_1}{N_2 N_3} \cdot r_1 t}}$$

$$x_0(t) = \frac{N_0 (N_1 N_2 N_3 - w_0) \cdot x_0(0)}{\beta N_1 N_2 N_3 x_0(0) + \varphi_0 e^{-\frac{N_1 N_2 N_3 - w_0}{N_1 N_2 N_3} \cdot r_0 t}}$$

where $w_3 = N_2 - a_{32} x_2$, $w_2 = N_3 - a_{23} x_3$, $w_1 = N_2 a_{13} x_3 + N_3 a_{12} x_2$, $w_0 = N_1 N_2 a_{03} x_3 + N_1 N_3 a_{02} x_2 +$

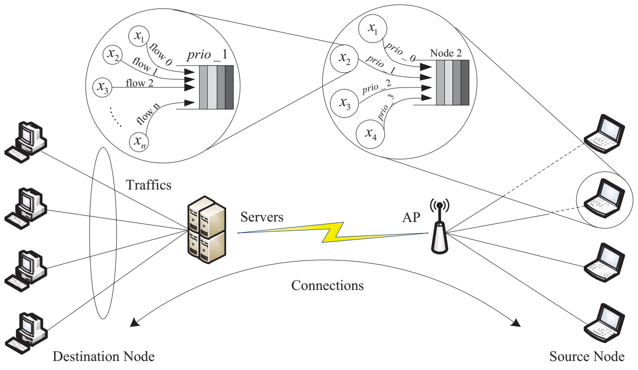

Fig. 2. Network topology

$N_2N_3a_{01}x_1$, $\varphi_1{=}N_1\left(N_2N_3-w_1\right)-\beta N_2N_3x_1\left(0\right)$, $\varphi_0 = N_0\left(N_1N_2N_3-w_0\right)-\beta N_1N_2N_3x_0\left(0\right)$.

In order to guarantee the stability of WLANs, the proposed rate control scheme should be sure that the real-time transmission rate can converge to a stable equilibrium point (EP) as soon as possible. There are sixteen stable EPs by solving the Equation (2), however, it is meaningless unless all the elements in the EP are positive, i.e. $x_0^*>0$, $x_1^*>0$, $x_2^*>0$ and $x_3^*>0$.

Then the stable equilibrium point $x^*$, i.e. the desirable transmission rate of each flow, can be calculated as:

$$\left\{\begin{aligned} x_3^* &= \tfrac{a_{32}-\beta}{a_{23}a_{32}-\beta^2}N_3 \\ x_2^* &= \tfrac{a_{23}-\beta}{a_{23}a_{32}-\beta^2}N_2 \\ x_1^* &= \tfrac{N_1}{\beta}\left[1-\tfrac{a_{12}(a_{23}-\beta)+a_{13}(a_{32}-\beta)}{a_{23}a_{32}-\beta^2}\right] \\ x_0^* &= \tfrac{N_0}{\beta}\left\{1-\tfrac{a_{03}(a_{32}-\beta)+a_{02}(a_{23}-\beta)}{a_{23}a_{32}-\beta^2}\right. \\ &\quad \left. -\tfrac{a_{01}}{\beta}\left[1-\tfrac{a_{13}(a_{32}-\beta)+a_{12}(a_{23}-\beta)}{a_{23}a_{32}-\beta^2}\right]\right\} \end{aligned}\right. \tag{3}$$

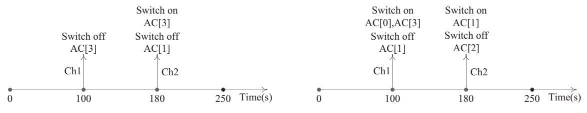
## V. Performance Assessment

### A. Experiment environment and setting

In order to evaluate the performance of the proposed bio-inspired rate control scheme for IEEE 802.11e EDCA WLANs, simulation studies are used to evaluate the performance in terms of graceful performance degradation, self-adaptivity, scalability and service differentiation. In addition, evaluation studies investigate how parameters affect the performance of our approach in terms of stability, convergence and provide effective parameter setting rules. The simulation experiments are conducted in a WLANs, the data flows are transmitted by wireless medium through Access Point (AP) to the Destination Node (DN) as shown in Fig.2. The time interval between successive evaluations of the number of bytes sent by Source Node (SN) is set to 1 second. The parameters (Para) of the proposed rate control scheme shown in Equation (3) are set in Table II.

TABLE II
Parameter setting

| Para | value | Para | value | Para | value | Para | value |
|---|---|---|---|---|---|---|---|
| $a_{01}$ | 1 | $a_{13}$ | 1.3 | $r_1$ | 1 | $N_1$ | 1024 |
| $a_{02}$ | 1.4 | $a_{23}$ | 1.1 | $r_2$ | 1 | $N_2$ | 1024 |
| $a_{03}$ | 1.5 | $a_{32}$ | 1 | $r_3$ | 1 | $N_3$ | 1024 |
| $a_{12}$ | 1.2 | $r_0$ | 1 | $N_0$ | 1024 | $\beta$ | 4 |



(a) Test 1

(b) Test 2

Fig. 3. Removing and/or injecting traffic flow

### B. Stability analysis under different traffic loads

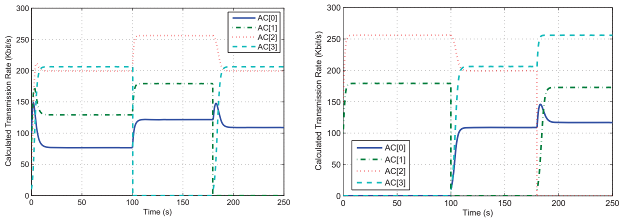
Two random network scenarios (i.e. Test1 and Test2) with two changes, such as removing or injecting traffic flows, are used to evaluate the performance of the proposed rate control scheme, such as the stability, scalability and adaptivity. Each scenario with random initial rate of traffic flows has two changing network states, change1 (Ch1) and change2 (Ch2)), as shown in Fig.3 and three global stable states (i.e. stable, stable1 and stable2) as shown in Table III. In Test1, we switch off the flow $AC[3]$ at $t = 100s$, and then switch $AC[3]$ on and $AC[1]$ off at $t = 180s$. While in Test2, we switch $AC[0]$, $AC[3]$ on and $AC[1]$ off at $t = 100s$, and then switch $AC[1]$ on again and $AC[2]$ off at $t = 180s$. Individual element in Table III is the transmission rate. Moreover, assuming that all traffic flows have the same characteristics of the growth rate $r$, the intra-specific competition coefficient $\beta$ and the maximum capacity $N$ of each data flow.

TABLE III
The EP of the proposed mechanism under different network conditions

| Test | Priority | Initial | Stable | Stable1 | Stable2 |
|---|---|---|---|---|---|
| | | 0s | 100s | 180s | 250s |
| Test1 | $AC[0]$ | 100.0 | 76.6 | 121.6 | 108.9 |
| | $AC[1]$ | 80.0 | 129.2 | 179.2 | 0.0 |
| | $AC[2]$ | 40.0 | 199.3 | 256.0 | 199.3 |
| | $AC[3]$ | 10.0 | 206.1 | 0.0 | 206.1 |
| Test2 | $AC[0]$ | 0.0 | 0.0 | 108.9 | 116.8 |
| | $AC[1]$ | 100.0 | 179.2 | 0.0 | 172.8 |
| | $AC[2]$ | 150.0 | 256.0 | 199.3 | 0.0 |
| | $AC[3]$ | 0.0 | 0.0 | 206.1 | 256.0 |

As observed in Table III, the experiments of Test1 and Test2 have the same values of stable EP, i.e. The point (76.6,129.2,199.3,206.1) is the global stable EP for all flows co-existing in the bandwidth-limited WLANs. When the flow $AC[3]$ becomes extinct at $t = 100s$ for some unknown reasons in Test1, the other priority flows will soon adaptively reach another new EP (121.6,179.2,256.0,0.0). After the instant $t = 180s$, the flow $AC[3]$ is injected into the network again, at the same time $AC[1]$ is switched off, then the system converges to a new EP. Similarly, Test2 also shows the excellent performance of the proposed mechanism in terms of adaptivity, scalability and stability. When $AC[1]$ is switched off and $AC[0]$, $AC[3]$ are switched on at $t = 100s$, the system reaches the stable EP (108.9,0.0,199.3,206.1), and then the WLANs will reach another new stable EP (116.8,172.8,0.0,256.0) after switching off $AC[2]$ and switching on $AC[1]$ at $t = 180s$ in Test2.

Fig. 4 takes a close look at the behavior of all traffic flows with differentiated priority under changing network load. We aim to reveal the process of the system keeping stable after changes in network state. As can be seen, when the data flow is changed for some reasons, the system can re-converge to a new stable EP quickly for its characteristic of self-adaptive. Moreover, the proposed mechanism provides smooth calculated transmission rates for all the traffic flows, which also assists in avoiding the probability of buffer overflow and network congestion. When some high priority emergency data streams are injected into the network, the proposed mechanism can also achieve graceful performance degradation.



(a) Test 1

(b) Test 2

Fig. 4. Calculated transmission rates

### C. Parameter setting and analysis

According to the second assumption of Section IV.A, the effect of intra-specific competition of any traffic flow is a constant, the impact of coefficient $\beta$ on a realistic network environment in investigated in this section. Each scenario, concerning different combinations of $a_{ij}$, $\beta$, $r$ and $N$ values, is executed 10 times and the average values of metrics over all scenarios are presented below.

When $\beta$ increases from 1.5 to 5 as shown in Fig. 5, the difference in transmission rates of all data flows is reduced, the remaining difference in data flow rate is only caused by the different inter-specific competition coefficients. With the increasement of value $\beta$, i.e. the competitive effect of flow $j$ on the sending rate of flow $i$ is much less than that from the inside of flow $i$, the total sending rate of all data flow is decreased. Even though there is no upper bound for $\beta$ value, it is worth pointing out that as $\beta$ increases, the EP value decreases and the quality of the received data at the DN may be reduced.

The phase plane of the scenarios with different values of $\beta$ as shown in Fig. 6 illustrates the stability, rapid convergence and differentiation of the transmission rate of the four different priority flows. As observed in Fig. 6(c) when $\beta = 4$, the transmission rate of each flow can converge to the global stable point without any fluctuations. Moreover, with the increment

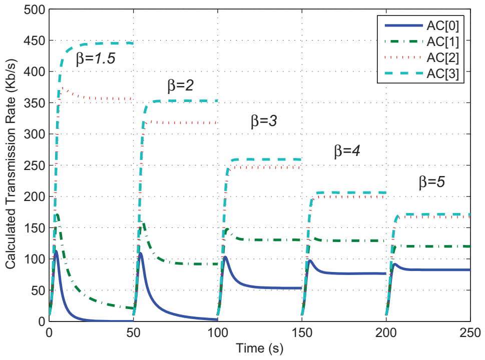


Fig. 5. The equilibrium point with different $\beta$ values

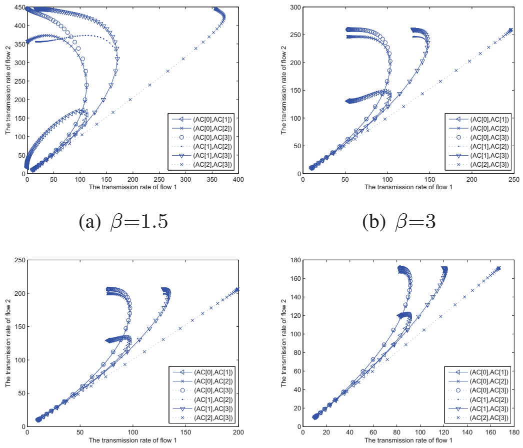
of intra-specific competition coefficient $\beta$, the phase plane inclines to a small region (the EP), which means that there is less difference among four species. However, when the value of intra-specific competition coefficient is equal to 1.5(i.e. the inequality $a_{ij} < \beta$ is not satisfied, for $a_{12} = 1.5$), the network system is not very stable as shown in Fig.6(a), which is identical to the analysis of Section IV.A and can be effectively avoided from proper parameter settings.



(a) $\beta$=1.5

(b) $\beta$=3

(c) $\beta$=4

(d) $\beta$=5

Fig. 6. Phase plane of two species

Fig.7 shows the throughput of different priority flows with $\beta$ varies from 1.5 to 5. The throughput of higher priority AC is much bigger than that of lower priority AC. And according to the curved surface, the value of intra-specific $\beta$ can be set for special purpose.

## VI. Conclusion

In this paper, we proposed a novel bio-inspired rate control scheme to meet the differentiated QoS requirements for various applications in IEEE 802.11e EDCA WLANs. Based on the extended competitive Lotka-Volterra model, the proposed rate control scheme considers traffic flows with differentiated QoS requirements. And the effect of injected bursty traffic

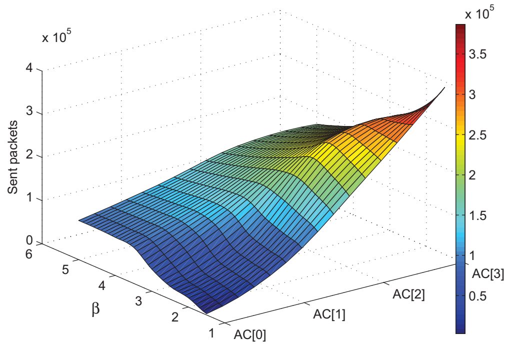


Fig. 7. The throughput of each priority flow with different $\beta$ values

flows on the system stability was also taken into consideration based on the limited network resources and competitions from other traffic flows. It was proven that the scheme has a global stable EP and can fast re-converge to a new EP under changing network conditions, while keeping all traffic flows co-existing and serviced with differentiated QoS. The source traffic rates could be adjusted optimally according to the value of EP. From the analysis of simulation results, we illustrated how the variations of the scheme's parameters influence stability, scalability and distinction of traffic flows. Performance evaluations suggested certain values for parameters $a_{ij}$, $\beta_i$ and $r_i$ that are able to avoid the network congestion and guarantee bandwidth for high priority real time traffic.

## ACKNOWLEDGMENT

***Abstract*—This paper investigates the global bounded consensus problem of Networked Multi-Agent Systems exhibiting nonlinear, non-identical agent dynamics with communication time-varying delay. Globally bounded controlled consensus conditions based on pinning control method and adaptive pinning control method are derived. The proposed consensus criteria ensures that all agents eventually move along desired trajectories in terms of boundedness. The proposed controlled consensus criteria generalizes the case of identical agent dynamics to the case of non-identical agent dynamics, and many related results of other researches in this area can be viewed as special cases of the above results. We finally demonstrate the effectiveness of the theoretical results by means of a numerical simulation.**

## I. Introduction

Networked Multi-Agent Systems (NMAS) has attracted many attention due to the broad applications of NMAS in many areas. How to design appropriate protocols and algorithms such that the set of agents can realize common objective, such as consensus, is a critical problem, especially for the case of unreliable information exchange and communication delays, and some relevant important contributions have been made in recent years [1], [2], [3], [4].

The consensus problem requires an agreement to be reached that depends on the state of all agents. The topic has been studied across many fields of science and engineering [5], [6], [7], [8], [9], [10], [11], [12], [13], [14], [15], [16], [17], [18], [19], [20]. It is noted that the agent dynamics in most existing works are often restricted to linear and identical ones. Obviously, in practice, this is not always the case. The controlled consensus problem of NMAS with nonlinear agent dynamics and communication delay are more complicated and just a few results have been made [21], [22]. In addition, most research in consensus problems usually assume that the final consensus value to be a constant, which may not be the case in the sense that the information state of each agent may be dynamically evolving in time according to some inherent dynamics. It is interesting to study controlled consensus problems where the final consensus value evolves with time or as a function of environmental dynamics.

The behavior of the NMAS with non-identical agent dynamics is much more complicated than the identical case. Usually, no common equilibrium for all agents exists even if each agent has an equilibrium, neither does a consensus manifold exist in the classical sense. The NMAS with non-identical agent dynamics cannot be decoupled into a number of lower dimensional systems exactly like the identical-agent case. Yet, a NMAS with non-identical agents may still exhibit some kinds of consensus behaviors which are far from being fully understood. Certain reasonable and satisfactory boundedness of state motions errors between different agents can be taken as useful consensus properties. The present paper will focus on the global consensus problems of NMAS based on pinning control methods [23], [24], [25], [26], and the proposed controlled consensus property is formulated in terms of certain boundedness of state errors.

The rest of this paper is organized as follows. A controlled continuous-time NMAS model with communication time-delay is presented in Section II. The main results including pinning control and adaptive pinning control bounded consensus criterion are derived in Section III and IV respectively. Section V gives a numerical simulation example to verify the effectiveness of the proposed results, followed by conclusions in Section VI.

## II. Problem description

Let $G = (\mathcal{V}, \mathcal{A})$ be a graph of order $N$ consisting of a set of vertices $\mathcal{V} = \{v_1, v_2, \cdots, v_N\}$ and a set of edges $\mathcal{A} \subseteq \mathcal{V} \times \mathcal{V}$. An edge $(v_j, v_i)$ in graph $G$ means that agent $v_i$ sends some information to agent $v_j$. The set of neighbors of agent $v_i$ is denoted by $\mathcal{N}_i = \{v_j \in \mathcal{V} : (v_j, v_i) \in \mathcal{A}\}$.

We consider a NMAS consisting of $N$ non-identical agents with communication delay:

$$\dot{x}_i = f_i(x_i) + c \sum_{j \in \mathcal{N}_i} a_{ij} \Gamma x_j(t - \tau(t)), i = 1, 2, \cdots, N, \quad (1)$$

where $x_i = (x_{i1}(t), x_{i2}(t), \cdots, x_{in}(t))^T \in R^n$ are the state variables of the agent $v_i$, $f_i(x_i) : R^n \to R^n$ are continuously differentiable mappings with Jacobian $Df_i$, representing the self-dynamics of the agent $v_i$, $c > 0$ denotes the coupling strength, $\Gamma = (\gamma_{ij}) \in R^{n\times n}$ is the inner coupling matrix, and where $\gamma_{ij} \neq 0$ means two connected agents are linked via their $i$th and $j$th state variables, respectively. The adjacency matrix $A = (a_{ij}) \in R^{N\times N}$ (which is symmetric and irreducible) represents the communication topology relation of the NMAS, and is defined by $a_{ij} = a_{ji} = 1(v_j \in \mathcal{N}_i)$, $a_{ij} = 0(v_j \notin \mathcal{N}_i)$ and $a_{ii} = -\sum_{j\neq i} a_{ij}$. $\tau(t)$ is a time-varying coupling delay which reflects the reality that the agent $v_i$ can't obtain information from agent $v_j$ instantaneously.

The average dynamic of all agents is defined by the vector field $\bar{f}(x(t)) = \frac{1}{N}\sum_{k=1}^{N} f_k(x(t))$ with Jacobian $D\bar{f}_i(x(t))$.

The average state trajectory is chosen as the desired moving trajectory

$$s(t) = \frac{1}{N}\sum_{k=1}^{N} x_k(t). \tag{2}$$

We now discuss the problem of global consensus for the system (1). The consensus problem here will be depicted instead via certain boundedness of $x_i(t) - x_j(t)$, $\forall i, j = 1, 2, \cdots, N$ as $t \to \infty$. This better reflects reality as it is impossible for NMAS (1) to achieve exact consensus. To address this case we will focus on making the states of all agents converge to a bounded set.

We denote $x(t)$, $s(t)$, $u(t)$, $e(t)$, $w(t)$, $d_i(t)$ and $V(w(t), t)$ as $x$, $s$, $u$, $e$, $w$, $d_i$ and $V$ respectively.

## III. Linear feedback pinning controller

To achieve the goal, we apply the feedback control strategy on a small fraction $\delta$ $(0 < \delta \leq 1)$ of the agents in system (1). Suppose that nodes $i_1, i_2, \cdots, i_l$ are selected to be under control, where $l = [\delta N]$ stands for the smaller but nearest integer to the real number $\delta N$. This controlled NMAS can be described as

$$\begin{cases} \dot{x}_{i_k} = f_{i_k}(x_{i_k}) + c\sum_{j\in\mathcal{N}_i} a_{i_k j}\Gamma x_j(t-\tau(t)) \\ \qquad +u_{i_k}, \qquad\qquad 1 \leq k \leq l, \\ \dot{x}_{i_k} = f_{i_k}(x_{i_k}) + c\sum_{j\in\mathcal{N}_i} a_{i_k j}\Gamma x_j(t-\tau(t)), \\ \qquad\qquad\qquad\qquad l+1 \leq k \leq N. \end{cases} \tag{3}$$

The local linear negative feedback control law is chosen as follows:

$$\begin{cases} u_{i_k} = -d_{i_k}(x_{i_k} - s), & 1 \leq k \leq l, \\ u_{i_k} = 0, & l+1 \leq k \leq N, \end{cases} \tag{4}$$

where the feedback gain $d_{i_k} > 0$.

Combine (3) and (4) and rearrange the order of the nodes in the network. Let the first $l$ nodes be controlled, and $e_i = x_i - s$, $i = 1, 2, \cdots, N$. It's obvious that $\frac{c}{N}\sum_{k=1}^{N}\sum_{j\in\mathcal{N}_i} a_{kj}\Gamma x_j(t-\tau(t)) = 0$ and $\sum_{i=1}^{N} e_i = 0$. Then by applying the Newton-Leibniz formula, error systems can be written as

$$\begin{cases} \dot{e}_i = D\bar{f}(s)e_i + c\sum_{j\in\mathcal{N}_i} a_{ij}\Gamma e_j(t-\tau(t)) \\ \quad + \int_0^1 (Df_i(s+\tau e_i) - D\bar{f}(s))e_i d\tau \\ \quad - \frac{1}{N}\sum_{k=1}^{N}\int_0^1 Df_k(s+\tau e_k)e_k d\tau \\ \quad + f_i(s) - \bar{f}(s) - d_i e_i, \quad 1 \leq i \leq l, \\ \dot{e}_i = D\bar{f}(s)e_i + c\sum_{j\in\mathcal{N}_i} a_{ij}\Gamma e_j(t-\tau(t)) \\ \quad + \int_0^1 (Df_i + \tau e_i) - D\bar{f}(s))e_i d\tau \\ \quad - \frac{1}{N}\sum_{k=1}^{N}\int_0^1 Df_k(s+\tau e_k)e_k d\tau \\ \quad + f_i(s) - \bar{f}(s), \quad l+1 \leq i \leq N. \end{cases} \tag{5}$$

The following work will focus on simplifying the error systems (5) by means of a series of transformations using a procedure similar to [22].

Define the following matrix

$$D = diag(D_1, D_2, \cdots, D_N) \in R^{nN\times nN},$$

where $D_i = diag\{-d_i, -d_i, \cdots, -d_i\} \in R^{n\times n}$.

Let $e = (e_1^T, e_2^T, \cdots, e_N^T)^T$, then (5) becomes

$$\dot{e} = \bar{\Sigma}(t)e + cA\otimes\Gamma e(t-\tau(t)) + I(t)e - \frac{1}{N}H(t)e + F(t), \tag{6}$$

where $I(t) = diag\{\int_0^1 (Df_1(s+\tau e_1) - D\bar{f}(s))d\tau \cdots \int_0^1 (Df_N(s+\tau e_N) - D\bar{f}(s))d\tau\}$, $\bar{\Sigma}(t) = I_N \otimes D\bar{f}(s) + D$, $H^T(t) = (H_1^T(t), \cdots, H_N^T(t))$, $H_i(t) = (\int_0^1 Df_1(s + \tau e_1)d\tau, \cdots, \int_0^1 Df_N(s + \tau e_N)d\tau)$, $F_i^T(t) = (f_1^T(s) - \bar{f}^T(s), \cdots, f_N^T(s) - \bar{f}^T(s))$.

Since $A$ is symmetric and irreducible, according to [22], there exists a unitary matrix $\Phi = (\varphi_{ij})_{N\times N} = (\Phi_1, \Phi_2, \cdots, \Phi_N)$. This together with $w(t) = (\Phi^T \otimes I_n)e$ gives

$$\begin{aligned} \dot{w} &= (\Phi^T\otimes I_n)\bar{\Sigma}(t)(\Phi\otimes I_n)w \\ &\quad + (\Phi^T\otimes I_n)(cA\otimes\Gamma)(\Phi\otimes I_n)w(t-\tau(t)) \\ &\quad + (\Phi^T\otimes I_n)I(t)(\Phi\otimes I_n)w + (\Phi^T\otimes I_n)F(t) \\ &\quad - \frac{1}{N}(\Phi^T\otimes I_n)H(t)(\Phi\otimes I_n)w. \end{aligned} \tag{7}$$

Note that $H(t) = \sqrt{N}\sum_{k=1}^{N}(\mathbf{0}\ \cdots\ \mathbf{0}\ \bar{\Phi}_k\ \mathbf{0}\ \cdots\ \mathbf{0}) \otimes \int_0^1 Df_k(s + \tau e_k)d\tau$, where $\bar{\Phi}_k$ stands for the matrix with its $k$-th column equal to $\Phi_1$ and the remaining elements are zero. Then we have $\frac{1}{N}(\Phi^T \otimes I_n)H(t)(\Phi \otimes I_n) = \frac{1}{\sqrt{N}}\sum_{k=1}^{N}(\mathbf{0}\ \cdots\ \mathbf{0}\ I_k\ \mathbf{0}\ \cdots\ \mathbf{0})\otimes\int_0^1 Df_k(s+\tau e_k)d\tau(\Phi\otimes I_n)$, where $I_k$ stands for the matrix with its $k$-th column equals $(1\ 0\ \cdots\ 0)^T$ and the remaining of its elements are zero.

Thus, a simple calculation gives $\frac{1}{N}(\Phi^T \otimes I_n)H(t)(\Phi \otimes I_n) = \frac{1}{\sqrt{N}}\sum_{k=1}^{N}\begin{pmatrix} \Upsilon_k & 0 \end{pmatrix}^T \otimes \int_0^1 Df_k(s(t) + \tau e_k(t))d\tau$, where $\Upsilon_k \in R^{1\times N}$ and $0 \in R^{(N-1)\times N}$. Therefore, $\dot{w} = \bar{\Sigma}(t)w + c\Lambda\otimes\Gamma w(t-\tau(t)) + (\Phi^T\otimes I_n)I(t)(\Phi\otimes I_n)w - \begin{pmatrix} * & 0 \end{pmatrix}^T w + (\Phi^T \otimes I_n)F(t)$. Since $w_1 \equiv 0$, we only need to consider $w_2, w_3, \cdots, w_N$. Rewriting in the component form we have

$$\begin{aligned} \dot{w}_i &= \Sigma_i(t)w_i + c\lambda_i\Gamma w_i(t-\tau(t)) + (\Phi_i^T\otimes I_n)F(t) \\ &\quad + (\Phi_i^T\otimes I_n)I(t)(\Phi\otimes I_n)w,\ i = 2, 3, \cdots, N, \end{aligned} \tag{8}$$

where $\Sigma_i = \bar{D}f(s) + D_i$.

So far, we have transferred the consensus problem of system (1) to the stability problem of the $N-1$ of $n-$dimensional systems.

**Theorem 1** Suppose there exist positive definite matrices $P_i(t) \in \mathcal{PC}^1_{n\times n}$, $Q_i$ and constants $\zeta > 0$, $\gamma \geq 0$, $a > 0$ and $b > 0$ such that

$$a\|x\|^2 \leq x^T P_i(t) x + \int_{t-\tau(t)}^{t} w_i^T(\alpha) Q_i w_i(\alpha) d\alpha \leq b\|x\|^2,$$
$$\forall t \in R^+,\ x \in R^n, i = 2, 3, \cdots, N, \tag{9}$$

$$\dot{P}_i(t) + P_i(t)\Sigma_i(t) + \Sigma_i^T(t) P_i(t) + Q_i$$
$$+ c^2\lambda_i^2 P_i(t)\Gamma Q_i^{-1}\Gamma^T P_i(t) + \zeta I \leq 0,\ i = 1, 2, \cdots, N, \tag{10}$$

$$\|I(t)\| \leq \gamma,\ i = 1, 2, \cdots, N. \tag{11}$$

Let

$$\mu(t) = \|F(t)\| \tag{12}$$

be bounded and

$$\beta = (\sum_{i=2}^{N} \|P_i(t)\|^2)^{\frac{1}{2}}, \tag{13}$$

if $\zeta > 2\gamma\beta$, then system (6) converges to the set

$$M = \{e | \|e\| \leq \frac{2b}{a}\frac{\beta \overline{lim}_{t\to\infty}\mu(t)}{\zeta - 2\gamma\beta - \delta}\}, \tag{14}$$

for any time-varying delay $\tau(t) > 0$, namely, $e(t) = x_i(t) - \frac{1}{N}\sum_{k=1}^{N} x_k(t) \to \Omega$ as $t \to \infty$, where $\delta > 0$ is any constant satisfying $\delta < \zeta - 2\gamma\beta$, Furthermore, the NMAS (1) achieves bounded consensus for any fixed time delay $\tau(t) > 0$, $0 \leq \dot{\tau}(t) \leq 1$.

**Proof.** Choose the following Lyapunov-Krasovskii functional as

$$V = \sum_{i=2}^{N} V_i, \tag{15}$$

$$V_i = w_i^T P_i(t) w_i + \int_{t-\tau(t)}^{t} w_i^T(\alpha) Q_i w_i(\alpha) d\alpha. \tag{16}$$

Differentiating (16) along the trajectory of (8) gives

$$\begin{aligned}\dot{V}_i &= w_i^T(\dot{P}_i(t) + P_i(t)\Sigma_i(t) + \Sigma_i^T(t)P_i(t) + Q_i)w_i \\ &+ 2w_i^T P_i(t)(\Phi_i^T \otimes I_n) I(t)(\Phi_i \otimes I_n) w \\ &+ 2w_i^T P_i(t)(\Phi_i^T \otimes I_n) F(t) + 2w_i^T(c\lambda_i P_i(t)\Gamma) w_i(t-\tau(t)) \\ &- w_i^T(t-\tau(t)) Q_i w_i(t-\tau(t)).\end{aligned} \tag{17}$$

Applying the Young Inequality to the equality (17) results in

$$\begin{aligned}\dot{V}_i &\leq w_i^T(\dot{P}_i(t) + P_i(t)\Sigma_i(t) + \Sigma_i^T(t)P_i(t) + Q_i \\ &+ c^2\lambda_i^2 P_i(t)\Gamma Q_i^{-1}\Gamma^T P_i(t))w_i + 2w_i^T P_i(t)(\Phi_i^T \otimes I_n)F(t) \\ &+ 2w_i^T P_i(t)(\Phi_i^T \otimes I_n) I(t)(\Phi \otimes I_n) w.\end{aligned} \tag{18}$$

Condition (10) implies that the first term on the right hand side of (18) satisfies

$$\begin{aligned}&w_i^T(\dot{P}_i(t) + P_i(t)\Sigma_i(t) + \Sigma_i^T(t)P_i(t) + Q_i \\ &\quad + c^2\lambda_i^2 P_i(t)\Gamma Q_i^{-1}\Gamma^T P_i(t))w_i \leq -\zeta\|w_i\|^2.\end{aligned} \tag{19}$$

The second term on the right hand side of (18) satisfies

$$2w_i^T P_i(t)(\Phi_i^T \otimes I_n) F(t) \leq 2\mu(t)\|P_i(t)\|\|w_i\|. \tag{20}$$

Applying condition (11) we know the third term on the right hand side of (18) satisfies

$$2w_i^T P_i(t)(\Phi_i^T \otimes I_n) I(t)(\Phi_i \otimes I_n) w \leq 2\gamma\|P_i(t)\|\|w_i\|\|w\|. \tag{21}$$

Since $V = \sum_{i=2}^{N} V_i$, we have

$$\begin{aligned}\dot{V} &= \sum_{i=2}^{N} \dot{V}_i \\ &= -\zeta\|w\|^2 + 2(\gamma\|w\| + \mu(t))\sum_{i=2}^{N}\|w_i\|\|P_i(t)\| \\ &\leq -\zeta\|w\|^2 + 2(\gamma\|w\| + \mu(t))\|w\|(\sum_{i=2}^{N}\|P_i(t)\|^2)^{\frac{1}{2}} \\ &= \|w\|((2\gamma\beta - \zeta)\|w\| + 2\beta\mu(t)).\end{aligned} \tag{22}$$

Thus, when

$$\|w\| \geq \frac{2\beta\mu(t)}{\zeta - 2\gamma\beta - \delta}, \tag{23}$$

we have

$$\dot{V} \leq -\delta\|w\|^2. \tag{24}$$

Applying the result in [22] completes the proof.

## IV. Adaptive pinning controller

In this section, we will derive globally consensus criteria via direct adaptive pinning control method. Without loss of generality, we still assume that the first $l$ agents are selected as pinned agents with the adaptive controllers:

$$\begin{cases} u_i = -d_i(x_i - s), & 1 \leq i \leq l, \\ \dot{d}_i = h_i e_i^T P_i(t) e_i, & \\ u_i = 0, & l+1 \leq i \leq N, \end{cases} \tag{25}$$

where constant $h_i > 0$ and positive definite matrix $P_i(t) \in R^{n\times n}$. Applying Newton-Leibniz formula, then the error N-

MAS can be rewritten as

$$\begin{cases} \dot{e}_i = D\bar{f}(s)e_i + c\sum_{j\in\mathcal{N}_i} a_{ij}\Gamma e_j(t-\tau(t)) \\ \qquad + \int_0^1 (Df_i(s+\tau e_i) - D\bar{f}(s))e_i d\tau \\ \qquad -\frac{1}{N}\sum_{k=1}^N \int_0^1 Df_k(s+\tau e_k)e_k d\tau \\ \qquad +f_i(s) - \bar{f}(s) - d_i e_i, \qquad 1 \le i \le l, \\ \dot{d}_i = h_i e_i^T P_i(t) e_i, \\ \dot{e}_i = D\bar{f}(s)e_i + c\sum_{j\in\mathcal{N}_i} a_{ij}\Gamma e_j(t-\tau(t)) \\ \qquad + \int_0^1 (Df_i(s+\tau e_i) - D\bar{f}(s))e_i d\tau \\ \qquad -\frac{1}{N}\sum_{k=1}^N \int_0^1 Df_k(s+\tau e_k)e_k d\tau \\ \qquad +f_i(s) - \bar{f}(s), \qquad\qquad l+1 \le i \le N. \end{cases} \tag{26}$$

Repeating a similar procedure to the previous subsection, the controlled consensus problem of system (1) is equivalent to the stability problem of the following $N-1$ of $n$-dimensional systems.

$$\begin{cases} \dot{w}_i = D\bar{f}(s(t))w_i - d_i w_i + c\lambda_i\Gamma w_i(t-\tau(t)) \\ \qquad +(\Phi_i^T \otimes I_n)I(t)(\Phi \otimes I_n)w \\ \qquad +(\Phi_i^T \otimes I_n)F(t), \qquad\qquad 2 \le i \le l, \\ \dot{d}_i = h_i w_i^T P_i(t) w_i, \\ \dot{w}_i = D\bar{f}(s)w_i + c\lambda_i\Gamma w_i(t-\tau(t)) \\ \qquad +(\Phi_i^T \otimes I_n)I(t)(\Phi \otimes I_n)w \\ \qquad +(\Phi_i^T \otimes I_n)F(t), \qquad\qquad l+1 \le i \le N, \end{cases} \tag{27}$$

where $w_i$, $w$, $\Phi$, $\Phi_i$, $I(t)$ and $F(t)$ are the same as the previous subsection.

**Theorem 2** Suppose there exist positive definite matrices $P_i(t) \in \mathcal{PC}^1_{n\times n}$, $Q_i$ and constants $\bar{\zeta} > 0$, $\gamma \ge 0$, $a > 0$ and $b > 0$ such that

$$\begin{aligned} a\|x\|^2 \le x_i^T P_i(t)x_i + \int_{t-\tau(t)}^t x_i^T(\alpha)Q_i x_i(\alpha)d\alpha \\ + \frac{(d_i-d)^2}{h_i} \le b\|x\|^2, \forall t \in R^+,\ x \in R^n, i = 2, 3, \cdots, N, \end{aligned} \tag{28}$$

$$\begin{aligned} \dot{P}_i(t) + P_i(t)D\bar{f}(s) + (D\bar{f}(s))^T P_i(t) + Q_i - 2dP_i(t) \\ + c^2\lambda_i^2 P_i(t)\Gamma Q_i^{-1}\Gamma^T P_i(t) + \bar{\zeta} I \le 0,\ i = 1, 2, \cdots, N, \end{aligned} \tag{29}$$

(11) and $\bar{\zeta} > 2\gamma\beta$ are satisfied, then the system (6) converges to the set (14) for any time-varying delay $\tau(t) > 0$, where $\mu(t)$ and $\beta$ are the same as in (12) and (13) respectively, $\bar{\delta} > 0$ is any constant satisfying $\bar{\delta} < \bar{\zeta} - 2\gamma\beta$, and then the NMAS (1) achieves bounded consensus for any fixed time delay $\tau(t) > 0$, $0 \le \dot{\tau}(t) \le 1$.

**Proof.** Construct the following Lyapunov-Krasovskii functional as

$$V = \sum_{i=2}^N V_i + \sum_{i=2}^l \frac{(d_i-d)^2}{h_i}, \tag{30}$$

where

$$\begin{cases} V_i = w_i^T P_i(t) w_i + \int_{t-\tau(t)}^t w_i^T(\alpha)Q_i w_i(\alpha)d\alpha \\ \qquad + \frac{(d_i-d)^2}{h_i}, \qquad\qquad 2 \le i \le l, \\ V_i = w_i^T P_i(t) w_i + \int_{t-\tau(t)}^t w_i^T(\alpha)Q_i w_i(\alpha)d\alpha, \\ \qquad\qquad\qquad\qquad\qquad l+1 \le i \le N, \end{cases} \tag{31}$$

where $d$ is a positive constant to be determined.

Differentiating (31) along the trajectory of (27) gives

$$\begin{aligned} \dot{V}_i = {} & w_i^T(\dot{P}_i(t) + P_i(t)D\bar{f}(s) + (D\bar{f}(s))^T P_i(t) + Q_i \\ & - 2dP_i(t))w_i + 2w_i^T P_i(t)(\Phi_i^T \otimes I_n)I(t)(\Phi_i \otimes I_n)w \\ & + 2w_i^T P_i(t)(\Phi_i^T \otimes I_n)F(t) + 2w_i^T(c\lambda_i P_i(t)\Gamma)w_i(t-\tau(t)) \\ & - w_i^T(t-\tau(t))Q_i w_i(t-\tau(t)). \end{aligned} \tag{32}$$

The remaining part of the proof is similar to that of Theorem 1, so is therefore omitted here. This completes the proof.

## V. Examples

To demonstrate the theoretical results obtained above, we construct a NMAS consisting of 12 agents described as follows

$$\dot{x}_i(t) = f_i(x_i(t)) + c\sum_{j\in\mathcal{N}_i} a_{ij}\Gamma x_j(t-\tau(t)), \tag{33}$$

where $f_i(x_i(t)) = B_i x_i(t) + g(x_i(t))$, $B_i(i = 1, 2, \cdots, 6)$ and $B_i(i = 7, 8, \cdots, 12)$ are chosen as follows:

$$\begin{pmatrix} -10 + 0.1 \times (i-1) & 10 - 0.1 \times (i-1) & 0 \\ 1 & -1 & 1 \\ 0 & -15 - 0.1 \times (i-1) & 0 \end{pmatrix},$$

$$\begin{pmatrix} -10 - 0.1 \times (i-6) & 10 + 0.1 \times (i-6) & 0 \\ 1 & -1 & 1 \\ 0 & -15 + 0.1 \times (i-6) & 0 \end{pmatrix},$$

and

$$g(x_i(t)) = (-9.5sin(\frac{\pi x_{i1}(t)}{3.2} + \pi)\ 0\ 0)^T, \quad i = 1, 2, \cdots, 12.$$

The communication coupling matrix $C = (C_1^T C_2^T \cdots C_{12}^T)$, $C_1 = (-8\ 1\ 1\ 0\ 1\ 1\ 1\ 0\ 1\ 1\ 1\ 0)$, $C_2 = (1\ -8\ 1\ 1\ 1\ 0\ 1\ 0\ 1\ 1\ 1\ 0)$, $C_3 = (1\ 1\ -7\ 1\ 0\ 0\ 0\ 1\ 0\ 1\ 1\ 1)$, $C_4 = (0\ 1\ 1\ -6\ 0\ 1\ 1\ 0\ 0\ 1\ 0\ 1)$, $C_5 = (1\ 1\ 0\ 0\ -6\ 0\ 1\ 1\ 1\ 1\ 0\ 0)$, $C_6 = (1\ 0\ 0\ 1\ 0\ -5\ 1\ 0\ 1\ 1\ 0)$, $C_7 = (1\ 1\ 0\ 1\ 1\ 1\ -7\ 1\ 0\ 1\ 0)$, $C_8 = (0\ 0\ 1\ 0\ 1\ 0\ 1\ -6\ 0\ 1\ 1\ 1)$, $C_9 = (1\ 1\ 0\ 0\ 1\ 1\ 0\ 0\ -7\ 1\ 1\ 1)$, $C_{10} = (1\ 1\ 1\ 1\ 1\ 1\ 1\ 1\ 1\ -10\ 1)$, $C_{11} = (1\ 1\ 1\ 0\ 0\ 0\ 0\ 1\ 1\ 1\ -7\ 1)$, $C_{12} = (0\ 0\ 1\ 1\ 0\ 0\ 0\ 1\ 1\ 0\ 1\ -5)$. $\Gamma = diag\{2, 2, 2\}$, respectively, where the matrix $A$ is produced by means of the Scale-Free network program.

Design the following controllers

$$\begin{cases} u_{i_k} = -d_{i_k}(x_{i_k}(t) - s(t)), & i_k = 1, 2 \texttt{ and } 10, \\ u_{i_k} = 0, & \texttt{else}, \end{cases}$$

with $d_1 = 0.5$, $d_2 = 0.5$, $d_{10} = 0.5$ and

$$\begin{cases} u_{i_k} = -d_{i_k}(t)(x_{i_k}(t) - s(t)), & i_k = 1, 2 \texttt{ and } 10, \\ \dot{d}_{i_k}(t) = h_{i_k} e_{i_k}^T P_{i_k}(t) e_{i_k}, \\ u_{i_k} = 0, & \texttt{else}, \end{cases}$$

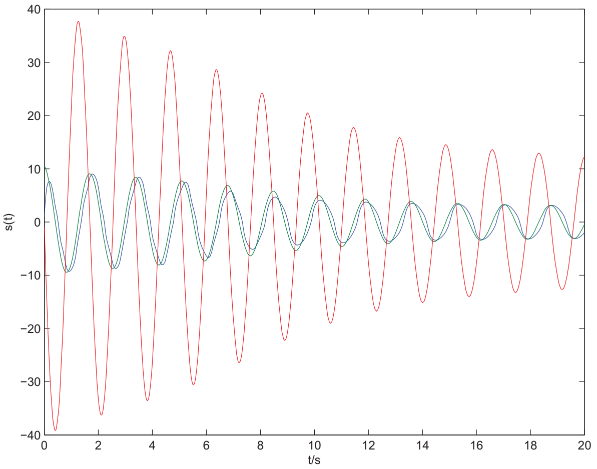

Fig.1. Desired agent dynamics under pinning control.

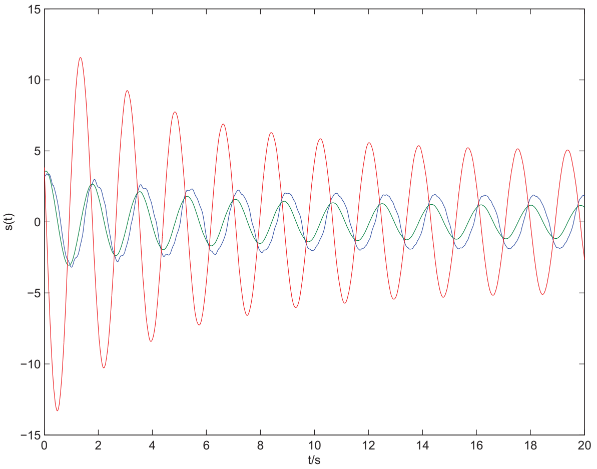

Fig.2. Desired agent dynamics under adaptive pinning control.

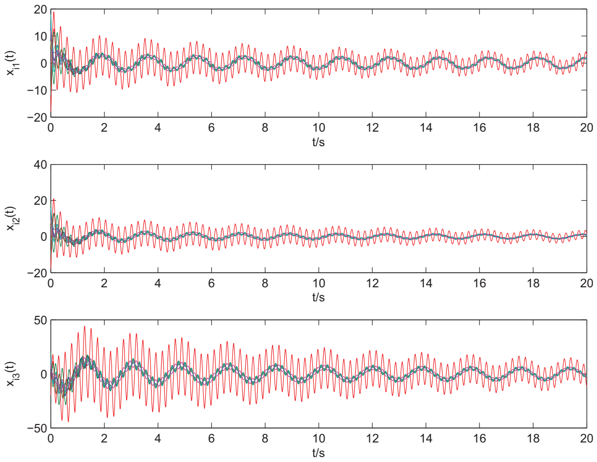

Fig.3. All agent dynamics under pinning control.

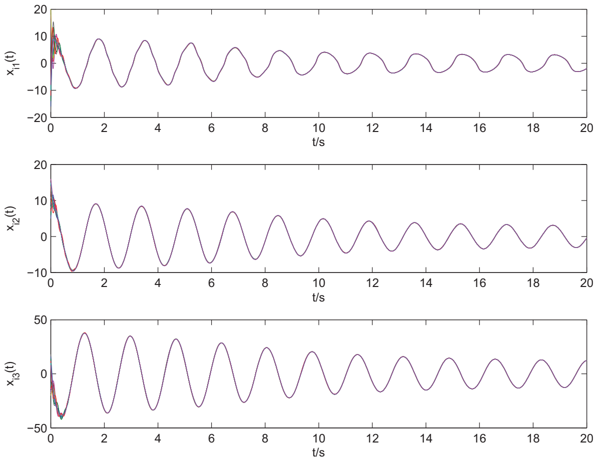

Fig.4. All agent dynamics under adaptive pinning control.

with $h_1 = 0.1$, $h_2 = 0.2$, $h_{10} = 0.3$, $s(t)$ can then be evaluated by simulation.

Given the initial values of 12 agents as $(10\ 5\ \ -10)^T$, $(12\ 6\ \ -12)^T$, $(14\ 7\ \ -14)^T$, $(16\ 8\ \ -16)^T$, $(18\ 9\ \ -18)^T$, $(20\ 10\ -20)^T$, $(-18\ 11\ 18)^T$, $(-16\ 12\ 16)^T$, $(-14\ 13\ 14)^T$, $(-12\ 14\ 12)^T$, $(-10\ 15\ 10)^T$, $(-8\ 16\ 8)^T$ respectively and $P_{i_k}(t) = I_3$, $d_1(0) = 1$, $d_2(0) = 1$, $d_{10}(0) = 1$ and $\tau(t) = \frac{\pi}{2} + arctan(t)$. The conditions of Theorem 1 and Theorem 2 are satisfied readily. Bounded consensus of the NMAS is achieved for any time varying delay satisfying $0 < \tau \leq \frac{\pi}{2} + arctan(t)$. Simulation results are depicted in Fig.1 to Fig.8 for $\tau(t) = \frac{\pi}{2} + arctan(t)$ and $c = 1$.

## VI. Conclusion

In this paper, we've investigated the controlled consensus problems of NMAS with different agent dynamics. The derived criteria are verified via theoretical analysis and numerical simulation. The consensus for the NMAS is achieved based on pinning control and adaptive pinning control methods. Many related results for the case of identical agent dynamics have been viewed as the special cases of the proposed results. However, it should be noted that the conditions are still restrictive and the time-varying delay is chosen as fixed case. Further investigations will focus on relaxing these limitations and more generalized cases.

***Abstract*—This paper investigates the global bounded consensus problem of Networked Multi-Agent Systems exhibiting nonlinear, non-identical agent dynamics with communication time-varying delay. Globally bounded controlled consensus conditions based on pinning control method and adaptive pinning control method are derived. The proposed consensus criteria ensures that all agents eventually move along desired trajectories in terms of boundedness. The proposed controlled consensus criteria generalizes the case of identical agent dynamics to the case of non-identical agent dynamics, and many related results of other researches in this area can be viewed as special cases of the above results. We finally demonstrate the effectiveness of the theoretical results by means of a numerical simulation.**

## I. Introduction

Networked Multi-Agent Systems (NMAS) analysis involves the study of how the network architectures and interactions between network components influence global control goals and some important contributions have been made in recent years [1], [2], [3], [4].

The consensus problem has been studied across many fields of science and engineering [5], [6], [7], [8], [9], [10], [11], [12], [13]. The controlled consensus problem of NMAS with non-identical agent dynamics is much more complicated than the identical case and few results have been reported to date [14].

The present paper will focus on the global consensus problems of NMAS based on pinning control methods [15], [16], [17], and the proposed controlled consensus property is formulated in terms of certain boundedness of state errors. In this paper, we'll generalize many existing results for the case of identical agent dynamics to the case of non-identical agent dynamics based on the pinning control method.

The rest of this paper is organized as follows. A controlled continuous-time NMAS model with communication time-delay is presented in Section II. The main results including pinning control and adaptive pinning control bounded consensus criterion are derived in Section III and V respectively. Section IV gives a numerical simulation example to verify the effectiveness of the proposed results, followed by conclusions in Section VI.

## II. Problem description

Let $G = (\mathcal{V}, \mathcal{A})$ be a graph of order $N$ consisting of a set of vertices $\mathcal{V} = \{v_1, v_2, \cdots, v_N\}$ and a set of edges $\mathcal{A} \subseteq \mathcal{V} \times \mathcal{V}$. An edge $(v_j, v_i)$ in graph $G$ means that agent $v_i$ sends some information to agent $v_j$. The set of neighbors of agent $v_i$ is denoted by $\mathcal{N}_i = \{v_j \in \mathcal{V} : (v_j, v_i) \in \mathcal{A}\}$.

We consider a MAS consisting of $N$ non-identical agents with communication delay:

$$\dot{x}_i = f_i(x_i) + c\sum_{j\in\mathcal{N}_i}^{N} a_{ij}\Gamma x_j(t-\tau), i = 1, 2, \cdots, N, \qquad (1)$$

where $x_i = (x_{i1}(t), x_{i2}(t), \cdots, x_{in}(t))^T \in R^n$ are the state variables of the agent $v_i$, $f_i(x_i) : R^n \to R^n$ are continuously differentiable mappings with Jacobian $Df_i$, representing the self-dynamics of the agent $v_i$, $c > 0$ denotes the coupling strength, $\Gamma = (\gamma_{ij}) \in R^{n\times n}$ is the inner coupling matrix, and where $\gamma_{ij} \neq 0$ means two connected agents are linked via their $i$th and $j$th state variables, respectively. The adjacency matrix $A = (a_{ij}) \in R^{N\times N}$ (which is symmetric and irreducible) represents the communication topology relation of the MAS, and is defined by $a_{ij} = a_{ji} = 1(v_j \in \mathcal{N}_i)$, $a_{ij} = 0(v_j \notin \mathcal{N}_i)$ and $a_{ii} = -\sum_{j\neq i} a_{ij}$. $\tau$ is a constant coupling delay which reflects the reality that the agent $v_i$ can't obtain information from agent $v_j$ instantaneously.

The average dynamic of all agents is defined by the vector field $\bar{f}(x(t)) = \frac{1}{N}\sum_{k=1}^{N} f_k(x(t))$ with Jacobian $D\bar{f}_i(x(t))$.

The average state trajectory is chosen as the desired moving trajectory

$$s(t) = \frac{1}{N}\sum_{k=1}^{N} x_k(t). \qquad (2)$$

We now discuss the problem of global consensus for the system (1). The consensus problem formulation in the present paper is quite different from many others, where the consensus problem is solvable if the states of all agents satisfy $x_i(t) \to x_j(t)$, $\forall i, j = 1, 2, \cdots, N$ as $t \to \infty$. The consensus problem here will be depicted instead via certain boundedness

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

of $x_i(t) - x_j(t)$, $\forall i, j = 1, 2, \cdots, N$ as $t \to \infty$. This better reflects reality as it is impossible for MAS (1) to achieve exact consensus. To address this case we will focus on making the states of all agents converge to a bounded set.

We denote $x(t)$, $s(t)$, $u(t)$, $e(t)$, $w(t)$ and $V(w(t), t)$ as $x$, $s$, $u$, $e$, $w$ and $V$ respectively.

## III. Linear feedback pinning controller

To achieve the goal, we apply the feedback control strategy on a small fraction $\delta$ $(0 < \delta \leq 1)$ of the agents in system (1). Suppose that nodes $i_1, i_2, \cdots, i_l$ are selected to be under control, where $l = [\delta N]$ stands for the smaller but nearest integer to the real number $\delta N$. This controlled MAS can be described as

$$\begin{cases} \dot{x}_{i_k} = f_{i_k}(x_{i_k}) + c\sum_{j=1}^{N} a_{i_k j}\Gamma x_j(t-\tau) + u_{i_k}, 1 \leq k \leq l, \\ \dot{x}_{i_k} = f_{i_k}(x_{i_k}) + c\sum_{j=1}^{N} a_{i_k j}\Gamma x_j(t-\tau), l+1 \leq k \leq N. \end{cases} \tag{3}$$

The local linear negative feedback control law is chosen as follows:

$$\begin{cases} u_{i_k} = -d_{i_k}(x_{i_k} - s), & 1 \leq k \leq l, \\ u_{i_k} = 0, & l+1 \leq k \leq N, \end{cases} \tag{4}$$

where the feedback gain $d_{i_k} > 0$.

Combine (3) and (4) and rearrange the order of the n-odes in the network. Let the first $l$ nodes be controlled, and $e_i = x_i - s$, $i = 1, 2, \cdots, N$. It's obvious that $\frac{c}{N}\sum_{k=1}^{N}\sum_{j=1}^{N} a_{kj}\Gamma x_j(t-\tau) = 0$ and $\sum_{i=1}^{N} e_i = 0$. Then by applying the Newton-Leibniz formula, error systems can be written as

$$\begin{cases} \dot{e}_i = D\bar{f}(s)e_i + c\sum_{j=1}^{N} a_{ij}\Gamma e_j(t-\tau) \\ \quad + \int_0^1 (Df_i(s+\tau e_i) - D\bar{f}(s))e_i d\tau \\ \quad - \frac{1}{N}\sum_{k=1}^{N}\int_0^1 Df_k(s+\tau e_k)e_k d\tau \\ \quad + f_i(s) - \bar{f}(s) - d_i e_i, & 1 \leq i \leq l, \\ \dot{e}_i = D\bar{f}(s)e_i + c\sum_{j=1}^{N} a_{ij}\Gamma e_j(t-\tau) \\ \quad + \int_0^1 (Df_i + \tau e_i) - D\bar{f}(s))e_i d\tau \\ \quad - \frac{1}{N}\sum_{k=1}^{N}\int_0^1 Df_k(s+\tau e_k)e_k d\tau \\ \quad + f_i(s) - \bar{f}(s), & l+1 \leq i \leq N. \end{cases} \tag{5}$$

The following work will focus on simplifying the error systems (5) by means of a series of transformations using a procedure similar to [14].

Define the following matrix

$$D = diag(D_1, D_2, \cdots, D_N) \in R^{nN \times nN},$$

where $D_i = diag\{-d_i, -d_i, \cdots, -d_i\} \in R^{n \times n}$.

Let $e = (e_1^T, e_2^T, \cdots, e_N^T)^T$, then (5) becomes

$$\dot{e} = \bar{\Sigma}(t)e + cA \otimes \Gamma e(t-\tau) + I(t)e - \frac{1}{N}H(t)e + F(t), \tag{6}$$

where $I(t) = diag\{\int_0^1 (Df_1(s+\tau e_1) - D\bar{f}(s))d\tau \cdots \int_0^1 (Df_N(s+\tau e_N) - D\bar{f}(s))d\tau\}$, $\bar{\Sigma}(t) = I_N \otimes D\bar{f}(s) + D$, $H^T(t) = (H_1^T(t), \cdots, H_N^T(t))$, $H_i(t) = (\int_0^1 Df_1(s+\tau e_1)d\tau, \cdots, \int_0^1 Df_N(s+\tau e_N)d\tau)$, $F_i^T(t) = (f_1^T(s) - \bar{f}^T(s), \cdots, f_N^T(s) - \bar{f}^T(s))$.

Since $A$ is symmetric and irreducible, according to [14], there exists a unitary matrix $\Phi = (\varphi_{ij})_{N\times N} = (\Phi_1, \Phi_2, \cdots, \Phi_N)$. This together with $w(t) = (\Phi^T \otimes I_n)e$ gives

$$\begin{aligned} \dot{w} = {} & (\Phi^T \otimes I_n)\bar{\Sigma}(t)(\Phi \otimes I_n)w \\ & + (\Phi^T \otimes I_n)(cA \otimes \Gamma)(\Phi \otimes I_n)w(t-\tau) \\ & + (\Phi^T \otimes I_n)I(t)(\Phi \otimes I_n)w \\ & - \frac{1}{N}(\Phi^T \otimes I_n)H(t)(\Phi \otimes I_n)w + (\Phi^T \otimes I_n)F(t). \end{aligned} \tag{7}$$

Note that $H(t) = \sqrt{N}\sum_{k=1}^{N}(\mathbf{0}\ \cdots\ \mathbf{0}\ \bar{\Phi}_k\ \mathbf{0}\ \cdots\ \mathbf{0}) \otimes \int_0^1 Df_k(s+\tau e_k)d\tau$, where $\bar{\Phi}_k$ stands for the matrix with its $k$-th column equal to $\Phi_1$ and the remaining elements are zero. Then we have $\frac{1}{N}(\Phi^T \otimes I_n)H(t)(\Phi \otimes I_n) = \frac{1}{\sqrt{N}}\sum_{k=1}^{N}(\mathbf{0}\ \cdots\ \mathbf{0}\ I_k\ \mathbf{0}\ \cdots\ \mathbf{0}) \otimes \int_0^1 Df_k(s+\tau e_k)d\tau(\Phi \otimes I_n)$, where $I_k$ stands for the matrix with its $k$-th column equals $(1\ 0\ \cdots\ 0)^T$ and the remaining of its elements are zero.

Thus, a simple calculation gives $\frac{1}{N}(\Phi^T \otimes I_n)H(t)(\Phi \otimes I_n) = \frac{1}{\sqrt{N}}\sum_{k=1}^{N}\begin{pmatrix} \Upsilon_k \\ 0 \end{pmatrix} \otimes \int_0^1 Df_k(s(t)+\tau e_k(t))d\tau$, where $\Upsilon_k \in R^{1\times N}$ and $0 \in R^{(N-1)\times N}$. Therefore, $\dot{w} = \bar{\Sigma}(t)w + c\Lambda \otimes \Gamma w(t-\tau) + (\Phi^T \otimes I_n)I(t)(\Phi \otimes I_n)w - \begin{pmatrix} * \\ 0 \end{pmatrix} w + (\Phi^T \otimes I_n)F(t)$. Since $w_1 \equiv 0$, we only need to consider $w_2, w_3, \cdots, w_N$. Rewriting in the component form we have

$$\begin{aligned} \dot{w}_i = {} & \Sigma_i(t)w_i + c\lambda_i\Gamma w_i(t-\tau) + (\Phi_i^T \otimes I_n)F(t) \\ & + (\Phi_i^T \otimes I_n)I(t)(\Phi \otimes I_n)w,\ i = 2, 3, \cdots, N, \end{aligned} \tag{8}$$

where $\Sigma_i = \bar{D}f(s) + D_i$.

So far, we have transferred the consensus problem of system (1) to the stability problem of the $N-1$ of $n-$dimensional systems.

**Theorem 1** Suppose that $\|I(t)\| \leq \gamma$ is satisfied. If there exist matrices $P_i(t) \in \mathcal{PC}_{n\times n}^1$, $Q_i > 0$, $\Theta_i > 0$, $\Pi_i > 0$, $X_i$, $Y_i$ and $Z_i$ of appropriate dimensions such that

$$B = \begin{pmatrix} B_1 & B_2 \\ B_2^T & B_3 \end{pmatrix} < 0, \quad \begin{pmatrix} X_i & Y_i \\ Y_i^T & Z_i \end{pmatrix} \geq 0, \tag{9}$$

for $i = 2, 3, \cdots, N$, where $B_1 = \dot{P}_i(t) + P_i(t)\Sigma_i(t) + \Sigma_i^T(t)P_i(t) + hX_i + Y_i^T + Y_i + Q_i + h\Sigma_i^T(t)Z_i\Sigma_i(t)$, $B_2 = c\lambda_i P_i(t)\Gamma - Y_i + hc\lambda_i\Sigma_i^T(t)Z_i\Gamma$ and $B_3 = \Pi_i^{-1} + \Theta_i^{-1} - Q_i + hc^2\lambda_i^2\Gamma^T Z_i\Gamma$, then the MAS (1) will achieve bounded consensus for the time-invariant delay $\tau \in [0, h]$ for some $h < \infty$.

**Proof.** Construct the following Lyapunov-Krasovskii functional as

$$V = \sum_{i=2}^{N}\sum_{k=1}^{3} V_k, \tag{10}$$

where

$$\begin{aligned} V_1 &= w_i^T P_i(t) w_i, \\ V_2 &= \int_{-\tau}^{0} \int_{t+\beta}^{t} \dot{w}_i^T(\alpha) Z_i \dot{w}_i(\alpha) d\alpha d\beta, \\ V_3 &= \int_{t-\tau}^{t} w_i^T(\alpha) Q_i w_i(\alpha) d\alpha. \end{aligned}$$

The $i$-th ($i = 2, 3, \cdots, N$) equation in system (8) can be written as

$$\begin{aligned} \dot{w}_i = (\Sigma_i(t) + c\lambda_i \Gamma) w_i - c\lambda_i \Gamma \int_{t-\tau}^{t} \dot{w}_i(\alpha) d\alpha \\ + (\Phi_i^T \otimes I_n) I(t) (\Phi \otimes I_n) w + (\Phi_i^T \otimes I_n) F(t). \quad (11) \end{aligned}$$

Defining $a(.)$, $b(.)$ and $M$ in [18] as $a(\alpha) = w_i(t)$, $b(\alpha) = \dot{w}_i(\alpha)$ and $M = c\lambda_i P_i(t)\Gamma$ for all $\alpha \in [t-\tau, t]$ then we have

$$\begin{aligned} \dot{V}_1 \le w_i^T [\dot{P}_i(t) + P_i(t)\Sigma_i(t) + \Sigma_i^T(t) P_i(t) \\ + hX_i + Y_i^T + Y_i] w_i + \int_{t-\tau}^{t} \dot{w}_i^T(\alpha) Z_i \dot{w}_i(\alpha) d\alpha \\ + 2w_i^T (c\lambda_i P_i(t)\Gamma - Y_i) w_i(t-\tau) \\ + 2w_i^T P_i(t) (\Phi_i^T \otimes I_n) I(t) (\Phi_i \otimes I_n) w \\ + 2w_i^T P_i(t) (\Phi_i^T \otimes I_n) F(t). \quad (12) \end{aligned}$$

Moreover, $\dot{V}_2$ can be enlarged as

$$\begin{aligned} \dot{V}_2 \le h[\Sigma_i(t) w_i + c\lambda_i \Gamma w_i(t-\tau)]^T Z_i [\Sigma_i(t) w_i \\ + c\lambda_i \Gamma w_i(t-\tau)] + 2h(\Sigma_i(t) w_i)^T Z_i (\Phi_i^T \otimes I_n) I(t) \\ (\Phi \otimes I_n) w + 2h(\Sigma_i(t) w_i)^T Z_i (\Phi_i^T \otimes I_n) F(t) \\ + 2h(c\lambda_i \Gamma w_i(t-\tau))^T Z_i (\Phi_i^T \otimes I_n) I(t) (\Phi \otimes I_n) w \\ + 2h(c\lambda_i \Gamma w_i(t-\tau))^T Z_i (\Phi_i^T \otimes I_n) F(t) \\ + 2h((\Phi_i^T \otimes I_n) I(t) (\Phi \otimes I_n) w)^T Z_i (\Phi_i^T \otimes I_n) F(t) \\ + h((\Phi_i^T \otimes I_n) F(t))^T Z_i ((\Phi_i^T \otimes I_n) F(t)) \\ + h((\Phi_i^T \otimes I_n) I(t) (\Phi \otimes I_n) w)^T Z_i ((\Phi_i^T \otimes I_n) I(t) \\ (\Phi \otimes I_n) w) - \int_{t-\tau}^{t} \dot{w}_i^T(\alpha) Z_i \dot{w}_i(\alpha) d\alpha. \quad (13) \end{aligned}$$

and

$$\dot{V}_3 = w_i^T Q_i w_i - w_i^T(t-\tau) Q_i w_i(t-\tau). \quad (14)$$

Applying the Young Inequality, then we have $2h(c\lambda_i \Gamma w_i(t - \tau))^T Z_i (\Phi_i^T \otimes I_n) I(t) (\Phi \otimes I_n) w \le w_i^T(t-\tau) \Pi_i^{-1} w_i(t-\tau) + h^2 c^2 \lambda_i^2 w^T ((\Phi \otimes I_n)^T I(t) (\Phi_i^T \otimes I_n)^T Z_i \Gamma \Pi_i \Gamma^T Z_i (\Phi_i^T \otimes I_n) I(t) (\Phi \otimes I_n)) w(t)$, and $2h(c\lambda_i \Gamma w_i(t-\tau))^T Z_i (\Phi_i^T \otimes I_n) F(t) \le w_i^T(t-\tau) \Theta_i^{-1} w_i(t-\tau) + h^2 c^2 \lambda_i^2 F^T(t) (\Phi_i^T \otimes I_n)^T Z_i \Gamma \Theta_i \Gamma^T Z_i (\Phi_i^T \otimes I_n) F(t)$. Applying these two inequalities and the conditions of the theorem results

$$\begin{aligned} \dot{V} \le \sum_{i=2}^{N} \begin{pmatrix} w_i \\ w_i(t-\tau) \end{pmatrix}^T B \begin{pmatrix} w_i \\ w_i(t-\tau) \end{pmatrix} \\ + 2\mu(t)\beta + (\|w\|(2\gamma\beta + 2h\gamma\|\Sigma_i(t)\| \sum_{i=2}^{N} \lambda_{max}(Z_i) \\ + 2h\mu(t)\|\Sigma_i(t)\| \sum_{i=2}^{N} \lambda_{max}(Z_i) + h\gamma^2 \sum_{i=2}^{N} \lambda_{max}(Z_i) \\ + h^2 c^2 \gamma^2 \lambda_{max}^{\frac{1}{2}}(\Gamma\Gamma^T) \sum_{i=2}^{N} \lambda_{max}(\Pi_i) \lambda_i^2 \lambda_{max}^2(Z_i) \\ + h^2 c^2 \mu^2(t) \lambda_{max}^{\frac{1}{2}}(\Gamma\Gamma^T) \sum_{i=2}^{N} \lambda_{max}(\Theta_i) \lambda_i^2 \lambda_{max}^2(Z_i)) \|w\| \\ + 2h\gamma \sum_{i=2}^{N} \lambda_{max}(Z_i) \mu(t)) + h\mu^2(t) \sum_{i=2}^{N} \lambda_i^2 \lambda_{max}(Z_i). \quad (15) \end{aligned}$$

Thus when

$$\|w\| \ge \frac{2\mu(t)\beta + 2h\gamma \sum_{i=2}^{N} \lambda_{max}(Z_i)\mu(t)}{\varpi(t)},$$

we have

$$\dot{V} \le -\delta\|w\|^2 + h\mu^2(t) \sum_{i=2}^{N} \lambda_{max}(Z_i) \lambda_i^2, \quad (16)$$

where $\varpi(t) = -(2\gamma\beta + 2h\gamma\|\Sigma_i(t)\| \sum_{i=2}^{N} \lambda_{max}(Z_i) + 2h\mu(t)\|\Sigma_i(t)\| \sum_{i=2}^{N} \lambda_{max}(Z_i) + h\gamma^2 \sum_{i=2}^{N} \lambda_{max}(Z_i) + h^2 c^2 \gamma^2 \lambda_{max}^{\frac{1}{2}}(\Gamma\Gamma^T) \sum_{i=2}^{N} \lambda_{max}(\Pi_i) \lambda_i^2 \lambda_{max}^2(Z_i) + h^2 c^2 \mu^2(t) \lambda_{max}^{\frac{1}{2}}(\Gamma\Gamma^T) \sum_{i=2}^{N} \lambda_{max}(\Theta_i) \lambda_i^2 \lambda_{max}^2(Z_i)) - \delta$. Thus, according to [19] and Lyapunov stability theory, bounded consensus is ultimately achieved. This completes the proof.

## IV. Adaptive pinning controller

In this section, we will derive globally consensus criteria via direct adaptive pinning control method. Without loss of generality, we still assume that the first $l$ agents are selected as pinned agents with the adaptive controllers:

$$\begin{cases} u_i = -d_i(t)(x_i - s), & 1 \le i \le l, \\ \dot{d}_i(t) = h_i e_i^T P_i(t) e_i, & \\ u_i = 0, & l+1 \le i \le N, \end{cases} \quad (17)$$

where constant $h_i > 0$ and positive definite matrix $P_i(t) \in R^{n \times n}$. Applying Newton-Leibniz formula, then the error MAS can be rewritten as

$$\begin{cases} \dot{e}_i = D\bar{f}(s)e_i + c\sum_{j=1}^{N} a_{ij}\Gamma e_j(t-\tau) \\ \qquad + \int_0^1 (Df_i(s+\tau e_i) - D\bar{f}(s))e_i d\tau \\ \qquad -\frac{1}{N}\sum_{k=1}^{N}\int_0^1 Df_k(s+\tau e_k)e_k d\tau \\ \qquad +f_i(s) - \bar{f}(s) - d_i(t)e_i, \qquad 1 \le i \le l, \\ \dot{d}_i(t) = h_i e_i^T P_i(t) e_i, \\ \dot{e}_i = D\bar{f}(s)e_i + c\sum_{j=1}^{N} a_{ij}\Gamma e_j(t-\tau) \\ \qquad + \int_0^1 (Df_i(s+\tau e_i) - D\bar{f}(s))e_i d\tau \\ \qquad -\frac{1}{N}\sum_{k=1}^{N}\int_0^1 Df_k(s+\tau e_k)e_k d\tau \\ \qquad +f_i(s) - \bar{f}(s), \qquad l+1 \le i \le N. \end{cases} \tag{18}$$

Repeating a similar procedure to the previous subsection, the controlled consensus problem of system (1) is equivalent to the stability problem of the following $N-1$ of $n$-dimensional systems.

$$\begin{cases} \dot{w}_i = D\bar{f}(s(t))w_i - d_i(t)w_i + c\lambda_i\Gamma w_i(t-\tau) \\ \qquad +(\Phi_i^T \otimes I_n)I(t)(\Phi \otimes I_n)w \\ \qquad +(\Phi_i^T \otimes I_n)F(t), \qquad 2 \le i \le l, \\ \dot{d}_i(t) = h_i w_i^T P_i(t) w_i, \\ \dot{w}_i = D\bar{f}(s)w_i + c\lambda_i\Gamma w_i(t-\tau) \\ \qquad +(\Phi_i^T \otimes I_n)I(t)(\Phi \otimes I_n)w \\ \qquad +(\Phi_i^T \otimes I_n)F(t), \qquad l+1 \le i \le N, \end{cases} \tag{19}$$

where $w_i$, $w$, $\Phi$, $\Phi_i$, $I(t)$ and $F(t)$ are the same as the previous subsection.

**Theorem 2** Suppose that $\|I(t)\| \le \gamma$ is satisfied. If there exist matrices $P_i(t) \in \mathcal{PC}^1_{n\times n}$, $Q_i > 0$, $\Theta_i > 0$, $\Pi_i > 0$, $X_i$, $Y_i$ and $Z_i$ of appropriate dimensions and constant $d > 0$ such that

$$B = \begin{pmatrix} B_1 & B_2 \\ B_2^T & B_3 \end{pmatrix} < 0, \quad \begin{pmatrix} X_i & Y_i \\ Y_i^T & Z_i \end{pmatrix} \ge 0, \tag{20}$$

for $i = 2, 3, \cdots, N$, where $B_1 = \dot{P}_i(t) + P_i(t)(Df(s)) + (Df(s))^T P_i(t) - 2dP_i(t) + hX_i + Y_i^T + Y_i + Q_i + h\Sigma_i^T(t)Z_i\Sigma_i(t)$, $B_2 = c\lambda_i P_i(t)\Gamma - Y_i + hc\lambda_i\Sigma_i^T(t)Z_i\Gamma$ and $B_3 = \Pi_i^{-1} + \Theta_i^{-1} - Q_i + hc^2\lambda_i^2\Gamma^T Z_i\Gamma$, then the system (1) will achieve bounded consensus for the time-invariant delay $\tau \in [0, h]$ for some $h < \infty$.

**Proof.** Construct the following Lyapunov-Krasovskii functional as

$$V = \sum_{i=2}^{N}\sum_{k=1}^{3} V_k + \sum_{i=2}^{l}\frac{(d_i(t) - d)^2}{h_i}, \tag{21}$$

where

$$V_1 = w_i^T P_i(t) w_i,$$

$$V_2 = \int_{-\tau}^{0}\int_{t+\beta}^{t} \dot{w}_i^T(\alpha) Z_i \dot{w}_i(\alpha) d\alpha d\beta,$$

$$V_3 = \int_{t-\tau}^{t} w_i^T(\alpha) Q_i w_i(\alpha) d\alpha.$$

The remaining part of the proof is similar to that of Theorem 1 and is therefore omitted here. This completes the proof.

## V. EXAMPLE

To demonstrate the theoretical results obtained above, we construct a MAS consisting of 11 agents described as follows

$$\dot{x}_i(t) = f_i(x_i(t)) + c\sum_{j\in\mathcal{N}_i}^{N} a_{ij}\Gamma x_j(t-\tau), \tag{22}$$

where $f_i(x_i(t)) = B_i x_i(t) + g(x_i(t))$, $B_i (i = 1, 2, \cdots, 6)$ and $B_i (i = 7, 8, \cdots, 11)$ are chosen as follows:

$$\begin{pmatrix} -10 + 0.1 \times (i-1) & 10 - 0.1 \times (i-1) & 0 \\ 1 & -1 & 1 \\ 0 & -15 - 0.1 \times (i-1) & 0 \end{pmatrix},$$

$$\begin{pmatrix} -10 - 0.1 \times (i-6) & 10 + 0.1 \times (i-6) & 0 \\ 1 & -1 & 1 \\ 0 & -15 + 0.1 \times (i-6) & 0 \end{pmatrix},$$

and

$$g(x_i(t)) = (-9.5sin(\frac{\pi x_{i1}(t)}{3.2} + \pi)\ 0\ 0)^T, \quad i = 1, 2, \cdots, 11.$$

The communication coupling matrix $C = (C_1^T C_2^T \cdots C_{11}^T)$, $C_1 = (-8\ 1\ 1\ 0\ 1\ 1\ 1\ 0\ 1\ 1\ 1)$, $C_2 = (1\ -8\ 1\ 1\ 1\ 0\ 1\ 0\ 1\ 1\ 1)$, $C_3 = (1\ 1\ -6\ 1\ 0\ 0\ 0\ 1\ 0\ 1\ 1)$, $C_4 = (0\ 1\ 1\ -5\ 0\ 1\ 1\ 0\ 0\ 1\ 0)$, $C_5 = (1\ 1\ 0\ 0\ -6\ 0\ 1\ 1\ 1\ 1\ 0)$, $C_6 = (1\ 0\ 0\ 1\ 0\ -5\ 1\ 0\ 1\ 1\ 0)$, $C_7 = (1\ 1\ 0\ 1\ 1\ 1\ -7\ 1\ 0\ 1\ 0)$, $C_8 = (0\ 0\ 1\ 0\ 1\ 0\ 1\ -5\ 0\ 1\ 1)$, $C_9 = (1\ 1\ 0\ 0\ 1\ 1\ 0\ 0\ -6\ 1\ 1)$, $C_{10} = (1\ 1\ 1\ 1\ 1\ 1\ 1\ 1\ 1\ -10\ 1)$, $C_{11} = (1\ 1\ 1\ 0\ 0\ 0\ 0\ 1\ 1\ 1\ -6)$. $\Gamma = diag\{2, 2, 2\}$, respectively, where the matrix $A$ is produced by means of the Scale-Free network program.

Design the following controllers

$$\begin{cases} u_{i_k} = -d_{i_k}(x_{i_k}(t) - s(t)), & i_k = 1, 2 \texttt{ and } 10, \\ u_{i_k} = 0, & \texttt{else}, \end{cases}$$

with $d_1 = 0.5$, $d_2 = 0.5$, $d_{10} = 0.5$ and

$$\begin{cases} u_{i_k} = -d_{i_k}(t)(x_{i_k}(t) - s(t)), & i_k = 1, 2 \texttt{ and } 10, \\ \dot{d}_{i_k}(t) = h_{i_k} e_{i_k}^T P_{i_k}(t) e_{i_k}, \\ u_{i_k} = 0, & \texttt{else}, \end{cases}$$

with $h_1 = 0.1$, $h_2 = 0.2$, $h_{10} = 0.3$, $s(t)$ can then be evaluated by simulation.

Given the initial values of 11 agents as $(10\ 5\ -10)^T$, $(12\ 6\ -12)^T$, $(14\ 7\ -14)^T$, $(16\ 8\ -16)^T$, $(18\ 9\ -18)^T$, $(20\ 10\ -20)^T$, $(-18\ 11\ 18)^T$, $(-16\ 12\ 16)^T$, $(-14\ 13\ 14)^T$, $(-12\ 14\ 12)^T$, $(-10\ 15\ 10)^T$ respectively and $P_{i_k}(t) = I_3$. We may verify the conditions of Theorem 1 and Theorem 2 readily. This demonstrates the bounded consensus of the MAS is achieved for any time delay $0 < \tau \le 0.061$. Simulation results are depicted in Fig.1 to Fig.4 for $\tau = 0.061$ and $c = 1$.

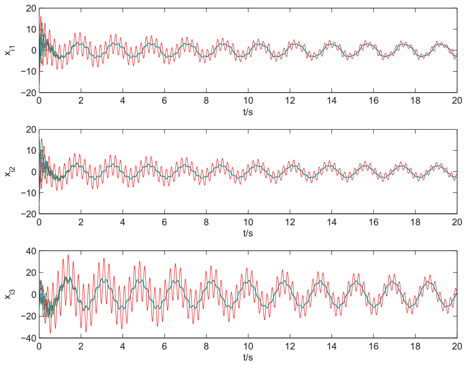

Fig.1. All agent dynamics under pinning control.

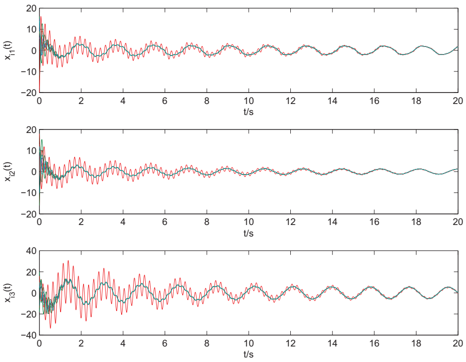

Fig.2. All agent dynamics under adaptive pinning control.

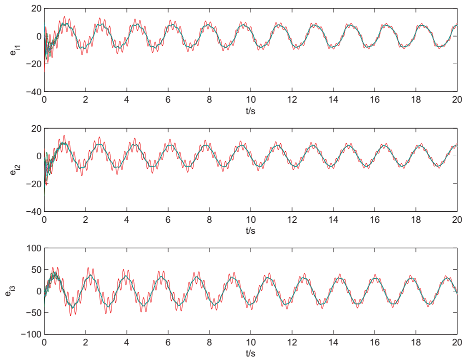

Fig.3. All agent error dynamics under pinning control.

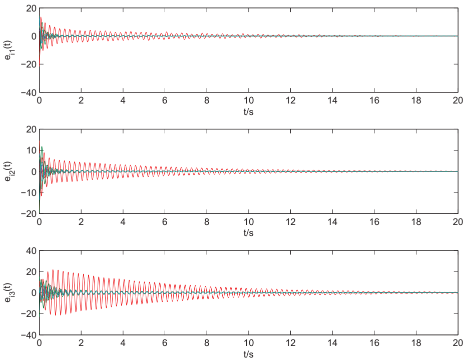

Fig.4. All agent error dynamics under adaptive pinning control.

## VI. Conclusion

In this paper, we've investigated the controlled consensus problems of NMAS with different agent dynamics. The derived criteria are verified via theoretical analysis and numerical simulation. The consensus for the NMAS is achieved based on pinning control and adaptive pinning control methods. It should be noted that the conditions are still restrictive and all the delays are the same. Further investigations will focus on relaxing these limitations.

*Abstract*— **This paper presents a novel technique for the real time estimation of the contact conditions by using a combination of multi-Kalman filtering and fuzzy logic approach. The proposed solution exploits the variations in the dynamic behaviour of a railway wheelset with the changes in wheel-rail contact condition. The proposed system involves the use of multiple model based estimation of the wheelset dynamics in response to different track conditions. Each of the estimators is tuned to match one particular track condition to give the best results at the specific design point. Residuals of each filter are calculated and the level of matches/mismatches is reflected in the residual values of the models concerned. The residuals from all the models are then be assessed by a fuzzy inference system to determine the present operating condition and hence to give real time information about the track conditions.**

## I. Introduction

Adhesion is a very important factor in the operation of the railway vehicles. The delivery of traction and braking is achieved through the available adhesion at the wheel-rail interface. Insufficient level of adhesion can lead to severe safety and operational problems resulting in huge financial losses to railway industry around the world. Although in last few decades the railway industry is able to manage low adhesion to some extent but currently available measures are not sufficient to eliminate the safety incidents and train delays. This is because the adhesion is affected by a large number of parameters such as weather, season changes and contaminations and therefore cannot be predicted with certainty. Changes in the adhesion conditions can be rapid and also short-lived, and the adhesion coefficient can differ from position to position along a route depending upon the type and degree of contamination which presents a great scientific challenge to effectively design a suitable technique to tackle this problem.

Current wheel slip/slide protection (WSP) technologies for traction and braking systems are incorporated in the rail vehicles to maximize the use of available adhesion [1]. WSPs control the slip ratio (relative speed between a wheel and the train) below a pre-defined threshold to avoid slip/slide during traction or braking [1]. In general, WSPs are effectively reactive systems, i.e. only 'activated' to stop wheel slip/slide when detected by the sensors. There is still a need for a system which is proactive and can prevent slip/slide from its occurrence, such that real time information about the track condition can be provided to the traction and braking control systems to maximize the use of available adhesion. On the other hand, the wheel-rail contact mechanics is extremely complex and vary with time which presents a great scientific challenge to effectively design a suitable technique to tackle this problem.

A number of ideas have been proposed that is related to the monitoring of the running condition of the wheel-rail interface that use low cost inertial sensing mounted on the vehicle and advanced processing, e.g. an inverse modelling approach for the estimation of creep forces [2, 23-25]; and a model based estimation [3-4].

A multiple model approach has been proposed previously by the authors for the real time estimation of the wheel-rail contact conditions [5-8], this paper extends the study to take into account contact conditions that are directly used in design of the Kalman filters. This is of particular practice importance, as real track conditions can be affected by uncertain external factors and hence unpredictable. Furthermore, this paper also covers the complete design of fuzzy inference system and presents a formula to convert the fuzzy logic output into percentage adhesion.

## II. Modelling of Contact Mechanics

Wheelsets are a key component of railway vehicles that interacts directly with the track and consequently the dynamics of the wheelset are directly influenced by changing contact conditions - therefore this study focusses on a single solid axle wheelset and the outcome of the study may be readily extended to the full vehicles [9-19]. The dynamic behaviour of the railway wheelset is governed by the creep forces generated at the wheel rail contact patches. These creep forces are the result of creepages which are the relative speed of the wheels to rail and can be characterized as lateral ($\lambda_y$) and longitudinal creep ($\lambda_x$) in accordance with the direction of motion as given in equations 1-3 [5-8].

$$\lambda_{xL} = \frac{r_o \omega_L - v}{v} + [\frac{L_g \dot{\psi}}{v} + \frac{\gamma(y - y_t)}{r_o}] \tag{1}$$

$$\lambda_{xR} = \frac{r_o \omega_R - v}{v} - [\frac{L_g \dot{\psi}}{v} + \frac{\gamma(y - y_t)}{r_o}] \tag{2}$$

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

$$\lambda_y = \lambda_{yR} = \lambda_{yL} = \frac{\dot{y}}{v} - \psi \qquad (3)$$

where the subscripts $L$ and $R$ represent left and right wheels, $r_o$ is the nominal radius of the wheels, $v$ is the vehicle forward speed, $\gamma$ is the conicity of the wheels, $\Psi$ is the yaw angle, $L_g$ is the track half gauge, $\omega_L$ and $\omega_R$ are the angular velocities of the left and right wheels respectively, $y$ is the lateral motion, and $y_t$ represents the track irregularity in lateral direction. The total creepage $\lambda_j$ is the combination of the lateral and longitudinal creepages.

$$\lambda_j = \sqrt{\lambda_{ij}^2 + \lambda_{ij}^2} \qquad i = x, y \; and \; j = L, R \qquad (4)$$

The total creep force $F_j$ is a nonlinear function of the total creepage and can be represented using equation 5.

$$F_j = \mu_j N_j \qquad j = L, R \qquad (5)$$

The distribution of the contact forces in the longitudinal and lateral directions is thoroughly studied by Polach [20] and can be represented using (6).

$$F_{ij} = F_j . \frac{\lambda_{ij}}{\lambda_j}, \qquad i = x, y \; and \; j = L, R \qquad (6)$$

The equations of motion of the wheelset are given in equations (7-12).

$$\begin{aligned} M_v \ddot{x} = {} & \frac{\mu_R N_R}{\sqrt{\lambda_{xR}^2 + \lambda_{yL}^2}} \left[ \frac{r_o \omega_R - v}{v} - [\frac{L_g \dot{\psi}}{v} + \frac{\gamma(y - y_t)}{r_o}] \right] \\ & + \frac{\mu_L N_L}{\sqrt{\lambda_{xL}^2 + \lambda_{yL}^2}} \left[ \frac{r_o \omega_L - v}{v} + [\frac{L_g \dot{\psi}}{v} + \frac{\gamma(y - y_t)}{r_o}] \right] \end{aligned} \qquad (7)$$

$$\begin{aligned} I_w \ddot{\psi} = {} & \frac{\mu_R N_R}{\sqrt{\lambda_{xR}^2 + \lambda_{yL}^2}} \left[ \frac{r_o \omega_R - v}{v} - [\frac{L_g \dot{\psi}}{v} + \frac{\gamma(y - y_t)}{r_o}] \right] L_g \\ & - \frac{\mu_L N_L}{\sqrt{\lambda_{xL}^2 + \lambda_{yL}^2}} \left[ \frac{r_o \omega_L - v}{v} + [\frac{L_g \dot{\psi}}{v} + \frac{\gamma(y - y_t)}{r_o}] \right] L_g \text{ - } k_w \psi \end{aligned} \qquad (8)$$

$$m_w \ddot{y} = - \frac{\mu_L N_L}{\sqrt{\lambda_{xL}^2 + \lambda_{yL}^2}} \left[ \frac{\dot{y}}{v} - \psi \right] - \frac{\mu_R N_R}{\sqrt{\lambda_{xR}^2 + \lambda_{yL}^2}} \left[ \frac{\dot{y}}{v} - \psi \right] + F_c + F_g \qquad (9)$$

$$\begin{aligned} I_R \dot{\omega}_R = {} & T_t - K_s \theta_s - r_o \frac{\mu_R N_R}{\sqrt{\lambda_{xR}^2 + \lambda_{yL}^2}} [\frac{r_o \omega_R - v}{v} - (\frac{L_g \dot{\psi}}{v} + \\ & \frac{\gamma(y - y_t)}{r_o}) \end{aligned} \qquad (10)$$

$$\begin{aligned} I_L \dot{\omega}_L = {} & K_s \theta_s - r_o \frac{\mu_L N_L}{\sqrt{\lambda_{xL}^2 + \lambda_{yL}^2}} [\frac{r_o \omega_L - v}{v} + (\frac{L_g \dot{\psi}}{v} \\ & + \frac{\gamma(y - y_t)}{r_o})] \end{aligned} \qquad (11)$$

$$T_s = k_s \int (\omega_R - \omega_L) dt + C_s (\omega_R - \omega_L) \qquad (12)$$

where $M_v$ is the mass of the vehicle $\ddot{x}$ is the vehicle forward acceleration, $I_w$ is the yaw moment of inertia, $k_w$ is a yaw stiffness necessary to stabilise the wheelset, $m_w$ is the mass of the wheelset, $\ddot{y}$ is the lateral acceleration, $F_c$ is a centrifugal force which is taken into consideration when the wheelset runs on a curved track, $F_g$ is the gravitational stiffness force related to the lateral displacement and roll angle of the wheelset. The tractive torque $T_t$ is applied to one side of the wheelset (right side in this case) and the other wheel is driven by the torsional torque $T_s$. $\theta_s = \int(\omega_R - \omega_L)dt$. $k_s$ is the torsional stiffness of the shaft connecting the two wheels and $C_s$ is material damping of the shaft, which is usually very small.

## III. Design of Multiple Kalman Filters

The main objective of this study is to detect the changes in the wheel-rail contact condition with practical sensors. The design of the estimator is simplified by considering the wheelset modes that are directly related to contact conditions. Previous studies have suggested that the lateral and yaw dynamics are sufficient for the study of plan-view dynamics of a wheelset [4, 5, 6, 8, 15, 21-22]. The use of a simplified model has several advantages in the estimator design without having a significant effect on the results [5-8]. The major advantage is the simple design of the estimator with minimum number of states which will allow the estimator to converge quickly. The yaw and lateral dynamics are excited by lateral track irregularities. The contact forces given in (5) and (6) are nonlinear in nature and are linearized at specific points on the creep curves in order to enable the design of the Kalman filters. The small signal model of linearized creep forces is given in following equation [5-7].

$$\begin{bmatrix} \Delta\dot{y} \\ \Delta\dot{\psi} \\ \Delta\ddot{y} \\ \Delta\ddot{\psi} \end{bmatrix} = \begin{bmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & \frac{2g_{22}}{m_w} & -\frac{2g_{22}}{vm_w} & 0 \\ -\frac{2L_g\gamma g_{11}}{r_o I_w} & -\frac{k_w}{I_w} & 0 & -\frac{2L_g^2 g_{11}}{vI_w} \end{bmatrix} \begin{bmatrix} \Delta y \\ \Delta\psi \\ \Delta\dot{y} \\ \Delta\dot{\psi} \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ 0 \\ \frac{2L_g\gamma g_{11}}{r_o I_w} \end{bmatrix} \Delta y_{\mathrm{t}} \qquad (13)$$

The track disturbances ($y_t$) are very difficult/expensive to measure in practice and therefore highly undesirable to be used as an input to the Kalman filters, therefore (13) is reformulated to include the track input as an additional state, as

$$\frac{d}{dt} \begin{bmatrix} \Delta\psi \\ \Delta\dot{y} \\ \Delta\dot{\psi} \\ \Delta y_t \\ \Delta y - \Delta y_t \end{bmatrix} = \begin{bmatrix} 0 & 0 & 1 & 0 & 0 \\ \frac{2g_{22}}{m_w} & -\frac{2g_{22}}{vm_w} & 0 & 0 & 0 \\ -\frac{k_w}{I_w} & 0 & -\frac{2L_g^2 g_{11}}{vI_w} & 0 & -\frac{2L_g\gamma g_{11}}{r_o I_w} \\ 0 & 0 & 0 & N & 0 \\ 0 & 1 & 0 & 0 & 0 \end{bmatrix} \qquad (14)$$

$$\begin{bmatrix} \Delta\psi \\ \Delta\dot{y} \\ \Delta\dot{\psi} \\ \Delta y_t \\ \Delta y - \Delta y_t \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ 0 \\ 1 \\ -1 \end{bmatrix} \dot{y}_{\mathrm{t}}$$

A gyro sensor to measure yaw rate and accelerometer to measure lateral acceleration are found to be sufficient to produce satisfactory results. The output equation is given in (15).

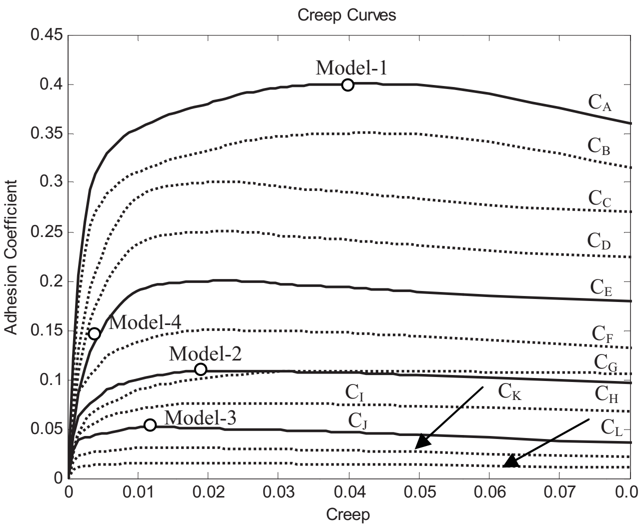

Figure 1. Creep Curves.

$$z(t)=\begin{bmatrix}0 & 0 & 1 & 0 & 0\\ \frac{2g_{22}}{m_w} & -\frac{2g_{22}}{vm_w} & 0 & 0 & 0\end{bmatrix}\begin{bmatrix}\Delta\psi\\ \Delta\dot{y}\\ \Delta\dot{\psi}\\ \Delta y_t\\ \Delta y-\Delta y_t\end{bmatrix}+v \qquad (15)$$

## IV. Estimation oF Contact Conditions

Several creep curves representing high to very low adhesion conditions are used for the design and the evaluation of the detection system. The creep curves used for the Kalman filter design are shown in solid lines and the creep curves shown in dotted lines are used as additional cases for the assessment of detection system. The proposed scheme is shown in Fig.2. This scheme identifies the contact condition based on the residuals of the Kalman filters, which are the difference generated by the observations and the system's mathematical model. The design of each Kalman filter is based on linerised creep coefficients $g_{11}$ and $g_{22}$ values. At the saturation point of creep curves, $g_{11}$, which depends upon the slope of the creep curve $d\mu/d\lambda$, is zero and $g_{22}$, which depends upon traction ratio $\mu/\lambda$, is different for different adhesion levels. Therefore the residual signal of a Kalman filter designed and tuned to operate in specific contact condition is expected to be at lowest when the vehicle is operated in similar contact condition, in comparison with those from other Kalman filters. In this study, four Kalman filters are found to be sufficient to detect the changes in the contact conditions. Model-1 is tuned to operate at the saturation region of the creep curve $C_A$, model-2 is designed to operate on the saturation region of the creep curve $C_C$, model-3 is designed to operate on the saturation region of creep curve $C_D$ and model-4 is designed to operate in the linear region of creep curve $C_B$. The purpose of the model-4 is to identify whether the wheelset is operating at the saturation region of the creep curve or not.

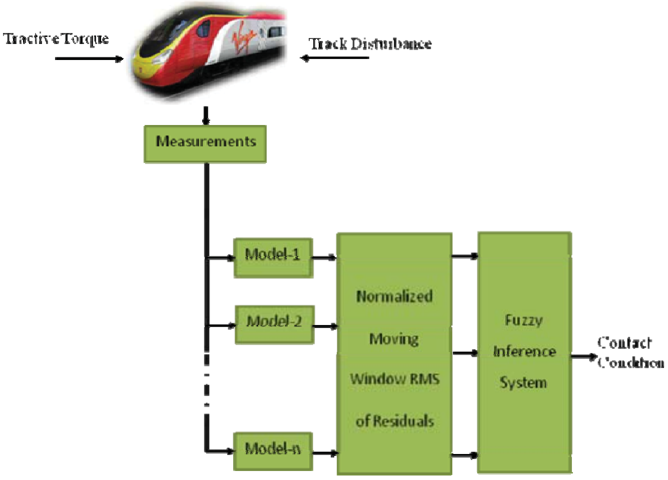

Figure 2. Contact Condition Estimation Scheme

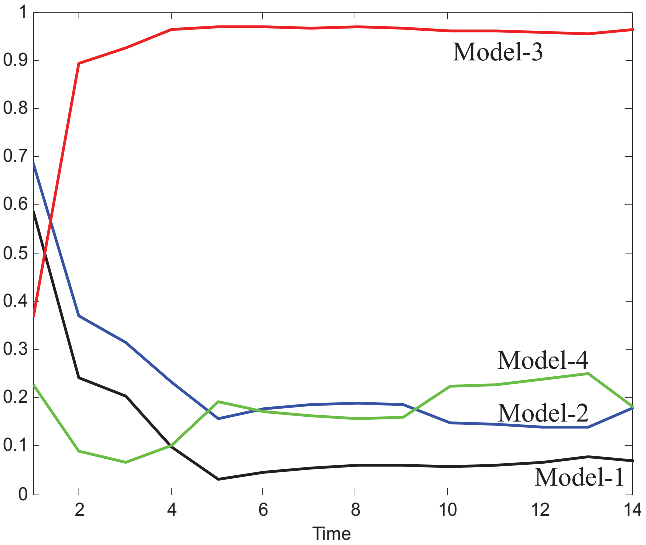

Figure 3. Residuals of filters at $P_1$

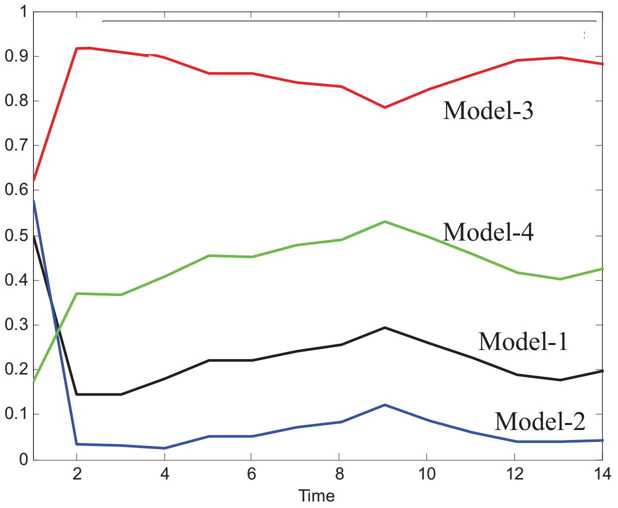

Figure 4. Residuals of filters at $P_3$

Fig.3 shows the residuals of the filters when the wheelset is operated at the saturation region of the creep curve-1. The residual of model-1 is the lowest as expected confirming that the wheelset is operating at $P_a$. When the wheelset is operated at $P_c$ the residual of model-2 is at the lowest and the residual of model-1 is increased as shown in Fig.4. If the wheelset is not operated on the saturation points of the creep curves the residual of model-4 designed at $P_e$ is at the lowest. For instance when the wheelset is operated in the linear region of the creep curve-1 the residual of model-4 is at the lowest as shown in Fig.5.

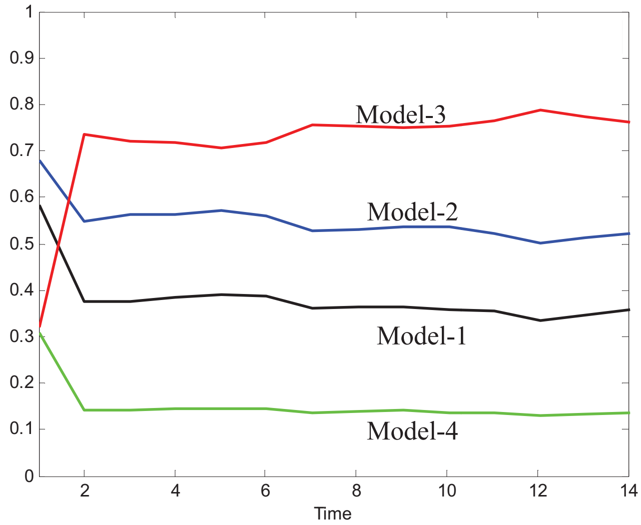

Figure 5. Residuals the when the wheelset is operated in linear region of $C_A$

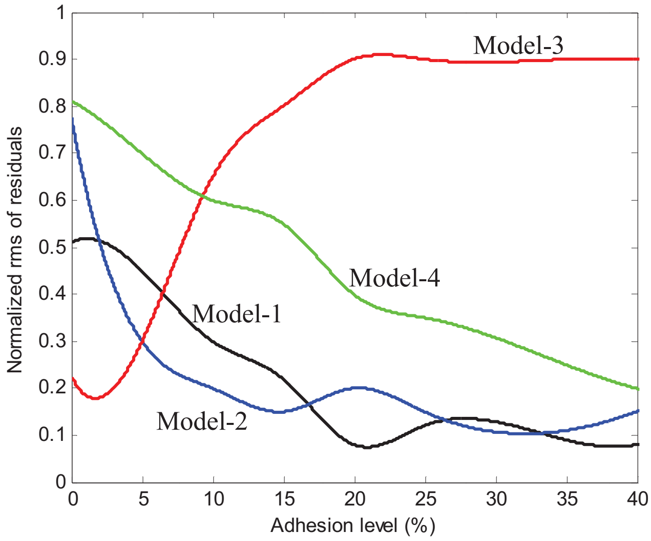

Figure 6. Residuals of filters after interpolation

As only four models are used in the proposed detection scheme, it is necessary to evaluate how the models would respond to other contact conditions that are not directly included in the design. This is carried out by simulating the filters in different contact conditions shown in figure-1 and the residual data is interpolated (Fig.6) to develop a fuzzy logic based detection system to detect other possible contact conditions.

## V. Design Of Fuzzy Inference System

The basic idea of the fuzzy inference system is that if wheelset operating point is at the saturation region of the creep curve then the residual information together with the tractive torque can easily be used to determine the adhesion level. The fuzzy inference system (FIS) that analyzes the residuals and the tractive torque is shown in Fig.7. As any other fuzzy logic system it has three main divisions. First part is the input division which scales and weighs the inputs and determines the magnitude of participation in producing output. The inputs are then processed according to set rules and the final output is determined by the averaging the output of individual rules.

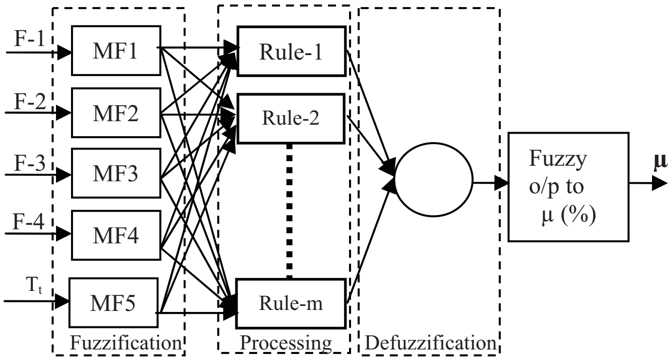

Figure 7. Fuzzy Inference System

The residual of each model in Fig.6 is divided as 'Low', 'Moderate' and 'High' to develop input membership function. Input membership function for residual of model and modle-2 are shown in Fig.8 and Fig.9 respectively.

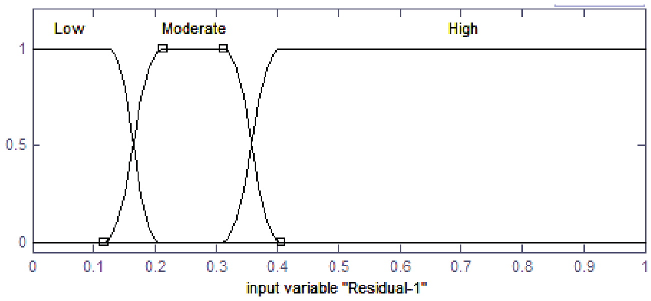

Figure 8. Input membership function of Residual-1

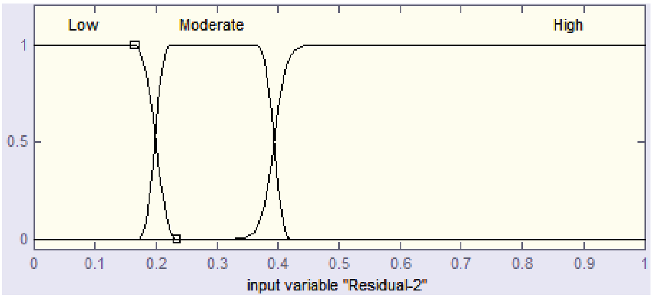

Figure 9. Input membership function of Residual-2

After the residual values are scaled and weighted they are processed according to set rules. The fuzzy logic rules are developed by examining the residual values in different contact conditions e.g. in 40% adhesion level the value of residual of model-1 is 'Low', the value of residual of Model-2 is 'Low', the value of residual of model-3 is 'High' and the value of residual of model-4 is 'Moderate'. Similarly rules for other possible contact conditions are developed and some of the rules are given below.

If *Residual-1* is '*Low*' and *Residual-2* is '*Low*' and *Residual-3* is '*High*' and *Residual-4* is '*Moderate*' and $T_t$ is '$T_8$' then '$\mu \geq 40\%$'.
If *Residual-1* is '*Low*' and *Residual-2* is '*Low*' and *Residual-3* is '*Moderate*' and *Residual-4* is '*Low*' and $T_t$ is '$T_3$' then '$20\% \geq \mu \geq 10\%$'.

The output is determined by averaging the outcome of all the rules and final numeric output ranging from 0 to 100 is produced. The output fuzzy set is shown in Fig-10.

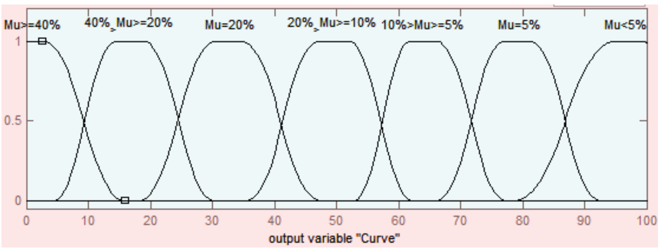

Figure 10. Input membership function of Residual-2

The final stage is to convert the fuzzy logic output into percentage adhesion, which is done by fitting a sixth order polynomial on fuzzy output data set and following equation is obtained.

$$\mu = -2.213\times10^{-6} n_1^{\;4} + 0.00042 n_1^{\;3} - 0.0205 n_1^{\;2} - 0.38 n_1 + 42 \quad (16)$$

where $n_1$ is fuzzy logic output and $\mu$ is percentage adhesion level. The simulations are run different contact conditions and the results are given below.

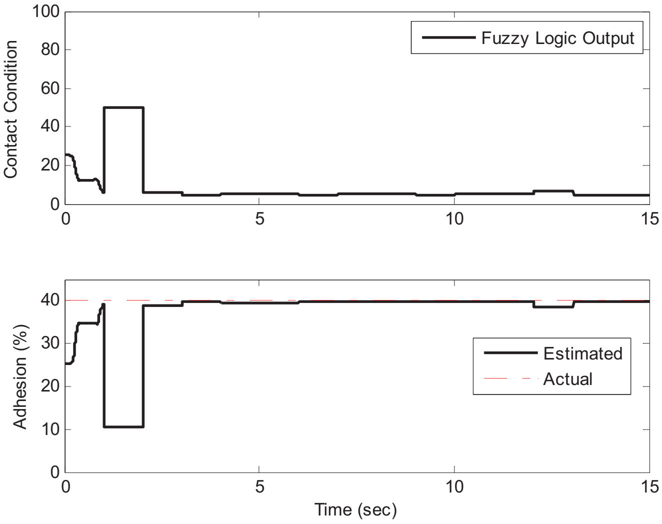

Figure 11. Simulation carried out using creep Curve $C_A$

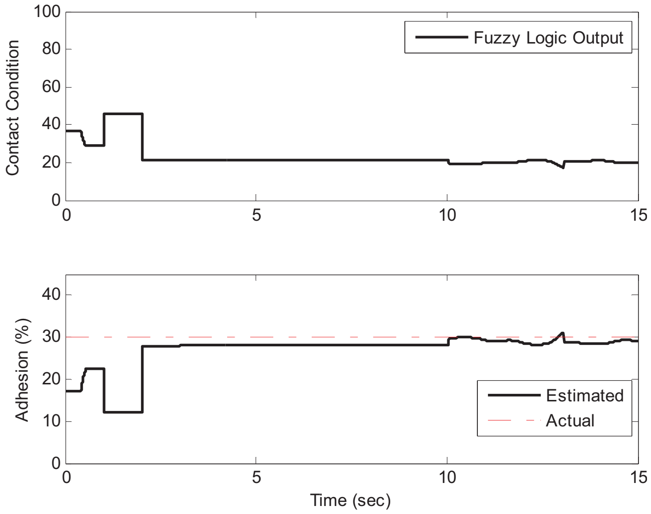

Figure 12. Simulation carried out using creep Curve $C_C$

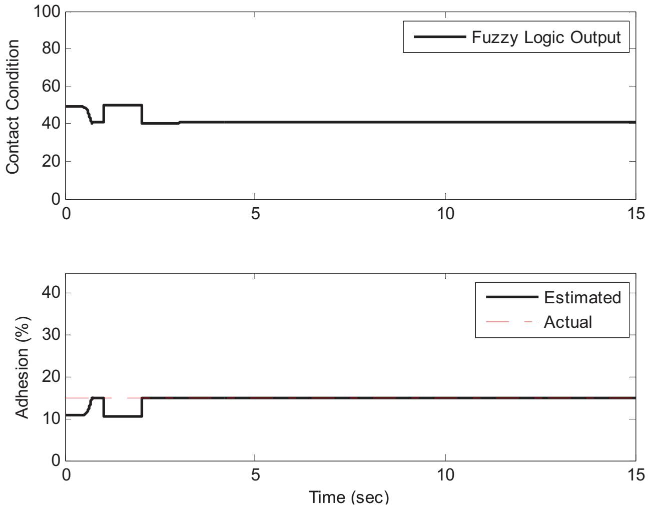

Figure 13. Simulation carried out using creep Curve $C_F$

Fig.11 shows the output of the fuzzy inference system when the system is operated on creep curve $C_A$. the fuzzy logic output is converted to adhesion information using (16). The system takes approximately two seconds to react and produce correct output. The delay in this case is due to the time needed in computer simulation to reach steadily contact conditions and also due to the time required to calculate the windowed rms of residuals. After 2 seconds the output fuzzy logic system is steady and the estimated adhesion level is almost equal to the simulated adhesion level. Fig.12 shows the result obtained by simulating the creep curve $C_C$. Again the steady output is produced after a delay of approximately 2 seconds. In practice while the wheelset already be in motion the amount of delay would not be as much. After the expected delay, the estimated adhesion level is approximately equal to the actual adhesion level. The difference in the actual output and the estimated output is caused by several reasons that include inaccuracy in fuzzy interpretation and the error due to curve fitting formula. Similarly Fig.13 shows the result of the simulation when the wheelset is operated on creep curve $C_F$.

## VI. Conclusion and Further Work

The problem of low adhesion and its adverse impact on train control systems and rail network operations present a significant technological challenge to the railway industry. Measures taken by railway industries around the world, such as sanding, water jetting, WSPs e.t.c, have solved the problems caused by low adhesion to some extent. But these measures are not sufficient to eliminate the problems completely. The adhesion detection method presented in this paper lays a scientific foundation for a new way forward. The simulation results presented in this paper affirm the potential of the idea presented. Further work, e.g. track testing and experimental validation, will be needed before it can be put into practice.

*Abstract*—**This paper has studied the application of wavelet package energy spectrum and frequency energy spectrum analysis in the diesel engine fault diagnosis. Extracting the fault features by wavelet package energy spectrum and frequency energy spectrum analysis of the fault angle of fuel supply decreased 2.5° and plug of air filter, then making those as the input character of neural networks and implementing the fault diagnosis. It is concluded that frequency energy spectrum analysis is more strongly of the practicability than wavelet package energy spectrum analysis by comparing the test results.**

***Keywords-wavelet packet; energy spectrum; neural networks; fault diagnosis***

## I. INTRODUCTION

With today's society development of the industrialization level, the diesel engine as a common power mechanical equipment, fault diagnosis has become an important research object in the fault diagnosis research field. Main signals used for the analysis of diesel engine's state are vibration signal, noise signal, pressure signal and temperature signal, etc. In diesel engine fault diagnosis, mainly adopts the vibration signal analysis method, and the methods of vibration signal processing include amplitude spectrum, power spectrum, zoom spectral analysis, energy spectrum analysis, cepstrum analysis and other many kinds analysis methods. Diesel engine in the actual operation, the frequency range is not the same in the energy spectrum of the response from the different components. If the energy spatial distribution of some output signals compared with normal system output changes, can distinguish the frequency band corresponding to the component should be in the abnormal working state. Usually some frequency components significantly inhibited, the band signal energy is reduced, and some components are enhanced, the frequency band energy increase. On the energy spectrum density or power spectral density for the analysis, which can be concluded that all kinds of fault characteristic features, so the energy spectrum analysis on fault diagnosis is practical and feasible[1]. This paper based on the energy spectrum analysis on fault diagnosis, is mainly to the wavelet packet energy spectrum analysis and energy spectrum analysis are compared.

## II. WAVELET PACKET ENERGY SPECTRUM ANALYSIS

If the use of wavelet analysis to fault diagnosis of diesel engine, although able to signal the effective time-frequency decomposition, but only on the low frequency band signals decomposition effect is good, the high frequency frequency resolution is poor. Wavelet packet analysis wavelet transform is an improvement of wavelet analysis, it can do further decomposition to the high frequency part for no analysis, is a more accurate analysis method, effectively improves the time-frequency resolution[2]. So here only discuss the wavelet packet energy spectrum analysis method[3].

Steps of Extracting wavelet packet energy spectrum are:

(1) Do wavelet packet decomposition to the sampling signal, this paper adopts four layer wavelet packet decomposition.

(2) on each layer of wavelet packet decomposition coefficients were reconstructed, extracting each frequency band signal on fourth layers, using $S_{4i}$ signify the reconstructed signal of nodes *(4, i)* .

(3) calculation of the frequency band energy

Set $S_{4i}$ corresponding energy is $E_{4i}$ , to seek the total energy of each frequency band signal. It is $E_{4i} = \int \left|S_{4i}(t)\right|^2 dt = \sum_{k=1}^{n} \left|x_{i,k}\right|^2$ . where, $x_{i,k}$ is the amplitude of discrete points of reconstruction signal $S_{4i}$ , and n is sampling points the signal. With these energy values to structure feature vector T, $T = \left[E_{41}, E_{42}, \cdots, E_{415}\ \right]$.

(4) To construct the feature vector. If the each frequency band energy values are larger, then the amount of computation required is large, therefore needs will feature vector is normalized, normalized formula is $S_i = E_{4i}/E$ , where, the total energy E expression is $E = sqrt\left(\sum_{i=0}^{15} \left|E_{4i}\right|^2\right)$.

## III. FREQUENCY DOMAIN ENERGY SPECTRUM ANALYSIS

When the diesel engine system is the normal operation, the system's vibration signal with certain frequency spectrum, if the system in a component failure occurs, with the vibration changes will make the original vibration composition changes, corresponding to its spectrum will have change[4]. Energy spectrum described signal energy along the frequency axis

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

distribution, frequency domain energy spectrum expression is $E = \left| fft\left(x(t)\right)\right|^2$.

The specific method is, this paper adopted the data after reduced frequency, the sample frequency is 10KHz, after FFT transform analysis frequency is 5000Hz. So is will 0 Hz ~ 5000 Hz frequency domain is divided into N bands, separately calculate the each frequency band energy. When the energy is larger, corresponding to the energy of each frequency band value is relatively large, so in order to calculate conveniently, need to put all the energy values for the normalized. Normalized formula is $a_i = \dfrac{a_{\max} - a_i}{a_{\max} - a_{\min}}$

Where, $a_i$ is the each frequency band energy value, $a_{\max}$ expressed the maximum value in $a_i$, $a_{\min}$ is the minimum value in $a_i$. Normalized values can be used as feature value required diesel engine fault diagnosis.

## IV. Application of Neural Networks in Fault Diagnosis

The nature of the fault diagnosis is through the fault symptom conclude fault reason, and the artificial neural network is through to simulate the infer function of human brain to fault diagnosis, and can through the adaptive learning and adjusting the network size, to achieve pattern recognition and feature extraction. Currently main neural network used in fault diagnosis be the BP network, Elman network and RBF network. Which BP network is a multilayer feed-forward neural network, and because of its simple structure, training algorithm is much, so it has been widely used in practice[5].

The BP network learning process includes forward computation and the error back propagation calculation within network, after all training samples input to neural network to calculate the output of the network. If the data from the output layer is not the desired output, then the network automatically enter the error back propagation, by modifying the weights value and the threshold of each layer neurons, and the error is reduced gradually, in this way, until meet the requirements, then train stop. This paper will be mentioned in the wavelet energy spectrum analysis method and frequency domain energy spectrum analysis of the feature value as the input of neural network, select the number of training samples and test samples, through the training to review output, which testified in front of the feasibility of the proposed method[6].

## V. Diesel Engine Fault Diagnosis Example Analysis

In this paper, the experimental data are in the normal operation of diesel engines, artificial set of fuel supply advance angle decreased 2.5 degree and the air filter is clogged two fault, through the acquisition of diesel engine vibration signal to do fault diagnosis. To collecting data the sampling frequency is 40KHz, diesel engine speed is 1500r / min.

First the collected vibration signals preprocessing, then using wavelet packet transform to extract signals feature vector. the vector signal. Using the previously described extracting wavelet packet energy spectrum method, using the db1 of in Daubechies wavelet series do 4 layer wavelet decomposition of signal, a total of 16 frequency bands. Extracting the fourth layer wavelet packet each frequency band energy spectrum scales as the neural network's input vector P, namely *P = [E40 / E, E41 / E, E42 / E, E43 / E, E44 / E, E45 / E, E46 / E, E47 / E, E48 / E, E49 / E, E410 / E, E411 / E, E412 / E, E413 / E, E414 / E, E415 / E]*.

Each condition calculation six samples, set the number of training sample is 12, in which the normal sample number, fault sample number of fuel supply advance angle decreased 2.5 degree and fault sample number of air filter clog all are 4. The test samples were set to 6, normal and two kinds of fault sample number all are 2. Because there are two kinds of failure mode and a normal state, so the network output is expressed as follow, fuel supply advance angle decreased 2.5 degree fault is (1,0,0), the air filter is clogged fault is (0,1,0), the normal state is (0,0,1). The training samples and test samples are shown as Table 7 and Table 1.

| Ideal Output | 100 | 100 | 010 | 010 | 001 | 001 |

Set the input layer neuron number is 16, the output layer neuron number is 3, number of hidden layer neurons is approximately 33, the number of training is 1000, target of the training error is 0.00001, the learning rate is 0.1. After setting up parameters, establishes the BP neural network, and got the training results are shown as figure 1.

From the diagram that the curve of training error can be seen, after 70time after training, the network can achieve our learning goals. Then will the test sample as a neural network's input, to get the test results are shown as Table 2.

From the test results, and we expected output consistent with, can accurate analysis the failures, this method is desirable, but consume time is longer.

Repeat the above, using the wavelet db5 of in Daubechies wavelet series do 4 layer signal decomposition, the same extracting the fourth layer wavelet packet each frequency band energy spectrum scales as the neural network's input vector P, output mode and the above ware same, training samples and test samples used the same calculation method, to train of neural network set up the same parameters, get training results are shown as figure 2.

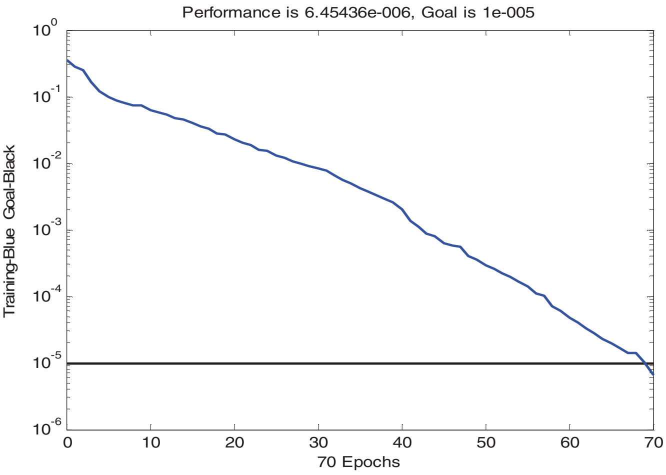

Figure 1. BP neural network error training curve of wavelet packet transform db1

TABLE II. TESTING RESULTS

| Sample Output | 1 | 2 | 3 | Testing Results |
|---|---|---|---|---|
| 1 | 0.9998 | 0.0000 | 0.0001 | Fuel supply advance angle decreased 2.5° |
| 2 | 0.9855 | 0.0001 | 0.0003 | Fuel supply advance angle decreased 2.5° |
| 3 | 0.0000 | 1.0000 | 0.0091 | Air filter clog |
| 4 | 0.0000 | 1.0000 | 0.0019 | Air filter clog |
| 5 | 0.0141 | 0.0000 | 0.9978 | Normal state |
| 6 | 0.0000 | 0.0000 | 1.0000 | Normal state |

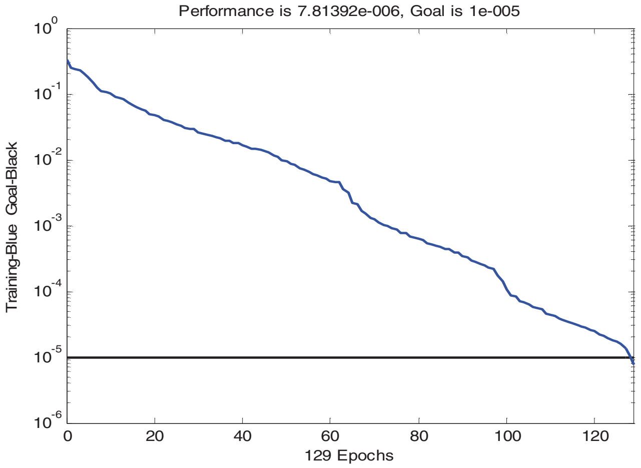

Figure 2. BP neural network error training curve of wavelet packet transform db5

After 129 time training, the error of the network meet the requirements. Then will the test sample as the input of neural network, to get the test results are shown in Table 3.

TABLE III. TESTING RESULTS

| Sample Output | 1 | 2 | 3 | Testing Results |
|---|---|---|---|---|
| 1 | 0.9997 | 0.0001 | 0.0004 | Fuel supply advance angle decreased 2.5° |
| 2 | 1.0000 | 0.0000 | 0.0000 | Fuel supply advance angle decreased 2.5° |
| 3 | 0.0009 | 0.5604 | 0.0002 | Air filter clog |
| 4 | 0.9888 | 0.9954 | 0.0000 | Can't judge |
| 5 | 0.0000 | 0.0228 | 1.0000 | Normal state |
| 6 | 0.0000 | 1.0000 | 0.3913 | Air filter clog |

From the test results, some value and our ideal output is not consistent, emerged condition of failure error separation, so this method is not desirable.

It is introduced with the frequency domain energy spectrum method to extract the feature vector. This paper uses the data sampling frequency is 40KHz. Because the frequency is too high, so the need to reduce analysis frequency, the reduced frequency is 10 KHz, after done power spectrum the frequency is 5 KHz, will this frequency are divided into 10 band, each band energy be calculated. Choose after normalized energy value S as fault diagnosis feature value, namely the neural network's input vector P, P = [S1, S2, S3, S4, S5, 'S6', S7, S8, S9, S10].

Similarly, each condition selection six samples, set the number of training sample is 12, in which the normal sample number and fault sample number all are 4. The test samples were set to 6, normal and two kinds of fault sample number all are 2. The network output is expressed as follow, fuel supply advance angle decreased 2.5 degree fault is (1,0,0), the air filter is clogged fault is (0,1,0), the normal state is (0,0,1). The training samples and test samples are shown as Table 8 and Table 4.

TABLE IV. TEST SAMPLES

| Serial Number | 1 | 2 | 3 | 4 | 5 | 6 |
|---|---|---|---|---|---|---|
| S0 | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 |
| S1 | 0.934 | 0.934 | 0.935 | 0.935 | 0.929 | 0.929 |
| S2 | 0.867 | 0.867 | 0.900 | 0.900 | 0.854 | 0.854 |
| S3 | 0.474 | 0.474 | 0.697 | 0.697 | 0.556 | 0.556 |
| S4 | 0.790 | 0.790 | 0.870 | 0.870 | 0.838 | 0.838 |
| S5 | 0.867 | 0.867 | 0.852 | 0.852 | 0.862 | 0.862 |
| S6 | 0.154 | 0.154 | 0.231 | 0.231 | 0.017 | 0.017 |
| S7 | 0.000 | 0.000 | 0.000 | 0.000 | 0.000 | 0.000 |
| S8 | 0.810 | 0.810 | 0.842 | 0.842 | 0.902 | 0.902 |
| S9 | 0.764 | 0.764 | 0.774 | 0.774 | 0.802 | 0.802 |
| Ideal Output | 100 | 100 | 010 | 010 | 001 | 001 |

Set the input layer neuron number is 10, the output layer neuron number is 3, number of hidden layer neurons is approximately 21, the number of training is 1000, training target is 0.00001, the learning rate is 0.1. After setting up parameters, establishes the BP neural network, and got the training results are shown as figure 3.

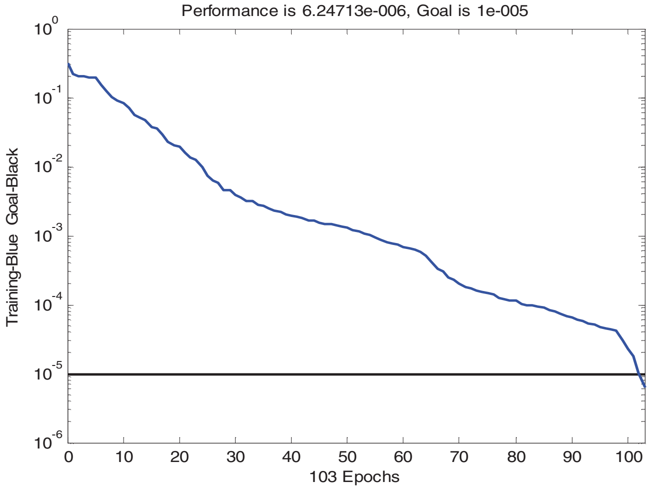

Figure 3. BP neural network error training curve of frequency domain energy spectrum

After 103 time training, the error of the network meet the requirements. Then will the test sample as the input of neural network, to get the test results are shown in Table 5.

TABLE V. TESTING RESULTS

| Sample Output | 1 | 2 | 3 | Test Results |
|---|---|---|---|---|
| 1 | 0.9983 | 0.0011 | 0.0012 | Fuel supply advance angle decreased 2.5° |
| 2 | 0.9983 | 0.0011 | 0.0012 | Fuel supply advance angle decreased 2.5° |
| 3 | 0.0036 | 0.9956 | 0.0003 | Air filter clog |
| 4 | 0.0036 | 0.9956 | 0.0003 | Air filter clog |
| 5 | 0.0006 | 0.0000 | 0.9998 | Normal state |
| 6 | 0.0006 | 0.0000 | 0.9998 | Normal state |

From the curve of training error, network can rapidly astringe. From the testing results, the fault separation accuracy is relatively high, and the time is short.

Using the three analysis methods to extract feature vector which input to BP neural network, the training time is respectively are shown in Table 6.

TABLE VI. TRAINING TIMES

| Analysys methode | wavelet packet transform db1 | wavelet packet transform db5 | Frequency domain energy spectrum |
|---|---|---|---|
| Elapsed_time | 39.5000 | 73.4540 | 3.3440 |

From the above two methods of comparison can be seen, the wavelet packet energy spectrum analysis although can to signal fine time-frequency decomposition, but the wavelet function selection is a difficult problem of the wavelet packet transform. Some can accurately diagnose the fault, but some can not, like the db5 used above. Because the kinds of fault could not only one, so want to choose for each fault are suitable wavelet packet transform is more difficult. Due to the signal decomposition and reconstruction, so the calculation amount is larger, longer time consuming, not suitable for online diagnosis. And the frequency domain energy spectrum analysis method needs less computation amount, shorter time, and the correct rate is higher, thus suitable for online diagnosis.

## VI. CONCLUSION

This paper uses wavelet packet energy spectrum analysis method and frequency domain energy spectrum analysis method to the diesel engine vibration signal fault diagnosis, after verification, if the problem of selecting wavelet function can be improved, then the wavelet packet energy spectrum analysis method is a good method of fault diagnosis on the above analysis, the results show the frequency domain energy spectrum method in the practical application is feasible, less time-consuming, accuracy is relatively high.

## ACKNOWLEDGMENT

The work described in this paper has been supported by National Natural Science Foundation of China under the grant No. 51175480, National Doctoral Fund of Ministry of Education under the grant No.20091420110002, Province Natural Science Foundation of Shanxi under the grant No.2011011019 and Shanxi Scholarship Council of China. The authors would like to express their gratitude for the support of this study.

*Abstract*—**With the digital technology and very large scale integrated circuit technology widely used, the structure and function of electronic devices are becoming more and more complex, the defects of contact diagnosis has become increasingly prominent for using the probe or needle bed, it demands people began to in-depth study the diagnostic techniques of PCB non-contact. Based on magnetic image of the PCB fault diagnosis technology is a new non-destructive testing technology of PCB, developed in recent years, it can achieve rapid detection and location of the circuit board failure, improve the reliability of the circuit board. Aimed at the specific PCB, its different failure modes of the magnetic image of the PCB are attained by Ansoft software, are carried out through the magnetic image filtering, image enhancement technology; they are completed on multi-level wavelet decomposition, the construction and extraction of wavelet energy features of the magnetic image. The PCB fault diagnosis based on the magnetic image is completed by using the improved momentum-adaptive rate neural network algorithm. The results show that the magnetic image method is effectively diagnosis method for PCB, and it's a new fault diagnosis approach of PCB.**

## I. INTRODUCTION

As we all know, the circuit board is in the state of power, the current line and the circuit board components are magnetized, such as resistors, integrated chips will produce electromagnetic radiation, and a particular magnetic field is formed in space [1]. It has one to one relationship between the magnetic field distribution characteristics of the circuit and current distribution characteristics of the circuit. When a component or circuit of the circuit board appears failure, it will cause the change of the current size and direction, and the magnetic field strength at any point in the near-field region of board depends on the size of current and its distribution, it makes nearly magnetic field distribution also undergo corresponding changes. The state of the circuit board is determined by detecting the magnetic field distribution in the circuit or system work, and it will be able to achieve non-contact detection and diagnosis, the fault diagnosis of the magnetic image is based on [2].

During the circuit board fault diagnosis, the first it needs to add excitation source, it makes the circuit board works in the largest working condition, then the magnetic field distribution of the circuit board is detected, and a test data is formed. Comparing the measured magnetic field distribution data of the circuit board with the trouble-free data, if the circuit board presences the fault, both of the magnetic field distribution data must be some difference. According to the difference, the faulty components on the circuit board can be determined and located. If it can not locate to the fault components, it can compress the range of failure, and add power in possible malfunction of the various components, it makes them on the maximum working state, measures the magnetic field distribution, extracts the characteristics vector of test data, based on the correspondence relation between the failure and characteristics vector of the magnetic image, reasoning judge, to determine the fault source, and show the location and types of faults.

## II. SYSTEM COMPONENTS AND FUNCTIONS

Based on the magnetic image of PCB fault diagnosis system, the first, it need process the input magnetic image, extract the characteristics information of the magnetic image of board in the work state, and the characteristics information are as neural network inputs, the corresponding fault cause are as network output and network is trained. Until the network training is completed, the magnetic image of the pre-test circuit board is inputted, and the relevant features are extracted, and the board working states can be diagnosed. The fault diagnosis system block diagram is shown in Fig.1.

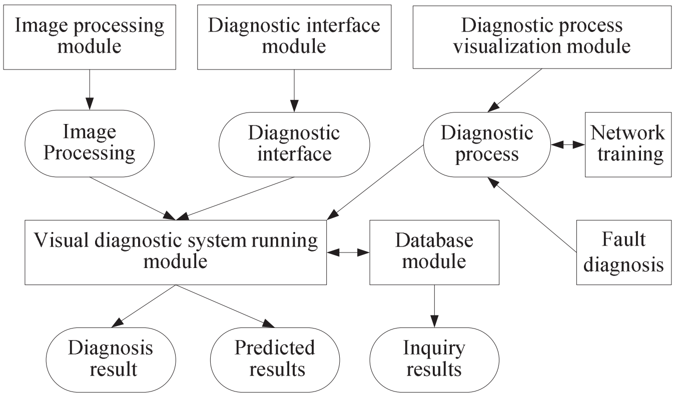

Figure 1. The design frame of system

## III. To Obtain The Magnetic Images

Sometimes the magnetic images can be obtained by the EMSCAN devices and software simulation. In this paper, the electromagnetic image in near-field experimental data is indirectly obtained by Ansoft Designer simulation software, and it provides a new diagnostic method for circuit board.

The electromagnetic near-field image of a circuit board by simulating is shown in Fig. 2. As the software simulation from the distribution of near-field magnetic image is color, making image analysis must be conducted before the gray-scale image processing.

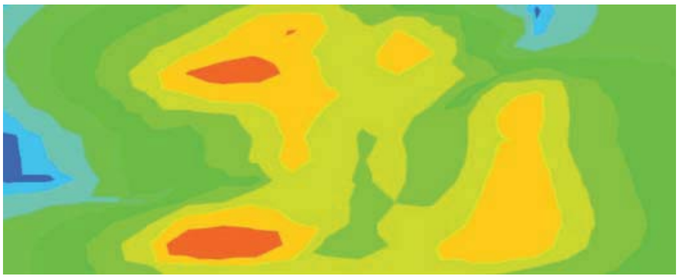

Figure 2. Simulation image of a circuit board magnetic image

## IV. The Magnetic Image Processing Techniques

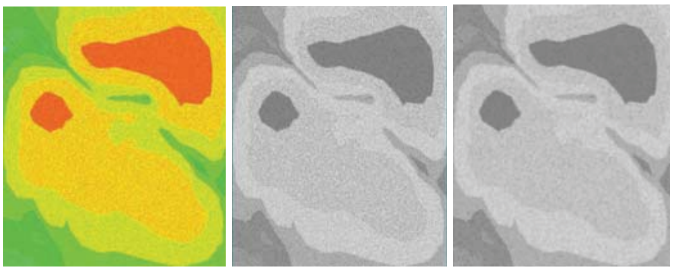
In practice, the magnetic image in the detection process is affected by noise, electromagnetic interference and other external factors, always makes the original image acquires a certain degree of distortion, the images must be digital processing before the magnetic image is analyzed, the images processing in this system includes image filtering, enhancement, and edge sharpening and so on.

### A. Gray-scale and filter of the magnetic image

Gray-scale image is the process transforms a color image into grayscale image. The magnetic image is a color image, shown in Fig. 3(a). Color images contain a large number of R, G, B color information, it not only would take a lot of storage space, but also it will require the system to assign a lot of resources in the image application process. As the grayscale images can be the overall reaction and the local color, brightness distribution and characteristics of the whole image. It can save a variety of hardware and software resources when color images convert to grayscale images.

By detecting the magnetic field data to generate the magnetic field grayscale images, it reflects the magnetic field distribution of the circuit board. Image grayscale of the magnetic images generation process includes the magnetic field data acquisition, extracting the maximum and minimum of array data classification and the data is conversed into the magnetic image gray-scale values.

The gray-scale magnetic image is shown in Fig. 3(b). It can be seen from Fig. 3(b), there are some noise points in the image, therefore, median filtering is used in the grayscale image, the point in digital image is replaced by the median value of brightness of each point in a little neighborhood, so that it can protect the edge of the image, and it has good results to the filter pulse interference and scanning image noise [3].



(a)Source image (b)Gray-scale images (c)Median filtered image

Figure 3. The contrast image from source image with gray-scale image and median filtering image

Set the number of groups: $X_1, X_2, \cdots X_n$,If the order is as follows: $X_{i1} \le X_{i2} \le X_{i3} \le \cdots \le X_{in}$, then:

$$Y = Med\{X_1, X_2, \cdots X_n\} = \begin{cases} X_{i[(n+1)/2]} & n \text{ is odd number} \\ \frac{1}{2}\left[X_{i[(n/2]} + X_{i[(n/2+1]}\right] & n \text{ is even number} \end{cases} \qquad (1)$$

Y is called the median of $X_1, X_2, \cdots X_n$, and it is extended to two-dimensional, then the median filtering of the output is:

$$Y_i = med\{X_{ij}\} = med\{X_{(i+r)(j+s)}(r,s) \in A, (i,j) \in I^2\} \qquad (2)$$

According to the characteristics of the magnetic image, selecting the 5×5 window median filtering method to obtain the magnetic image, it not only can improve the edge characteristics of image signal, and also get faster processing speed and higher accuracy. After filtering the image is shown in Fig.3(c), it can be seen that the noise points in the image are significantly reduced, the smoothness of magnetic image is better, the overall effect is satisfactory.

### B. The magnetic image enhancement

Gray value of pixels within the image is an important data of the image, the result of magnetic image gray value is often less than ideal due to testing equipment or filtering effect. Image enhancement can highlight some interesting information or attenuate no interesting information in image, and it is more effective than the original image in the specific application.

Common methods of image enhancement are gray-scale transformation and Histogram Equalization. The histogram equalization method is adopted in this paper. The basic idea of Histogram equalization is to increase the image's pixel gray value dynamic range. The actual processing of histogram correction achieves on the cumulative distribution function transformation. For digital images, the transformation function is set as follow:

$$s_k = T(r_k) = \sum_{j=0}^{k} \frac{n_j}{n} = \sum_{j=0}^{k} p(r_j) \qquad (3)$$

Where, $0 \le r_j \le 1, k = 0,1,\cdots,L-1, p(r_j)$ is the gray probability that gray level appears, and $T(r_k)$ is the cumulative distribution function of *r*. In practice, according to meet the actual needs in digital image processing, the conversion result is a real number, also need to re-quantitative, quantitative formula is as follow:

$$\hat{s}_k = INT\left[\frac{s_k - s_{\min}}{1 - s_{\min}}(L-1) + 0.5\right] \qquad (4)$$

Fig.4 shows the magnetic image before and after histogram equalization. It can be seen, with the histogram correction, the gray-scale range and gray level intervals of the image histogram are pulled larger, the image become clearer.

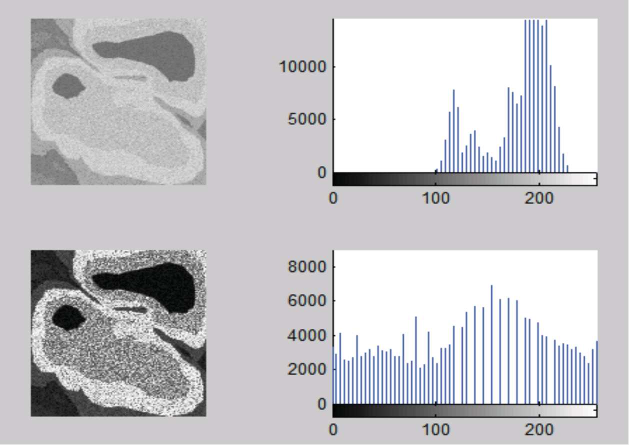


Figure 4. The magnetic image after the Histogram equalization

### *C. Sharpen edge of the magnetic image*

In the image smoothing process, it tends to the image boundaries, contours and details become blurred due to image conversion system transfer function attenuation effects on high-frequency components. In order to reduce these impacts, the image enhancement techniques are adopted in various parts of the contour lines and details of more clarity in the image [4].

Laplacian is selected because it has better effect when it is used in edge detection, and it has rotation invariance. Laplacian is a linear quadratic differential operators, it can meet the different sharpening image requirements.

For images $F(x,y)$ , the expression for the Laplacian operator is as follow:

$$\nabla^2 F(x,y) = \frac{\partial^2 F(x,y)}{\partial^2 x} + \frac{\partial^2 F(x,y)}{\partial^2 y} \qquad (5)$$

Figure 5 shows the magnetic image of PCB after edge sharpening by Laplacian.

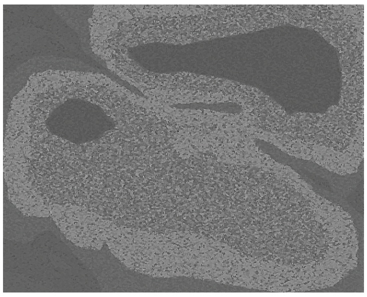

Figure5. Magnetic image of edge sharpening

## V. WAVELET ENERGY FEATURE EXTRACTION OF MAGNETIC IMAGE

In practice fault diagnosis, it is always hope to collect a number of samples to train the neural network, and the fault diagnosis is more accurate and reliable. But too much input sample can cause not only the training time is too long, or even obstruct the convergence effects of network, mainly the training accuracy can not arrive, and ultimately affect the circuit board fault diagnosis. Therefore, it requires to extract useful information is a greater contribution to the faults diagnosis from the sample, image feature extraction is to use existing image samples by mapping (or function transformation) to construct a lower dimensional feature space, the original image contains useful information is mapped in a few features.

The two-dimensional discrete wavelet transform (DWT) is adopted because the wavelet transformation has a good effect in the signal weakened or even removed the correlation between the various characteristics by selecting the appropriate filter function, and it has a multi-scale, multi-resolution features. It can be used correlation analysis in the low frequency band by high frequency resolution and low time resolution; at high frequencies, the available low-frequency resolution and high time resolution achieve correlation analysis, and the magnetic image data processing is a two-dimensional gray-scale image data [5].

### *A. Two-dimensional discrete wavelet transform*

First, define the scale and translation functions as follow:

$$\varphi_{j,m,n}(x,y) = 2^{j/2}\varphi\left(2^j x - m, 2^j y - n\right) \qquad (6)$$

$$\psi^i_{j,m,n}(x,y) = 2^{j/2}\psi^i\left(2^i x - m, 2^j y - n\right), i = \{H,V,D\} \qquad (7)$$

Thereinto, $\varphi(x,y)$ represents a two-dimensional scaling function, $\psi^H(x,y)$、$\psi^V(x,y)$、$\psi^D(x,y)$ represent two-dimensional wavelet measurement function, respectively. The properties of $\varphi(x,y)$、$\psi^H(x,y)$、$\psi^V(x,y)$、$\psi^D(x,y)$ are as follow:

$$\varphi(x,y) = \varphi(x)\varphi(y) \qquad (8)$$

$$\psi^H(x,y) = \psi(x)\varphi(y) \qquad (9)$$

$$\psi^V(x,y) = \varphi(x)\psi(y) \qquad (10)$$

$$\psi^D(x,y) = \psi(x)\psi(y) \qquad (11)$$

These wavelet measured functions are changed along different directions of the image gray value: $\psi^H$ changes along the image column, $\psi^V$ changes along the line of the image, $\psi^D$ changes along the diagonal direction of the image.

Matrix of size $M \times N$ image $f(x,y)$ of the discrete wavelet transformation is as follow:

$$W_\varphi(j_0,m,n) = \frac{1}{\sqrt{MN}}\sum_{x=0}^{M-1}\sum_{y=0}^{N-1} f(x,y)\varphi_{j_0,m,n}(x,y) \qquad (12)$$

$$W^i_\psi(j_0,m,n) = \frac{1}{\sqrt{MN}}\sum_{x=0}^{M-1}\sum_{y=0}^{N-1} f(x,y)\varphi^i_{j,m,n}(x,y), i = \{H,V,D\} \qquad (13)$$

$j_0$ is beginning scale, it can be taken any value, $W_\varphi(j_0,m,n)$ coefficient defined in the scale $j_0$ factor approximation of $f(x,y)$ · $W_\psi^i(j,m,n)$ coefficient will be additional the horizontal, vertical and diagonal details if $j \geq j_0$. In normal circumstances, let $j_0 = 0$ , $M = N = 2^j$ , $j = 0,1,2,\cdots,J-1, m,n = 0,1,2,\cdots 2^j - 1$ , equation (12) and (13) give the value of $W_\phi$ and $W_\psi^i$ , the original image $f(x,y)$ can be got by inverse discrete wavelet transformation, it expresses as follow:

$$f(x,y) = \frac{1}{\sqrt{MN}} \sum_m \sum_n W_\varphi(j_0,m,n) \varphi_{j_0,m,n}(x,y) \tag{14}$$
$$+ \frac{1}{\sqrt{MN}} \sum_{i=H,V,D} \sum_{j=j_0}^{\infty} \sum_m \sum_n W_\varphi(j_0,m,n) \psi_{j,m,n}^{i}(x,y)$$

*B. The structure and extraction of wavelet energy feature*

Set, $H_i$ 、 $V_i$ and $D_i$ are the details of the image in the $i^{\text{th}}$ wavelet decomposition in the horizontal direction, vertical direction and diagonal direction, the wavelet energy of image in different directions of the $i^{\text{th}}$ level is defined as[6]:

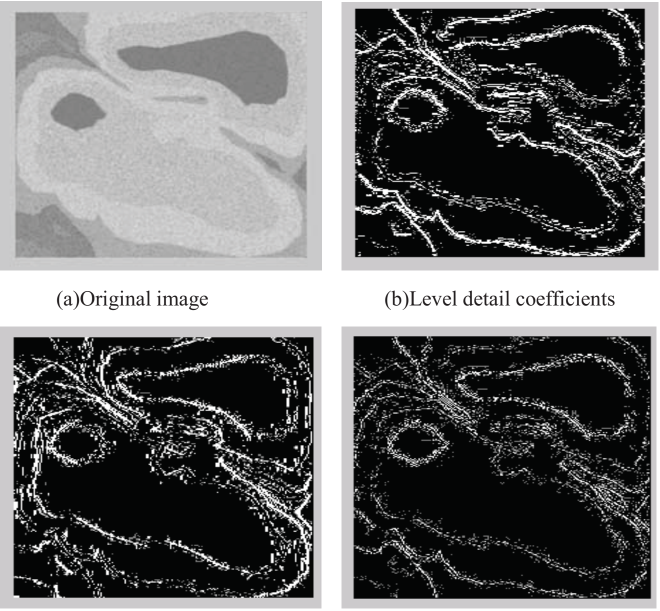
$$E_i^h = \sum_{x=1}^{M} \sum_{y=1}^{N} [H_i(x,y)]^2 \tag{15}$$

$$E_i^v = \sum_{x=1}^{M} \sum_{y=1}^{N} [V_i(x,y)]^2 \tag{16}$$

$$E_i^d = \sum_{x=1}^{M} \sum_{y=1}^{N} [D_i(x,y)]^2 \tag{17}$$

From (15) to (17), they stand for the intensity information of the horizontal, vertical and diagonal directions in the $i^{\text{th}}$ level wavelet decomposition of images, respectively.

The wavelet decomposition details image in each direction of the circuit board's magnetic image are shown in Figure 6.



(a)Original image

(b)Level detail coefficients

(c) Vertical detail coefficients

(d) Diagonal detail coefficients

Figure 6 Image single decomposition

During image wavelet decomposition, the non-oscillating signal wavelet coefficient will increase with the wavelet decomposition series increases, the coefficients of wavelet decomposition level become the maximum when the oscillation signal is corresponding with the oscillation frequency. Therefore, the energy of the non-oscillation of the magnetic image part is concentrated in the large-scale wavelet decomposition detail image, and the energy of the oscillation of the magnetic image part is mainly concentrated in the smaller-scale wavelet decomposition detail image.

The vector of the energy component by wavelet decomposition level is as follow:

$$\left(E_i^h, E_i^v, E_i^d\right)_{1,2,\cdots M} \tag{18}$$

It can reflect the energy distribution of the magnetic image. Where, $M$ is the maximum series number of wavelet decomposition.

Obviously, equation (18) describes the overall information of the magnetic image, and it can not describe some local information of the magnetic image distribution. To solve this problem, the each images details are divided into $S$×$S$ disjoint blocks, and the each wavelet energy is calculated. Finally, the local feature vector $\widetilde{V}$ contains many details of the resolution information are composed by the energy of these blocks:

$$\widetilde{V} = \left(\widetilde{V}_{(1)}^1, \widetilde{V}_{(2)}^1, \cdots \widetilde{V}_{(3\times S\times S)}^1, \cdots \widetilde{V}_{(1)}^M, \widetilde{V}_{(2)}^M, \cdots, \widetilde{V}_{(3\times S\times S)}^M\right) \tag{19}$$

Where, M is the total series number of wavelet decomposition, $\widetilde{V}_{(j)}^1 (j = 1,\cdots,3 \times S \times S)$ are each images block energy that detail coefficients image $H_i$、 $V_i$、 $D_i$ of the $i^{\text{th}}$ level wavelet decomposition is divided into $S \times S$ blocks. Since the wavelet energy feature is a combination of the each level wavelet energy feature, the local features can be reflected the image at different resolutions, different locations, different directions, it can be used as basis to system identification or diagnosis.

Typically, the various samples eigenvalues are required normalized before the image feature value is as the basis for fault diagnosis, it is better identification or diagnosis when the normalized eigenvalues replace the original features.

$$V = \left(V_{(1)}^1, V_{(2)}^1, \cdots V_{(3\times S\times S)}^1, \cdots V_{(1)}^M, V_{(2)}^M, \cdots, V_{(3\times S\times S)}^M\right) \tag{20}$$

$$V_{(j)}^i = \frac{\widetilde{V}_{(j)}^i}{\sum_{k=1}^{M} \sum_{l=1}^{3\times S\times S} \widetilde{V}_{(l)}^k} \quad (i = 1,\cdots,M; j = 1,\cdots,3 \times S \times S \tag{21}$$

The feature vector $V$ is the wavelet energy feature.

$i^{\text{th}}$ level wavelet energy feature is as follow:

$$V^i = \left(V_{(1)}^i, V_{(2)}^i, \cdots V_{(3\times S\times S)}^i\right) \tag{22}$$

Wavelet energy feature is combined by the wavelet energy levels character, as the magnetic image, the wavelet energy feature of image is combined all levels coefficients of the wavelet energy feature by the wavelet decomposition, and multi-scale wavelet analysis of texture features is obtained, it can reflect the characteristics of the magnetic image distribution.

## VI. The Diagnosis Algorithm Of The Magnetic Images

### A. Improved BP Algorithm

To speed up the learning speed of the network, the improved BP network learning algorithms- Momentum - adaptive learning rate BP algorithm is used when the weights and thresholds are adjusted. The algorithm synthesis the advantage of momentum BP algorithm can avoid training process causes local minima during and adaptive variable learning rate back-propagation (VLBP) algorithm has character of weight adjustment smooth and short training time.

Momentum BP algorithm: when the momentum BP algorithm amend its weight, it not only to consider the error role in the gradient, but also it consider the change trends in the error surface. It adds a proportional the previous weight change value in the each weights change, and according to the back-propagation method to generate a new weight change. Its essence is through a momentum factor to transfer the impacts of weight change in the last time. The weight adjustment formula with additional momentum factor is as follow:

$$mc = \begin{cases} 0 & SSE(k) \succ 1.04 \cdot SSE(k-1) \\ 0.95 & SSE(k) \prec SSE(k-1) \\ mc & \text{other} \end{cases} \tag{23}$$

*k* is the training times, mc is the momentum factor, it is generally 0.95.

Adaptive Variable Learning Rate Back-propagation, aimed at ensuring the algorithm is stable, the convergence speed of network is faster, and the learning time is short. The learning rate is appropriately adjusted by the error surface. The weight of the correction value is checked whether it really lowers the error function. The adjustment formula of adaptive variable learning rate Back-propagation is as follow:

$$\eta(k+1) = \begin{cases} 1.05\eta(k) & SSE(k) \prec SSE(k-1) \\ 0.7\eta(k) & SSE(k) \succ 1.04 \cdot SSE(k-1) \\ \eta(k) & other \end{cases} \tag{24}$$

The selection of initial learning rate η(0) is very arbitrary.

Figure 7 and Figure 8 respectively show error convergence graph in the normal BP algorithm and improved BP algorithm when the network structure parameters are same.

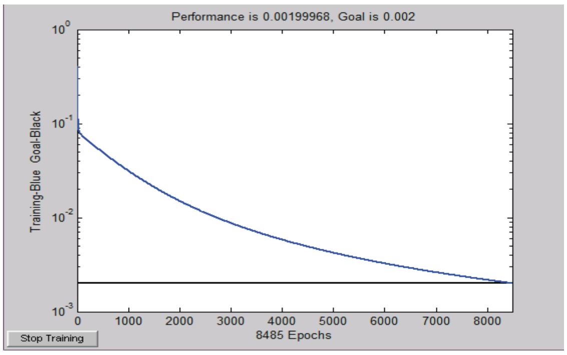


Figure 7. Error convergence graph of ordinary BP algorithm

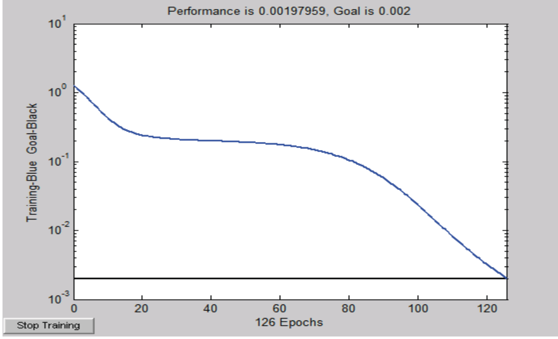

Figure 8. Error convergence graph of improved BP algorithm

It can be seen from Figure 7 and 8, the number of network training improved BP algorithm uses momentum-adaptive learning rate is much less than ordinary BP algorithm, it is the high diagnostic accuracy. It indicates that it is a very effective training method.

### B. The integration diagnosis of wavelet analysis and improved BP network

The magnetic image is resolved by wavelet packet analysis method, the wavelet energy eigenvalues are extracted when the corresponding wavelet coefficients are obtained. Wavelet energy features normalized are as neural network input sample, the network is trained by using improved BP neural network algorithm, and circuit board fault diagnosis is achieved. When the circuit board runs, it will inevitably happen one way or another failure, the effective and timely diagnosis of these main failures are effective means to ensure the normal operation of the board. Table 1 shows 5 common component failure modes of the circuit board.

Because of failure modes and failure causes have one to one relationship, that is, a magnetic image sample corresponds to a failed state. In the paper, the magnetic image features in the circuit board failure mode is as the network input, the corresponding failure cause is as the network output to train the neural network.

TABLE I. PCB FAILURE MODE AND FAILURE MECHANISM ANALYSIS

| fault symptoms | | Fault reason | | |
|---|---|---|---|---|
| **failure mode** | **fault sample** | **fault symbol** | **failure category name** | **failure category encoding** |
| x1 | I1.jpg | y1 | LM8361 fault | 00001 |
| x2 | I2.jpg | y2 | DS-3 U4 fault | 00010 |
| x3 | I3.jpg | y3 | DS-3 U5 fault | 00100 |
| x4 | I4.jpg | y4 | DS-3 U6 fault | 01000 |
| x5 | I5.jpg | y5 | DS-3 U7 fault | 10000 |

Because the pixels of image is too much, and there are many redundant information, magnetic image three layer wavelet energy feature information $X = (x_1, x_2, \cdots, x_9)$ is extracted is as input of neural network, fault causes $Y = (y_1, y_2, \cdots, y_{10})$ is as output, the failure mode is caused different failure is as the training sample and learning, it establishes the corresponding relationship between failure modes and the fault cause. Table 2 is the coefficients energy eigenvalues in different failure modes 3 layer wavelet decomposition of the board magnetic image.

The characteristic values in accordance with equation (21) were normalized. Its failure mode coding is as a neural network corresponding output sample to train the neural network, and the output sample indicates the relative between the input magnetic image information and the component failure. The output samples are shown in Table 3.

Finally, by using the same failure mode of the different magnetic images (non-fault training samples), during the corresponding extracting wavelet energy feature is as the neural network input, judging fault diagnosis, verifying the diagnose ability of network. Test results are shown in Table 4.

TABLE II. THE INPUT SAMPLE OF WAVELET ENERGY EIGENVALUES

| Sample | Level 1 | | | Level 2 | | | Level 3 | | |
|---|---|---|---|---|---|---|---|---|---|
| | Horizontal | vertical | Diagonal | Horizontal | vertical | Diagonal | Horizontal | vertical | Diagonal |
| 1 | 0.2814 | 0.0384 | -0.0112 | 0.3507 | 0.0467 | -0.0016 | 0.2849 | 0.0031 | 0.0077 |
| 2 | 0.5094 | -0.2391 | -0.0350 | 0.6307 | -0.2114 | 0.0230 | 0.5435 | -0.2151 | -0.0058 |
| 3 | 0.4839 | -0.1187 | -0.0131 | 0.7172 | -0.1456 | -0.0034 | 0.3905 | -0.2957 | 0.0495 |
| 4 | 0.4835 | -0.0168 | 0.0060 | 0.3353 | -0.0107 | -0.0281 | 0.2352 | 0.0044 | -0.0086 |
| 5 | 0.1778 | 0.0419 | 0.0120 | 0.2476 | 0.2196 | -0.0127 | 0.2437 | 0.0894 | -0.0193 |

TABLE III. THE DESIRED OUTPUT CHARACTERISTICS OF NEURAL NETWORK

| Circuit State | y1 | y2 | y3 | y4 | y5 |
|---|---|---|---|---|---|
| Element 1 failure | 0 | 0 | 0 | 0 | 1 |
| Element 2 failure | 0 | 0 | 0 | 1 | 0 |
| Element 3 failure | 0 | 0 | 1 | 0 | 0 |
| Element 4 failure | 0 | 1 | 0 | 0 | 0 |
| Element 5 failure | 1 | 0 | 0 | 0 | 0 |

TABLE IV. TEST RESULTS

| Input data | y1 | y2 | y3 | y4 | y5 |
|---|---|---|---|---|---|
| Element 1 failure | 0.0035 | 0.0008 | 0.0072 | -0.0013 | 0.8998 |
| Element 2 failure | 0.0008 | -0.0016 | 0.0049 | 0.9360 | 0.0003 |
| Element 3 failure | -0.0022 | 0.0081 | 0.9221 | 0.0069 | 0.0053 |
| Element 4 failure | -0.0034 | 0.8982 | 0.0071 | -0.0025 | -0.0008 |
| Element 5 failure | 0.9243 | -0.0009 | -0.0046 | 0.0010 | 0.0106 |

Test results from Table 4 can be seen, the recognition results of the network is more accurate in given the different components failure mode, and its deviations with network desired outputs are very small, the SSE (sum of prescribing error)between analog output and the desired results are 0.1000. The identify effect is ideal. Network performance is stable and reliable, the network design is successful. The system also shows it is feasible and reliable method based on the magnetic image analyzing the circuit board fault diagnosis.

## VII. CONCLUSION

In the circuit board fault diagnosis process, the magnetic detection technology is introduced. The gray, median filtering, gray-scale transformation, histogram equalization and related image processing techniques of the magnetic image are studied when the magnetic image is as the test data. To extract the wavelet energy feature of the magnetic image to determine whether it is a failure occurs in pre-test board or not, the improved BP algorithm is melted into the magnetic image fault diagnosis process, which has an advantage of the weight adjustment smooth and a short training time, so the speed is fast, low cost, high accuracy of fault diagnosis. It can play a larger role, it accords with rapid and quick, intelligent direction trend of the fault diagnosis to the circuit board system debugging, monitoring and diagnosis.

*Abstract*—**This Vehicles sold in the US and Europe have to be equipped with a Diagnostics, called On-Board Diagnostics (OBD), which monitor the performance of various elements of the emission control system. The driver is informed as to any failures by the use of a Check Engine Light on the dashboard of the vehicle and then should return the vehicle to the dealership for rectification. The vehicle manufacturer's aim is to ensure that the Check Engine Light is only illuminated for legitimate failures. For the calibration of an On Board Diagnostics there needs to be sufficient separation between the response of a good sensor and a failed sensor, the setting of this threshold should be based upon a statistical model of the data so that the predicted failures rate can then be determined. By applying confidence limits to the models allows the engineer to understand how additional data points will effect the calculation of the failure threshold. This gives the engineer the ability to determine the tradeoff between the number of data points and a confidence in the estimated statistical model.**

***Keyword-components:*** ***Automobiles, Detection, Diagnosis, Engines***

## I. INTRODUCTION

Vehicles sold throughout the world are subject to an increasingly stringent set of emission thresholds. To achieve certification, all sensors and vehicle sub-systems that may affect vehicle exhaust emissions have to be monitored by an On-Board Diagnostic (OBD) system that is part of the Engine Management System (EMS) or any other embedded controller [1]. This requirement was first introduced in the US in 1988 for OBD1, for open and short circuit faults, and in 1994 for OBD2, for changes in sensor and actuator responses [2]. For Europe this legislation, denoted EOBD, has been introduced for all vehicles built after January 2000 [3]. Both sets of legislation link the performance of the different diagnostics to emission thresholds. In the event of component or sub-system failure, a ‘check engine’ light must be illuminated as an indication to a driver that there is a problem, so corrective action can be taken to minimise the pollution caused by such a fault. As the emissions thresholds are continually reduced, more sophisticated techniques are required to be employed to meet these increasingly tightening thresholds.

As the Vehicle Emission Legislation drives down vehicle pollution the impact on the diagnostics is that they have had to become increasing more complex to determine a failed system. As a consequence the diagnostics are becoming have become increasing more like models of the functions that they are monitoring, if only over a restricted set of operating conditions, and as such the diagnostic results that they produce are becoming more likely to fit to a Gaussian Distribution.

OBD Diagnostic Calibration engineers develop test plans that invoke the worse conditions for the diagnostics, by introduction of variety of test conditions. These are typically different fuel specifications, operations at different ambient conditions (hot, cold and altitude), with different driving styles and tolerance sensors. Each diagnostic will have it’s own set of worse case test conditions which have been developed through the experience of the engineer and lessons learnt. The approach used by the calibration engineer is to collect data for these conditions and then fit a Gaussian distribution to the data to set thresholds to ensure that 'normal' systems does not false flags and that 'failed' system flag in a timely manner.

By making use of these Gaussian models and through the information obtained by the use of confidence interval of these models allows a more conservative and robust threshold to be set. Since the variation in the models reduces as the more data is collected they also provide the Engineer with a way of gauging whether collected any more data will significantly change their results. This is especially useful when collecting Fault condition data which where it is difficult to generate a large amount of data either because it requires specialist hardware setup or a specific environmental condition for which there might be a limited amount of testing time available.

The paper is organised as follows: Section II Problem Formulation which outlines the diagnostic used within this paper, Section III defines the Diagnostic Specification which outlines the set of conditions for setting the diagnostic thresholds, Section IV which defines the calculation of the Confidence Interval, Section V Process Monitoring and

Analysis details the implementation and analysis and finally, Section VI details further work and concludes the paper.

## II. Problem Formulation

On modern engines the air fuel ratio (AFR) has to be tightly controlled so that the Three Way Catalyst is operating at it's optimum and providing the correct emissions control [4]. AFR is measured as the ratio between the mass of air and the mass of fuel for pure octane the stoichiometric mixture is approximately 14.7:1. The exact composition of fuels varies seasonally and geographically so modern engines use a more convenient measure of lambda (λ) rather than AFR to allow them to control combustion process. Lambda (λ) is defined as the ratio of measured AFR to stoichiometric AFR for that given mixture. A Lambda of 1.0 is stoichiometry, rich mixtures are less than 1.0, and lean mixtures are greater than 1.0.

In this paper the calibration of an Individual Cylinder Air Fuel Ratio Diagnostic is investigated. This is a diagnostic which was first introduced for vehicles sold as 2010 Model Year vehicles [5,6]. Since this is still a relatively new diagnostic it was decided to carry out a more detailed analysis of the diagnostic results. The data analysed in this paper was collected from a cold ambient environment trip, this condition being deemed as being the worse case condition potentially giving the smallest separation between a fault free and the failed set of data.

Prior to the test trip the failure condition for both a rich and lean shift in λ for individual cylinders was determined by carrying out tests over an Emissions Drive Cycle. A failure condition being determined when the fuelling shift resulted in an emissions test result being 1.5 times the certify emissions standard. The failure threshold is set as the amount of shift in λ. The diagnostic infers the amount of Fuelling shift that each cylinder is experiencing from λ = 1 to determine a failure.

## III. Diagnostic Threshold Setting

Ideally the failure threshold should be set so you can capture all of the diagnostic results. However, in practice this may not always be possible so a minimum target of 90% of the data which contains a fault condition should result in the diagnostic bring on the Check Engine Light. To put on the Check Engine Light in USA requires that a failure is detected on two successive diagnostic operations. So to achieve the 90% detection on two successive tests requires that for a single test the failure threshold should be set at a level approximately 95% (100√0.9). To determine the Failure Thresholds in Section 4 it is more convenient to convert this figure into a Standard Deviation. In the case we are assuming that the threshold will only occur on one side of the distribution closest to the Fault Free set of data. On the Failure Threshold side of the distribution the point at which 45% of the population is represented by a Standard Deviation of 1.64, the other 50% of the data being containing the other half of the distribution.

For the fault free set of data we need to ensure that the fault thresholds are greater than 3×Standard Deviations from either side of the distribution we will refer to this as the Rich or Lean Robustness Threshold. This will then allow 99.74% of the data to be correctly identified as being fault free for a single diagnostic result. For the two successive diagnostic results this would then lead to the possibility of flagging a fault free system as having a fault as being 1 in 148,000 tests.

## IV. Problem Formulation

The set of data collected from the diagnostic cannot precisely define the characteristics of the population. The sample can only define a range of values for both the probable mean position and the probable standard deviation value. Confidence interval calculations are used to define a probable range of values for the population mean $\bar{x}_U$ (Upper) and $\bar{x}_L$ (Lower) and the population standard deviation $\sigma_U$ and $\sigma_L$. This then generates a range of possible statistical models that will include the population model with a given confidence.

Equation (1) [7] is used to Calculation of the Confidence Interval for the Mean

$$\mu = \bar{x}_S \pm t_{\beta,n-1}\frac{\sigma_S}{\sqrt{n}} \tag{1}$$

$\bar{x}_S$ is the sample mean $t$ is the Confidence Factor based upon the Student's t-Distribution, $\sigma_S$ is the Sample Standard Deviation, $n$ is the Sample Size and $\beta$ is either $\alpha$ for a single sided confidence Interval or $\alpha/2$ for two sided confidence interval. Where $\alpha$ is the significance level and for this paper a value of 5% or 0.05 will be used.

Calculation for the Confidence Limit for Standard Deviation is given by

Lower Limit    Upper Limit

$$\sigma_S\sqrt{\frac{n-1}{\chi^2_{\beta,n-1}}} \le \sigma \le \sigma_S\sqrt{\frac{n-1}{\chi^2_{1-\beta,n-1}}} \tag{2}$$

$\chi^2$ is the Confidence Factor based upon the Chi-Squared Distribution.

The results of equation (1) and (2) will produce a range of standard deviation and means values which will include the population model with a 95% confidence. This confidence increases and the range of these values reduces as there is an increase in the amount of data, $n$, as it is collected. Using this range of values it is then possible to choose a combination which will give the worse case Failure or Robustness thresholds. In terms of the Standard Deviation it is the Lower

Limit calculation in (2), $\sigma_L$ , which produces the maximum value of sigma and this will generate a model which produces a greater range of λ values. The means, $\bar{x}_L$ or $\bar{x}_U$ , are chosen so as to give the smallest separation between the Failure threshold and Fault free condition in each case.

## V. Process Monitoring and Analysis

From testing three specific sets of data were collected a the Fault Free, represented by under score F, a set of data in which a rich shift has been introduced to represent the emission failure threshold, represented by an underscore R, and a set of data for the lean shift, represented by an underscore L. This resulted in 6294 sets of results with a normal engine, 102 diagnostic results for the rich shift 106 results for the lean shift.

The first thing to check is that all of the data sets have a Gaussian distribution. This was done using the LilleTest function within MATLAB which performs a Lilliefors test [8, 9] of the default null hypothesis that the samples comes from a Gaussian distribution, against the alternative that it does not come from a Gaussian distribution. The test returns a 1 if it rejects the null hypothesis at the 5% significance level. For the fault free condition the set of data failed this test to future investigate this data is plotted on a Quartile-Quartile (QQ) Plot. This shows the raw data as blue crosses plotted against an ideal Gaussian model which is the red dashed line. This shows that for the bulk of the data between the 5% and 95% percentiles it fits a Gaussian distribution. It is only the tail information of the distribution which does not match this statistical model. From the shape of the tails in Figure 1 it indicates that the data has come from a ‘fat tailed distribution’ where the data extends further than for the tails of a Gaussian distribution. This can be seen by considering the 0.999 and the 0.001 percentile points which lie at points 0.925 and 1.07 respectively and should, for a Gaussian Distribution, lie at 0.94 and 1.06. Even though this statistical model does not accurately fit the data it was decided to assume that the fault free set of data could be considered to be Gaussian initially and then reviewed when the final thresholds for the Rich and Lean have been determined. The risk is by making this assumption that the variance used for the Fault Free Data will under estimate the true risk.

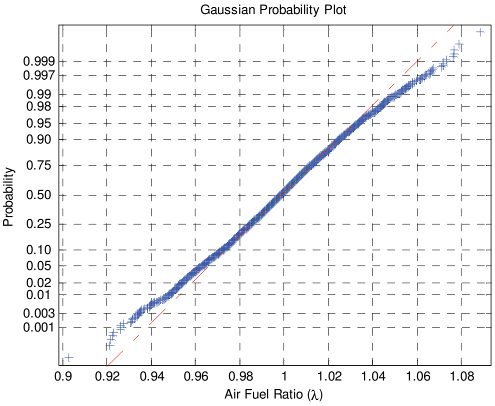

Figure 1: QQ plot for the Fault Free Data

| | $L_F$ | $S_F$ | $U_F$ |
|---|---|---|---|
| $\bar{x}$ | 0.9980 | 0.9985 | 0.9990 |
| Σ | 0.0217 | 0.0213 | 0.0209 |

Table 1: Statistical Model for Fault Free Data ($\beta$ = 0.025)

Table 1 has been calculated for $\beta = \alpha/2 = 0.025$ in Equations (1) and (2). The Standard Deviation $\sigma_{L_F}$ , from Table 1, gives the largest value of sigma and is used to calculate the Robustness Threshold for both the rich and lean sides of the distribution. For the Lean Robustness Threshold the mean $\bar{x}_{U_F}$ was used to give a value of 1.0640, the Rich Robustness Threshold was obtain using $\bar{x}_{L_F}$ which gives a value of 0.9330.

Table 2 shows the Rich Failure model information note that since we are considering a single side threshold then $\beta$ = 0.05. Figure 2 shows the Histogram of the raw Rich Failure data and the red solid line shows the worse case statistical model using $\bar{x}_{U_R}$ and $\sigma_{LR}$ . Using this model the Rich Failure threshold is calculated as 0.8579 and is shown on the graph by the solid vertical red line. The dotted blue vertical line shows the sample Rich Failure threshold of 0.8507 calculated by making use of $\sigma_{SR}$ and $\bar{x}_{SR}$ .

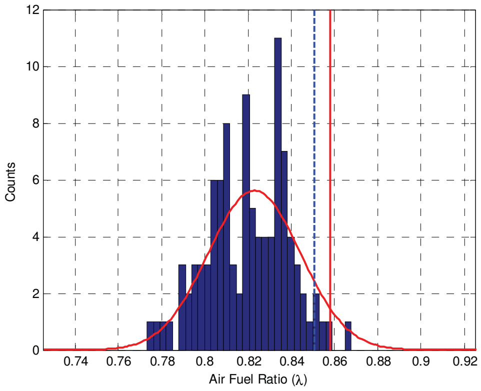

Figure 2: Statistical Results for Rich Failure Data

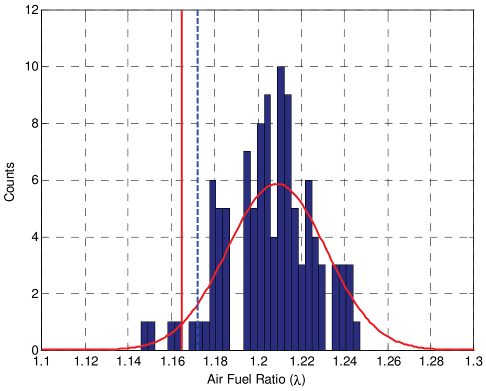

Figure 3: Statistical Results for Lean Failure Data

| | $L_R$ | $S_R$ | $U_R$ |
|---|---|---|---|
| $\bar{x}$ | 0.8166 | 0.8197 | 0.8229 |
| Σ | 0.0214 | 0.0189 | 0.0170 |

Table 2: Statistical Model for Rich Failure Data ($\beta$ = 0.05)

| | $L_L$ | $S_L$ | $U_L$ |
|---|---|---|---|
| $\bar{x}$ | 1.2022 | 1.2055 | 1.2087 |
| Σ | 0.0229 | 0.0203 | 0.0182 |

Table 3: Statistical Model for Lean Failure Data ($\beta$ = 0.05)

Since we most concerned with the issue of falsely flagging a Fault Free System it is useful to take the difference between the Rich Failure Threshold at 0.8579 and the Rich Robustness Threshold at 0.9330 and then determine the amount of sigma separation there is between them. This difference is normalised by dividing by $\sigma_{L_F}$ to determine the amount of separation in terms of sigma and results in a separation of 3.46 $\sigma_{L_F}$

This then provides a clear robust threshold in terms of provide a detection which meets the requirements and provides a significant safety margin against falsely flagging and we have also taken into consideration the variability in the models by making use of the confidence interval

Figure 3 shows the response after introducing a lean failure shift again the graph shows the histogram of the raw data and the solid red line shows the distribution of the worse case statistic model derived from $\bar{x}_{L_L}$ and $\sigma_{L_L}$ in Table 3. The red vertical line shows the Lean Failure Threshold of 1.1647 from this model and the dotted blue vertical line at 1.1723 for derived from $\sigma_{S\,L}$ and $\bar{x}_{S\,L}$. Using the same metric as previously derived the differences between the Lean Failure Threshold and the Lean Robustness Threshold gives a separation of 4.64 $\sigma_{L_F}$ .

From the discussion earlier in the paper it has been highlighted that it can difficult to collect Fault condition so it is useful to be able to assess whether enough data has been collected to ensure that the real distribution of the Fault Condition has been captured. To determine this we have to make the assumption that the Sample model information that we have is the best estimate of the distribution model. So in the Rich Failure case the Sample values of $\sigma_{S\,R}$ and $\bar{x}_{S\,R}$ from Table 2 have been used and the value of n and the subsequent changes made to the t-distribution and Chi-Squared, in equations (1) and (2), can then be used to determine the effect on the threshold calculation.

In Figure 4 the blue solid line shows how the difference between the Rich Failure Threshold and the Nominal Rich Failure Threshold, normalised against the value of $\sigma_{S\,R}$ determined at n = 102, decays as the amount of data increases. The Red dot shows the current point Rich Failure Threshold Delta. In Figure 5 shows the same metric as in Figure 4 but for the Lean Failure Condition.

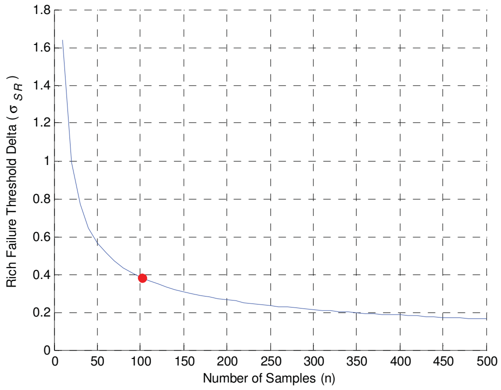

Figure 4: Rich Failure Threshold Delta

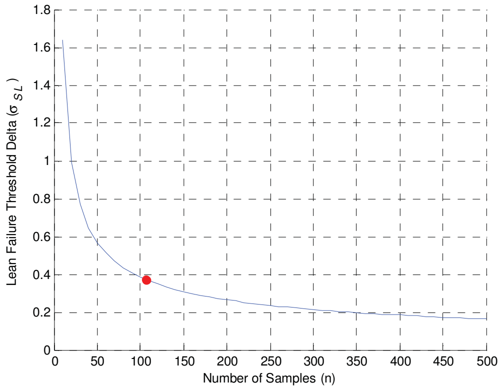

Figure 5: Lean Failure Threshold Delta

From the results shown in Figure 4 and 5 the current set of data obtained at around 100 samples gives an adequate confidence and subsequent testing would not necessarily lead to a significant change in the values of the Failure Thresholds. For example to reduce the current threshold, in both cases, by 50% would require an addition 250 tests.

| | Robust Threshold | Failure Threshold | Separation |
|---|---|---|---|
| Rich | 0.9330 | 0.8579 | $3.46\,\sigma_{L_F}$ |
| Lean | 1.0640 | 1.1647 | $4.64\,\sigma_{L_F}$ . |

Table 4: Summary of the Threshold Information

## VI. Conclusion

The results in Table 4 show the calculated Failure Thresholds and the Robustness Thresholds for Rich and Lean conditions and for this diagnostic there is a significant amount of separation between these two sets of thresholds has enabling the requirements laid out in Section 3 to be met. This amount of separation has reduced the risk of making use of a Gaussian Model to derive the information for the Fault Free set of data. If it were the case that there was not such a separation then further investigation would have to undertaken to understand the reason or determine perhaps a more valid statistical model.

The use of the Confidence Interval in the statistical models and the threshold setting enables the calibrators to determine when they have collected enough data to provide a robust calibration.

*Abstract*—**This paper presents the flight path angle tracking control of the longitudinal dynamics of a generic hypersonic flight vehicle(HFV). Due to the use of digital computers and microprocessors for controls applications, the discrete hypersonic flight control is investigated. The altitude command is transformed into the flight path angle information. The back-stepping scheme is applied for the attitude subsystem which includes flight path angle, pitch angle and pitch rate. The virtual control is designed with nominal feedback and Neural Network (NN) approximation. To use the information of throttle setting, the multi-rate sampling method is employed for the two subsystems where the velocity subsystem is considered as slow dynamics. Under the proposed controller, the semiglobal uniform ultimate boundedness (SGUUB) stability is guaranteed. The simulation is presented to show the effectiveness of the proposed control approach.**

## I. Introduction

Given the widespread use of digital computers and microprocessors for controls applications, the discrete-time case is certainly warranted [1]. For the control of flight vehicle and spacecraft, controller on the basis of continuous system is usually implemented by a digital computer with a certain sampling interval [2], [3]. Since modern aircraft are equipped with digital computers, the controller should be designed in discrete-time form [4]. There are two methods for designing the digital controller. One method, called emulation, designs a controller with the continuous-time system, and then discretizing the controller. The other is to design the controllers directly based on the discrete system. In contrast to the emulation method, the discrete controller is designed in a discrete domain so that the performance of the controller may not depend on the sampling rate and the upper bounds of the NN weight update rates guaranteeing the convergence can be estimated analytically while emulation method is otherwise [5].

In this paper, the discrete hypersonic flight control is analyzed. Hypersonic Flight vehicles are intended to present a reliable and more cost efficient way to access space with dramatic reductions in flight times. The longitudinal model of the dynamics is known to be unstable, non-minimum phase with respect to the regulated output, and affected by significant model uncertainty. In the last decade, considerable research focused on robust and adaptive hypersonic flight control [6], [7]. In [8], the control structure combines the inputs from the pilot model, baseline controller and adaptive controller. Based on the input-output linearization using Lie derivative notation, sliding mode control [9] is designed. The sequential loop closure controller design [10] is based on the decomposition of the equations into functional subsystems. The method followed the approach that combined robust adaptive dynamic inversion with back-stepping arguments to obtain control architecture. In [11], one high gain observer based controller is proposed for HFV control with only one NN to compensate the lumped uncertainty. In [12], the attitude states are considered as fast dynamics and the altitude control is transformed into the flight path angle tracking.

It is illustrated that sometimes the controller based on Euler approximate discrete-time model of the plant is superior to back-stepping controllers based on digital control based on continuous-time plant model [13]. In this way, the discrete HFV model is obtained and the dynamic inversion is applied in [14]. By proper assumptions the discrete model is transformed into the strict-feedback form where some theoretical results have been studied in [15]. For the nonlinearity and the coupling, the nominal part of the dynamics should be considered for the feedback control design to provide good performance. The back-stepping neural design is analyzed in [16], [17]. By considering the uncertainty with Gaussian distribution, the Kriging design [18] is studied. In this paper, we focused on the control of the altitude subsystem. Continued with the work in [16], the altitude tracking is done with flight path angle tracking. The controller is designed with nominal value of the control gain. In this way, there is no need to know the upper bound. By multi-rate sampling design, the throttle setting can be viewed as constant during the attitude subsystem controller design. In this way, the assumption of $Tsin\alpha$ in [16] is eliminated.

This paper is organized as follows. Section II describes the longitudinal dynamics of a generic hypersonic flight vehicle. The strict-feedback form is formulated and the discrete analysis model is obtained in Section III. The brief description of HONN is explained in Section IV. Section V presents the adaptive controller design. The simulation result is included in Section VI. Section VII presents several comments and final remarks.

## II. Hypersonic Aircraft Model

The control-oriented model of the longitudinal dynamics of a generic hypersonic aircraft is considered. This model is comprised of five state variables $X = [V, h, \alpha, \gamma, q]^T$ and two control inputs $U_c = [\delta_e, \beta]^T$ where $V$ is the velocity, $\gamma$ is the flight path angle, $h$ is the altitude, $\alpha$ is the attack angle, $q$ is the pitch rate, $\delta_e$ is elevator deflection and $\beta$ is the throttle setting.

$$\begin{aligned}
\dot{V} &= \frac{T\cos\alpha - D}{m} - \frac{\mu\sin\gamma}{r^2} && (1)\\
\dot{h} &= V\sin\gamma && (2)\\
\dot{\gamma} &= \frac{L + T\sin\alpha}{mV} - \frac{(\mu - V^2 r)\cos\gamma}{Vr^2} && (3)\\
\dot{\alpha} &= q - \dot{\gamma} && (4)\\
\dot{q} &= \frac{M_{yy}}{I_{yy}} && (5)
\end{aligned}$$

where $T$, $D$, $L$ and $M_{yy}$ represent thrust, drag, lift-force and pitching moment respectively, $m$, $I_{yy}$ and $\mu$ represent the mass of aircraft, moment of inertia about pitch axis and gravity constant. $r$ is the radial distance from center of the earth and $r = h + R_E$. The related definition can be found in [9].

This paper focused on the cruise control with no consideration of the reentry process. The main goal of this paper is to design the altitude and velocity controller separately to follow the tracking reference $h_d$ and $V_d$.

## III. System Transformation

### A. Strict-Feedback Formulation

*Assumption 1:* Since $\gamma$ is quite small, we take $\sin\gamma \approx \gamma$ in (2) for simplification.

*Remark 1:* Similar assumption is made in [10] where the value of the flight path angle is set to be inside $[-3°, 3°]$.

The velocity subsystem (1) can be rewritten as

$$\begin{aligned}
\dot{V} &= f_V + g_V u_V\\
u_V &= \beta\\
y_V &= V
\end{aligned} \tag{6}$$

where $f_V = -(D/m + \mu\sin\gamma/r^2) + \bar{q}S \times 0.0224\cos\alpha/m$, $g_V = \bar{q}S \times 0.00336\cos\alpha/m$ if $\beta > 1$. Otherwise $f_V = -(D/m + \mu\sin\gamma/r^2)$, $g_V = \bar{q}S \times 0.02576\cos\alpha/m$.

The tracking error of the altitude is defined as $\tilde{h} = h - h_d$ and the flight path command is chosen as

$$\gamma_d = \arcsin\left[\frac{-k_h\tilde{h} - k_I\int\tilde{h}dt + \dot{h}_d}{V}\right] \tag{7}$$

if $k_h > 0$ and $k_I > 0$ are chosen and the flight-path angle is controlled to follow the reference command $\gamma_d$, the altitude tracking error is regulated to zero exponentially.

Define $X_A = [x_1, x_2, x_3]^T, x_1 = \gamma, x_2 = \theta_p, x_3 = q$ where $\theta_p = \alpha + \gamma$.

Then the strict-feedback form equations of the attitude subsystem (3)-(5) are written as

$$\begin{aligned}
\dot{x}_1 &= f_1(x_1) + g_1(x_1)x_2\\
\dot{x}_2 &= f_2(x_1, x_2) + g_2(x_1, x_2)x_3\\
\dot{x}_3 &= f_3(x_1, x_2, x_3) + g_3(x_1, x_2, x_3)u_A\\
u_A &= \delta_e\\
y &= x_1
\end{aligned} \tag{8}$$

where $f_1 = -(\mu - V^2 r)\cos\gamma/(Vr^2) - \bar{q}S \times 0.6203/(mV) \times \gamma - T sin\alpha$, $g_1 = \bar{q}S \times 0.6203/(mV)$, $f_2 = 0$, $g_2 = 1$, $f_3 = \bar{q}S\bar{c}[C_M(\alpha) + C_M(q) - 0.0292\alpha]/I_{yy}$, $g_3 = 0.0292\bar{q}S\bar{c}/I_{yy}$.

In the analysis [11], the altitude is mainly up to elevator deflection while the velocity is controlled by throttle setting. By command transformation, we know attitude subsystem is controlled by elevator deflection. To obtain the information of $\beta$ from the velocity subsystem, the multi-rate sampling design is employed so that velocity and $\beta$ can be considered as constant during the altitude subsystem controller design. The similar idea is studied in [19] where the airspeed, altitude and flight path angle are selected as slow-dynamics variables and considered invariant during the controller design of the fast dynamics.

The control objective of system (8) is to design an adaptive controller, which makes $\gamma \to \gamma_d$, further $h \to h_d$ and all the signals involved are bounded.

*Assumption 2:* $f_i$ and $g_i$ are unknown smooth functions which can be decomposed into the nominal part $f_{iN}$, $g_{iN}$ and the unknown part $\Delta f_i$, $\Delta g_i$, $i = 1, 3, V$.

### B. Discrete-time Model

By Euler approximation with different sample time period $T_V$ and $T_s$, systems (6) and (8) can be approximated as

$$V(k+1) = V(k) + T_V[f_V(k) + g_V(k)u_V(k)] \tag{9}$$

$$\begin{aligned}
x_1(k+1) &= x_1(k) + T_s[f_1(k) + g_1(k)x_2(k)]\\
x_2(k+1) &= x_2(k) + T_s[f_2(k) + g_2(k)x_3(k)]\\
x_3(k+1) &= x_3(k) + T_s[f_3(k) + g_3(k)u_A(k)]
\end{aligned} \tag{10}$$

Here $T_V$ is selected four times as $T_s$. So during the design of attitude subsystem, the velocity and throttle setting could be considered as constant.

## IV. HONN Approximation

Higher order neural network (HONN) is one kind of linearly parameterized NNs. The structure of HONN is expressed as follows:

$$U(\omega, X) = \omega^T\theta(X) \quad \omega, \theta(X) \in R^N \tag{11}$$

$$\theta_i(X) = \prod_{j\in I_i}[s(X_j)]^{d_{ji}} \tag{12}$$

where $X \subset R^m$ is the input to HONN, $N$ is the NN nodes number, $\{I_1, I_2, ..., I_N\}$ is a collection of $N$ not-ordered subsets of $\{1, 2, ..., m\}$, specified by the designer, $d_{ji}$'s are prescribed nonnegative integers, $\omega$ is an adjustable synaptic weight vector, and $s(X_j)$ is a monotonically increasing and differentiable

sigmoidal function. In this paper, it is chosen as a hyperbolic tangent function, i.e.,$s(X_j) = (e^{X_j} - e^{-X_j})/(e^{X_j} + e^{-X_j})$.
For a desired function $U^*$, it is assumed there exists an ideal weight vector $\omega^*$ such that the smooth function vector can be approximated by an ideal NN on a compact set

$$U^* = \omega^{*T}\theta(X) + \varepsilon(X), \|\varepsilon(X)\| < \varepsilon_M \tag{13}$$

where $\varepsilon(X)$ is the bounded NN approximation error vector and $\varepsilon_M$ is the supreme of $\varepsilon(X)$.

## V. Discrete Control Design

### A. Adaptive NN Control for Attitude Subsystem

The errors are defined as

$$\begin{aligned} z_1(k) &= x_1(k) - x_{1d}(k) && (14)\\ z_2(k) &= x_2(k) - x_{2d}(k) && (15)\\ z_3(k) &= x_3(k) - x_{3d}(k) && (16) \end{aligned}$$

where $x_{2d}(k)$, $x_{3d}(k)$ are the virtual control inputs to be designed.
***Step 1***. From (14),

$$z_1(k+1) = x_1(k) + T_s[f_1(k) + g_1(k)x_2(k)] - x_{1d}(k+1) \tag{17}$$

where $x_{1d}(k+1)$ is acquired from (7).

Since $g_1(k)$ and $f_1(k)$ are unknown, the uncertainty is defined as

$$\begin{aligned} U_1(k) &= -\frac{1}{T_s g_1(k)}[-T_s f_1(k) - x_1(k) + x_{1d}(k+1)]\\ &+ \frac{1}{T_s g_{1N}(k)}[-T_s f_{1N}(k) - x_1(k) + x_{1d}(k)]\\ &= \omega_1^{*T}\theta_1(X_1(k)) + \varepsilon_1(X_1(k)) && (18) \end{aligned}$$

where $X_1(k) = [V(k), x_1(k), h(k), h_d(k), h_d(k+1)]^T$, $f_{1N}(k)$ and $g_{1N}(k)$ are the nominal parts of $f_1(k)$ and $g_1(k)$, $\omega_1^*$ is the optimal parameters for NN to approximate $U_1(k)$ and $\varepsilon_1(X_1)$ is the NN reconstruction error.
Take $x_2(k)$ in (17) as the virtual control input and design its desired value as

$$\begin{aligned} x_{2d}(k) &= \frac{1}{T_s g_{1N}(k)}[c_1 z_1(k) - T_s f_{1N}(k) - x_1(k) + x_{1d}(k)]\\ &+ \hat{\omega}_1^T(k)\theta_1(X_1(k)) && (19) \end{aligned}$$

where $\hat{\omega}_1$ is the estimation of $\omega_1^*$.

Combining (15), (17) and (19), the following equation can be obtained.

$$\begin{aligned} z_1(k+1) &= x_1(k) + T_s[f_1(k) + g_1(k)x_2(k)] - x_{1d}(k+1)\\ &= T_s g_1(k) z_2(k) + T_s g_1(k)[\tilde{\omega}_1^T(k)\theta_1(X_1(k)) - \varepsilon_1(X_1(k))]\\ &+ \frac{g_1(k)}{g_{1N}(k)} c_1 z_1(k) \end{aligned} \tag{20}$$

where $\tilde{\omega}_1(k) = \hat{\omega}_1(k) - \omega_1^*$. The robust updating algorithm for the NN weights is

$$\hat{\omega}_1(k+1) = \hat{\omega}_1(k) - \lambda_1 z_1(k+1)\theta_1(X_1(k)) - \delta_1\hat{\omega}_1(k) \tag{21}$$

where $\lambda_1 > 0$ and $0 < \delta_1 < 1$.

***Step 2***. From(15),

$$z_2(k+1) = x_2(k) + T_s[f_2(k) + g_2(k)x_3(k)] - x_{2d}(k+1) \tag{22}$$

Define $X_2(k) = [X_1^T(k), x_2(k), h_d(k+2)]^T$. From (19), $x_{2d}(k+1)$ involves $x_1(k+1)$, $f_1(k+1)$ , $z_1(k+1)$ and $x_{1d}(k+2)$. It can be concluded that $x_{2d}(k+1)$ is the function of $X_2(k)$ . The uncertainty $U_2(k)$ is defined and can be approximated by NN as

$$U_2(k) = x_{2d}(k) - x_{2d}(k+1) = \omega_2^{*T}\theta_2(X_2(k)) + \varepsilon_2(X_2(k)) \tag{23}$$

where $\omega_2^*$ is the optimal parameters and $\varepsilon_2(X_2(k))$ is the NN reconstruction error.

Take $x_3(k)$ in (22) as the virtual control input and design its desired value as

$$x_{3d}(k) = \frac{1}{T_s g_2(k)}[-x_2(k) + x_{2d}(k) + c_2 z_2(k)] + \hat{\omega}_2^T(k)\theta_2(X_2) \tag{24}$$

where $\hat{\omega}_2$ is the estimation of $\omega_2^*$. The result of (23) and (24) is due to the fact that $f_2 = 0$ and $g_2 = 1$.

The robust updating algorithm for the NN weights is

$$\hat{\omega}_2(k+1) = \hat{\omega}_2(k) - \lambda_2 z_2(k+1)\theta_2(X_2(k)) - \delta_2\hat{\omega}_2(k) \tag{25}$$

where $\lambda_2 > 0$ and $0 < \delta_2 < 1$.

***Step 3***. From (16),

$$z_3(k+1) = x_3(k) + T_s[f_3(k) + g_3(k)u_A(k)] - x_{3d}(k+1) \tag{26}$$

Define $X_3(k) = \left[X_2^T(k), x_3(k), h_d(k+3)\right]^T$. Similarly we can deduce that the uncertainty $U_3(k)$ is the function of $X_3(k)$ and it can be approximated by NN as

$$\begin{aligned} U_3(k) &= -\frac{1}{T_s g_3(k)}[-T_s f_3(k) - x_3(k) + x_{3d}(k+1)]\\ &+ \frac{1}{T_s g_{3N}(k)}[-T_s f_{3N}(k) - x_3(k) + x_{3d}(k)]\\ &= \omega_3^{*T}\theta_3(X_3(k)) + \varepsilon_3(X_3(k)) && (27) \end{aligned}$$

where $\omega_3^*$ is the optimal parameters for NN to approximate $U_3(k)$ and $\varepsilon_3(X_3(k))$ is the NN reconstruction error. The actual control input is designed as

$$\begin{aligned} u_A(k) &= \frac{1}{T_s g_{3N}(k)}[-T_s f_{3N}(k) - x_3(k) + x_{3d}(k) + c_3 z_3(k)]\\ &+ \hat{\omega}_3^T(k)\theta_3(X_3(k)) && (28) \end{aligned}$$

where $\hat{\omega}_3$ is the estimation of $\omega_3^*$. where $\tilde{\omega}_3(k) = \hat{\omega}_3(k) - \omega_3^*$. The update law for the NN weights is

$$\hat{\omega}_3(k+1) = \hat{\omega}_3(k) - \lambda_3 z_3(k+1)\theta_3(X_3(k)) - \delta_3\hat{\omega}_3(k) \tag{29}$$

where $\lambda_3 > 0$ and $0 < \delta_3 < 1$.

*Theorem 1:* Considering system (10) with the controller (28), virtual design (19), (24) and the update law (21), (25), (29), all the signals involved are semiglobal uniform ultimate bounded.

The proof is quite similar to [16] and thus omitted here to save space.

### B. Adaptive NN Control for Velocity Subsystem

Define $X_V(k) = [V(k), x_1(k), x_2(k), x_3(k), x_4(k), V_d(k+1)]^T$ and $z_V(k) = V(k) - V_d(k)$

$$\begin{aligned} z_V(k+1) &= V(k+1) - V_d(k+1) \\ &= V(k) + T_V[f_V(k) + g_V(k)u_V(k)] - V_d(k+1) \end{aligned} \tag{30}$$

The control input is designed as

$$\begin{aligned} u_V(k) &= \frac{1}{T_V g_{VN}}[-T_V f_{VN}(k) - V(k) + V_d(k+1)] \\ &+ \hat{\omega}_V^T(k)\theta_V(X_V(k)) \end{aligned} \tag{31}$$

where $\hat{\omega}_V$ is the estimation of $\omega_V^*$.

The robust updating law for NN weights is

$$\hat{\omega}_V(k+1) = \hat{\omega}_V(k) - \lambda_V z_V(k+1)\theta_V(X_V(k)) - \delta_V\hat{\omega}_V(k) \tag{32}$$

where $\lambda_V > 0$ and $0 < \delta_V < 1$.

*Theorem 2:* Considering system (9) with the controller (31) and the update law (32), the velocity is semiglobal uniform ultimate bounded. The proof is omitted here.

## VI. Simulations

In this section, we verify the effectiveness and performance of the proposed adaptive neural controller. The flight of the vehicle is at trimmed cruise condition $M = 15$, $V = 15,060$ft/s, $h = 110,000$ft. Reference commands are generated by the filter:

$$\frac{h_d}{h_c} = \frac{\omega_{n1}\omega_{n2}^2}{(s+\omega_{n1})(s^2 + 2\varepsilon_c\omega_{n2}s + \omega_{n2}^2)} \tag{33}$$

$$\frac{V_d}{V_c} = \frac{\omega_{n3}}{(s+\omega_{n3})} \tag{34}$$

where $\omega_{n1} = 0.2$, $\omega_{n2} = 0.2$, $\varepsilon_c = 0.7$, $\omega_{n3} = 0.1$.

The parameters for the controller are selected as $k_h = 0.2$, $k_I = 0.1$, $\lambda_1 = 0.05$, $\lambda_2 = 0.05$, $\lambda_3 = 0.05$, $\delta_1 = 0.02$, $\delta_2 = 0.02$, $\delta_3 = 0.02$, $T_s = 0.03$s, $T_V = 0.12$s, $c_1 = 0.9$, $c_2 = 0.8$, $c_3 = 0.2$, $c_V = 0.6$.

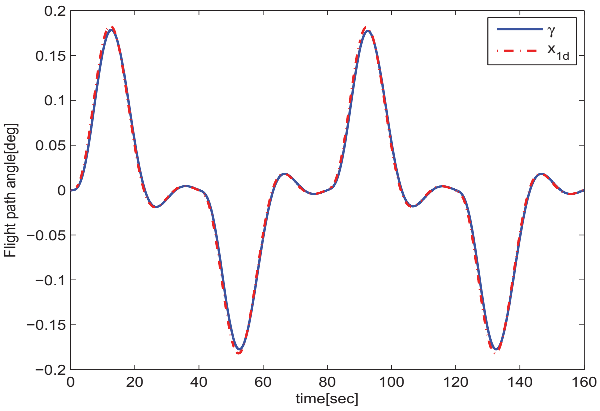

Fig. 9. Square Signal Tracking: Flight Path Angle Tracking

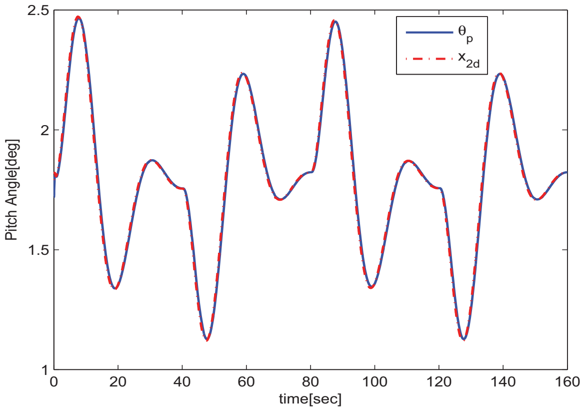

Fig. 10. Square Signal Tracking: Attack Angle

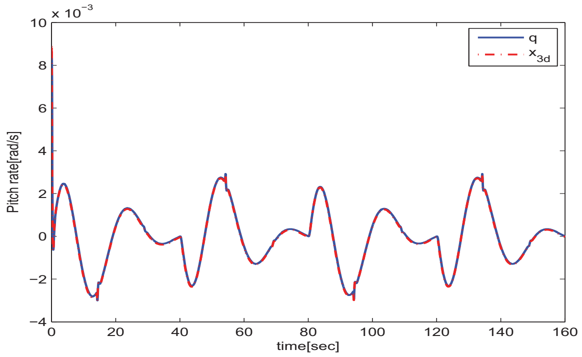

Fig. 11. Square Signal Tracking: Pitch Rate

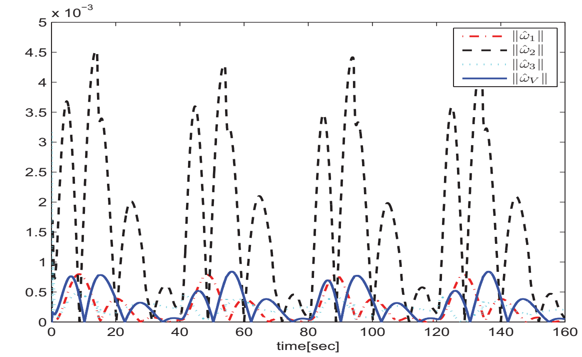

Fig. 12. Square Signal Tracking: Trajectories of NN weights

### A. Step Tracking

Fig.1 depicts the response performance that the altitude controller tracks the step change with magnitude 500ft while the velocity steps from 15060ft/s to 15160ft/s. The control inputs of the elevator deflection and the throttle setting are shown in Fig.2. Flight path angle tracks the reference command very well in Fig.3 so that the system tracks the altitude step change. From the pitch angle in Fig.4 and pitch rate response in Fig.5, we know the related system states are bounded. Also we find the NN weights are bounded in Fig.6.

### B. Square Signal Tracking

The system tracks the square signal with amplitudes 500ft and period 80 seconds while velocity is maintained in the neighborhood of 15060ft/s. The results are referred to Fig.7-12. It can be observed that all the system states are bounded and the velocity is regulated with a small error around the initial value. Also it is noted that the system states flight path angle, pitch angle, pitch rate perform good tracking response of altitude command, $x_{2d}$, $x_{3d}$ separately.

## VII. Conclusions

The altitude control of HFV is transformed into the flight path angle tracking. The two dynamics are sampled by different rate. In this way, the velocity and throttle setting from the slow dynamics can be employed for the design of attitude subsystem. Simulation results show the effectiveness of the method.

*Abstract*—**The aim of the work presented in this paper is to introduce a method for assisting the recovery of a given system in case of failure detection. The proposed method rely on a graph-based algorithm that allows the identification of the alternative system configuration. In this way, the method guarantees the system under study functionalities/missions even in case of fault. The method is detailed in the sequel. Furthermore, in order to provide user with automated means which are at the same time simple, intuitive and rigorous, the whole of the developed mechanisms have been implemented in a prototype tool with an intuitive graphical interface that offers interesting facilities in terms of system recovery. The method is illustrated using an intelligent and autonomous vehicle case study.**

## I. Introduction

Life-critical systems are systems that its dysfunction could cause human-life death as well as an important equipment damage or loss. Thereby, this kind of system (e.g. transportation systems, intelligent and autonomous vehicle, nuclear plants, manufacturing systems, medical devices) must achieve a high level of robustness, availability, reliability and safety. Usually, system life-cycle could be divided into two main phases : before implementation and after implementation. The former phase rely on some research topics such as specification, modelling design and V&V (validation and verification). For the later phase, one can find maintenance and system recovery in case of failure detection. In our case, we use system recovery to design a re-configuration or a new arrangement of the system functional units in case of failure. Various are the causes of failure: performance problems like access to shared resource (resource contention), hardware faults, software bugs, system operators misconfiguration, . . . [1]. Nevertheless, all failure causes are often due to a material, soft dysfunction or operator manipulation.

Given the human/material impact of critical system dysfunction, such systems must guarantee the availability of its services/missions. Availability express the quality of being at hand when needed. This including the case when failure occur. Therefore, a recovery technique is strangely recommended. The aim of the work presented here is to guide the user during the system recovery and control phase.

Intelligent and autonomous vehicle (IAV) is a vehicle that is expected to achieve different tasks without the intervention of a human operator. Several projects rely on IAV but the most famous ones are the NASA's rovers, for instance the Mars Exploration Rover Mission (MER) [3]. MER is an ongoing robotic space mission involving two rovers, Spirit and Opportunity, exploring the planet Mars. It began in 2003 and its cost raises to more than US$ 900 million. Actually, to guarantee expected tasks, IAV rely on set of services provided by several hardware components (sensors, actuators, . . . ) as well as software components. Nevertheless, due to failures, it is possible that one or more services are no longer available and thereby the achievement of some tasks becomes no longer guaranteed. IAV design rely on fault tolerant control procedures in order to define strategies allowing the system to continue its operations with the required performances despite component faults [4].

As mentioned previously in this paper, we focus on the system recovery step in case of failure detection. In fact, the idea is to propose assisting means that are easy to manipulate and, at the same time, accurate. However, the more accurate and rigorous a notation is, the more abstract and difficult to handle and understand it becomes. Therefore, one of the challenges that we faced while dealing with this work was to look at both intuition/simplicity and rigour/accuracy. To deal with this, we propose a graph-based algorithm able to cover system configuration and able to identify the alternative configuration in case of system-down. However, in order to hide all the formal aspects -met when dealing with system recovery- from user, a GUI tool have been implemented to automate this step.

The paper is organized as follows: in Section II, an overview of the context and related works is given. In Section III, we present the algorithm that we have proposed. The developed tool is introduced in Section IV. The method is illustrated using an intelligent and autonomous vehicle case study in section V before concluding and suggesting some future works in Section VI.

## II. Context and Related Work

Availability of a system is its capacity to achieve its missions/services in the occurrence of the failure of (or one or more faults within) some of its components [5]. One of the main properties that characterize availability is fault-tolerance [6]. Here, we focus on life-critical systems and thereby, given their failure cost, fault-tolerance is particularly sought-after such systems. In practice, some fault can cause a system failure by propagating the fault to the rest of the system. Therefore, fault tolerant systems (FTS) must deal with multiple failure types and thereby, must achieve fault isolation capacity and reversion modes availability (redundancy). Actually, FTS are typically based on three main concepts namely replication, redundancy and diversity [6]. These concepts could been defined as follows:

- Replication means providing multiple instances of the same system. Then, tasks/jobs are directed to all system instances in parallel. The correct result is determined by a quorum;
- Redundancy means providing multiple instances of the same system/service and switching to one of the remaining non-faulty instances, in case of a failure-detection;
- Diversity means providing various system implementations in order to deal with with errors in some specific implementation.

It should noticed that before recovery can be carried, one must first detect and diagnose the failure. Indeed, failure detection is to determine the instances while a system is facing dysfunctions. Afterwards comes the failure diagnosis which allow to locate the source of detected failure. Failure detection as well as failure diagnosis are not in the scope of this paper.

Severals studies dealing with system recovery have been proposed and published [6], [7], [8], [9], [10], [11]. Unlike this meantionned studies, our work propose a graph-based approach to tackle the system recovery issue. Furthermore, a GUI tool have been implemented to automate this step.

## III. Graph-based Method for System Recovery

### A. Idea

Let us here recall the aim of our study: we want to provide the user with simple means for assisting the system-recovery in case of failure detection. Our idea is to elaborate a supporting approach which hides the formal foundation to the user. Concretely, we will develop a GUI-tool that automate all the steps of system-recovery procedure.

The idea is to express the service-architecture of a system with a (directed) graph. In this graph the root element represents the system while the leaf represent the elementary services. We assume that a system is defined as a (non-empty) set of exploitation modes. At a given instance, only one exploitation mode is active. Each exploitation mode is composed of a (non-empty) set of missions. All missions of active exploitation mode should be active. Multiple versions are defined for each mission and thereby, at a given instant, only one version is active. A mission version is composed of (non-empty) set of service that, all of them, should be active. Various version of each service could be defined but only one service version is active at a given instance. A version service is (non-empty) set of elementary services that should be active, all of them. This description could be expressed as follow:

| | |
|---|---|
| **system** | = OR({Exploitation-Mode}) |
| **Exploitation-Mode** | = AND({Mission}) |
| **Missions** | = OR({Version-Mission}) |
| **Version-Mission** | = AND({Service}) |
| **Service** | = OR({Version-Service}) |
| **Version-Service** | = AND({Elementary-Service}) |

Where

- $E = AND$(s) means that an element $E$ is active if all the elements composing it are active and vice-versa;
- $E = OR$(s) means that an element $E$ is active if one and only one of elements composing it is active and vice-versa.

### B. Foundations and Problem's Formalization

A graph $\mathcal{G}$ [12] is a pair $\mathcal{G}$ = ($\mathcal{V}$,$\mathcal{E}$) where

- $\mathcal{V}$ is a finite set of vertices (nodes), and
- $\mathcal{E}$ is the set of edges, formed by pairs of vertices, $\mathcal{E}$ is a subset of $\mathcal{P}_2$(V) ($\mathcal{E} \subseteq (\mathcal{V} \times \mathcal{V})$).

Graphically, a graph is pictured by drawing a four-square (or point) for each vertex and representing each edge by a curve joining its endpoints.

Usually, *a simple graph* denotes a graph having no loops or multiple edges where each edge $e \in \mathcal{E}$ can be specified by its endpoints $(a, b) \in \mathcal{V}$ and is denoted $e = ab$. In this case, we say $a$ and $b$ are *adjacent*. Thereby, a path is defined as a set of consecutive and ordered nodes so that two nodes are adjacent if and only if they are consecutive in the ordering.

A graph variant is called directed graphs $\mathcal{D}$ = ($\mathcal{V}$, $\mathcal{E}$), where the edges have a direction. In other words, edges are ordered and $ab \neq ba$. Graphically, the edges are drawn as arrows.

### C. System description

In our case, a system is defined as directed graph $\mathcal{DS}$=($\mathcal{V}$, $\mathcal{E}$) where

- $\mathcal{V}$ is a finite set of nodes, $\mathcal{V} = Sys \cup EM \cup M \cup VM \cup S \cup VS \cup ES$:
    1) $Sys$ is the root element of the system under study,
    2) $EM$ is the set of exploitation modes of the system under study,
    3) $M$ is the set of missions defined by $EM$,

4) *VM* is the set of mission version (for each mission, one can define at least one mission version),
5) *S* is the set of services composing missions,
6) *VS* is the set of service version (for each service, one can define at least one service version),
7) *ES* is the set of all elementary services proposed by the system.

- $\mathcal{E}$ is a finite set of edges, $\mathcal{E} \subseteq (Sys \times EM) \cup (EM \times M) \cup (M \times VM) \cup (VM \times S) \cup (S \times VS) \cup (VS \times ES)$.

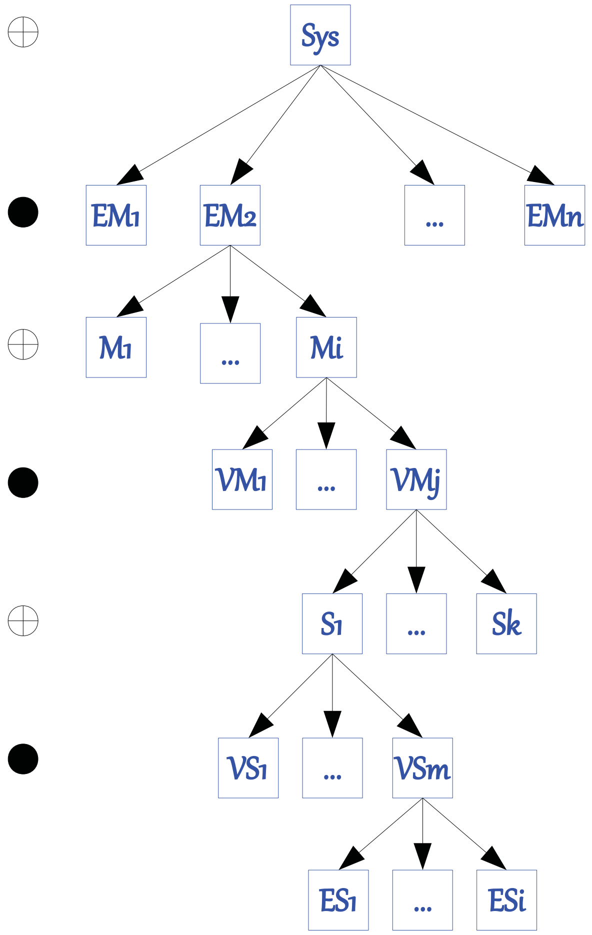

Fig. 1. System description as a directed graph

Figure 1 depicts graphically the system definition given in this section. To this definition, we add a set of binary relations (using AND and OR binary operators) between elements. Indeed, these relations define the type of composition between nodes, given above in section III-A. Actually, for each element type (node), a symbol is linked. Two kind of symbols are used: ⊕ and ●. Node linked to ⊕ is defined as OR-composition of its children. In the same way, node linked to ● is defined as AND-composition of its children.

### D. Algorithm

Failure detection is the task of identifying system dysfunction. Different source of failure could be identified in a given system. A recovery step is switching to an exploitation mode where all (or a part) of system capabilities/facilities are guaranteed in case of failure. Thereby, the exact cause of error is often not required for recovery to take place. Nevertheless, an automated approach for the recovery step is necessary in order to improve system availability. In this section, we propose an algorithm that automate this step. Given a graph model of the system under study and given the detected failure, the algorithm determine and update the list of the alternative exploitation modes. Actually, based on the system graph, the algorithm determine a sub-graph (recovery tree) that represent the non-faulty nodes.

In practice, for each node, we add two attributes: *statut* and *activity*. *Statut* denotes the statement of a node: *functional* or *not-functional*, where *activity* denotes the activity statement of a node: *active* or *not-active*. Furthermore, the approach that we propose require that the failure lists all the element that are no longer available. In other word, the failure should be defined as the set of nodes that are no longer available in the current system description model.

The recovery algorithm rely on two parameters, namely the system under study graph and the failure (a list of faulty elements), and is composed of three main functions and is conducted as follow:

1) the *statut* attribute of all faulty element is set to *not-functional* within the graph model of the system under study,
2) For each node n in the list of faulty elements (the detected failure), the failure spread function, *FS(n)*, is carried,
3) Determine alternative exploitation mode

**Failure spread function of a node n: *FS(n)***

**Step 1:** Set the *statut* attribute all children of n to *non-functional*,
**Step 2:** Set the *statut* attribute of n to *non-functional*,
**Step 3:** If parent of n is an AND-composition type element, then

1) n ← Parent_of(n),
2) go to **Step 2**.

**Step 4:** If parent of n is an OR-composition type element and if all sibling of node "n" are *non-fonctionnel*,then

1) n ← Parent_of(n),
2) go to **Step 2**.

**Determine alternative exploitation mode**

Once the failure is spread, the next step is to determine the alternative exploitation modes that could be activated. Actually, the aim of this task is to determine the sub-graph where all nodes have a *statut* attribute value as *functional*. In other words, the alternative graph is composed only by nodes that statut is *functional*.

Let $\mathcal{G} = (\mathcal{V},\mathcal{E})$ be the graph of system under study and let $\mathcal{G}' = (\mathcal{V}',\mathcal{E}')$ be the sub-graph of $\mathcal{G}$ where all nodes are *functional* and is determined as follow:

**Step 0:** $\mathcal{V}' = \emptyset \wedge \mathcal{E}' = \emptyset$,
**Step 1:** if root of $\mathcal{G}$ is faulty, exit algorithm
**Step 2:** the root of $\mathcal{G}$ is chosen and is added to $\mathcal{G}'$,
**Step 3:** a walk[1] $\omega$ that starts from the chosen node is constructed by adding only *functional* nodes.
**Step 4:** if all nodes of $\mathcal{G}$ are tested, then the walk $\omega$ represents the graph $\mathcal{G}'$ (break algorithm) else go to step 5,
**Step 5:** Select the parent of the last node of $\omega$, go to **Step 6**
**Step 6:** A walk $\omega'$ that starts from the chosen node is constructed by adding only *functional* nodes.
**Step 7:** $\omega \leftarrow$ concatenate($\omega$,$\omega'$). Go to **Step 4**

It is worthy to notice that the obtained walk is a connected graph $\mathcal{G}'$ since the start node of this function is the root node. This connected graph is equivalent to the *spanning tree* for the undirected graph representation of graph $\mathcal{G}$. Once the *spanning tree* is returned, a product of all possible exploitation mode configuration is computed based on it. Thereby, from the list of all possible configuration, the user (operator) could choose one (and only one) to activate.

## IV. Recovery Tool

The various mechanisms we have developed have been implemented within a software tool. This tool guides the user during the recovery step, it offers a quite intuitive graphical user interface. Actually, the tool rely on two main elements:

- Recovery algorithm: first, the developed tool displays the system description and lists its various parameters. Indeed, as shown above in the paper, the system description is based on a graph theory. A graphic representation of this graph is done ones its description (graph description of the system to check) is loaded. This representation is made on a tab within the recovery tool. Then, based on the algorithm discussed in section III-D and given a failure, the tool can automatically determine all possible alternative exploitation modes. Finally, the switch to the selected exploitation mode is carried.
- Data structure: since we aim that the developed tool can be used in combination with other tools within a global system supervision and control approach, we have chosen XML (Extensible Markup Language) [13] standard format for the input/output files. The main advantage of using the standard XML is that format of the encoding documents is both human-readable and machine-readable. Actualy, our tool rely on three different files: a system description which is an input/output file, the initial configuration file and the failure file, both are input files. The corresponding structure of each file has been defined by an XML schema. Listings 1, 2 and 3 define respectively the XML schema for the system description, the initial configuration and the failure.

Listing 1. System XML schema

```

        eservice*)>
```

In the sequel we will discuss the steps of a recovery process and we show how the tool facilities are helpful and useful when carrying this process (figure 2). From the menu bar (green box),

1) First, the user should start by loading the system specification. The uploaded description will be then drawn in the shape of tree (blue box),
2) Once the system description is uploaded, an initial configuration should be selected. In the same way, the initial configuration is then represented in the shape of tree (black box),

[1] A walk is a list $v_0, e_1, v_1 \dots e_n, v_n$ of nodes and edges such that for $1 \leqslant i \leqslant n$, the edge $e_i$ has endpoints $v_{i-1}$ and $v_i$.

3) Then, relying on the uploaded failure file, the recovery algorithm is carried automatically. Afterwards, a box showing (red box) all possible exploitation mode is shown and from which a system mode configuration could be selected (to update the current configuration.

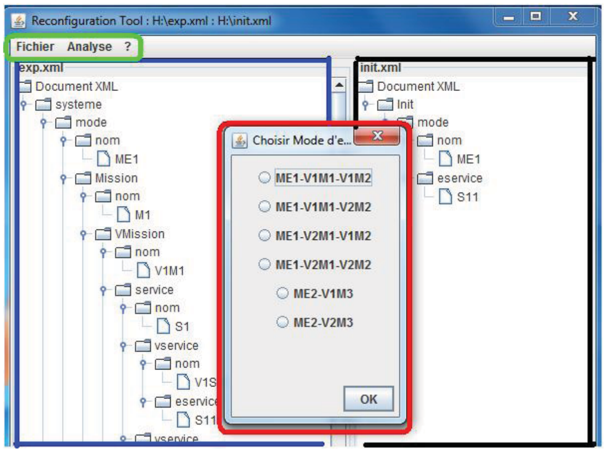

Fig. 2. Main GUI of the developed tool

In order to illustrate all this steps an IAV case study is presented hereafter.

## V. Application to IAV system

### A. System description

In real environment, an IAV could be repaired after the fault detection and isolation is carried. Nevertheless, within some critical environments, where the intervention (the necessary repairs) of a human operator is impossible, fault tolerance property must be provided to the IAV. In this case, IAV must be kept continuously operating even with a fault, such as when IAV operating in distant and/or dangerous areas. Consequently, IAV systems rely on service (component) redundancy in order to guarantee fault tolerance property. For illustration, let us consider an IAV described (Figure 3[2]) as follows :

- RoBuCar can carry two different exploitation modes : normal mode and degraded mode.
- Unlike normal mode where the four wheels are used, degraded mode rely on three or two wheels. Two main differences that distinguish the two exploitation modes: the maximum authorized speed and the weight of the transported goods for each mode.
- RoBuCar is expected to provide several missions : moving on, moving back, curbing, . . .
- Each wheel is equipped with two electrical motors : only one is used to move the wheel. The second motor is used in case of dysfunction of the first motor.
- To move a wheel, four services are required : (1) the generation of an electrical power, (2) the conversion of the electrical power to a mechanical one, (3) the transmission of the mechanical energy to the tire and (4) a measurement service required to control the motor in closed loop.
  1) The generation of an electrical power rely on three elementary services namely: (a) supply the motor, (b) induce an electrical power and (c) limit the electrical current.
  2) The conversion of the electrical power to a mechanical one is composed by one elementary service.
  3) The transmission of the mechanical energy to the tire is composed of two elementary services namely: (a) keep all the pieces in rotation and (b) load service.
  4) The measurement service is composed of three elementary services namely: (a) measure the electrical current, (b) measure the velocity and (c) measure distances.

Let us recall that, in order to keep system operating even in case of fault, service (component) redundancy is essential. Therefore, different versions of the same service as well as of the same mission are available.

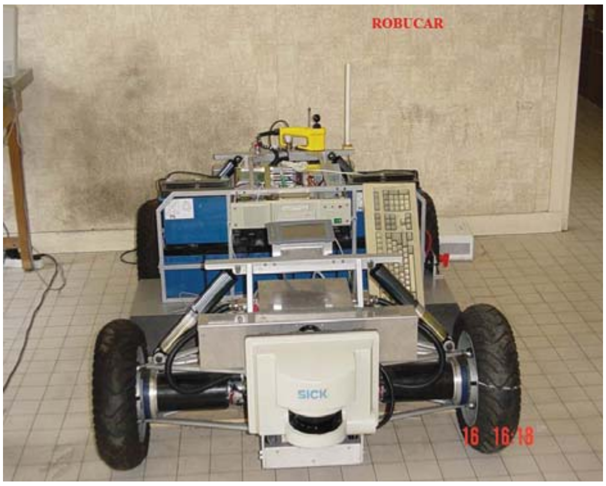

Fig. 3. RoBuCar

### B. Recovery procedure

The service graph associated to the RoBuCar system described above is depicted graphically in figure 4 (for simplicity reason, some details are omitted). The XML file describing this graph is used to carry on the recovery tool. Afterwards, in case of a failure detection, the recovery tool is carried.

For example, suppose that one of the four wheels is no longer available. In other words one of the two

[2] RoBuCar : is an IAV at LAGIS laboratory built by the Robosoft Company http://lagis.ec-lille.fr/

electrical motors that equippe the wheel is no longer available. The XML file describing this failure is defined according to the XML schema given above. The failure XML file is needed by the recovery tool. Once the failure file is loaded, the tool, automatically, finds alternative exploitation modes to keep the vehicle working despite the failure. In our case, two alternative exploitation modes are retuned :

1) Keep the "normal mode" by proposing to activate the second electrical motor of the wheel.
2) Skip to the "degraded mode" where only three wheel are used.

The main advantage is that the procedure is automatic and rely on standard format (XML) for systems exchange (the system description, the failure description, . . . ). Therefore, its integration in operating system supervision approach can easily be done.

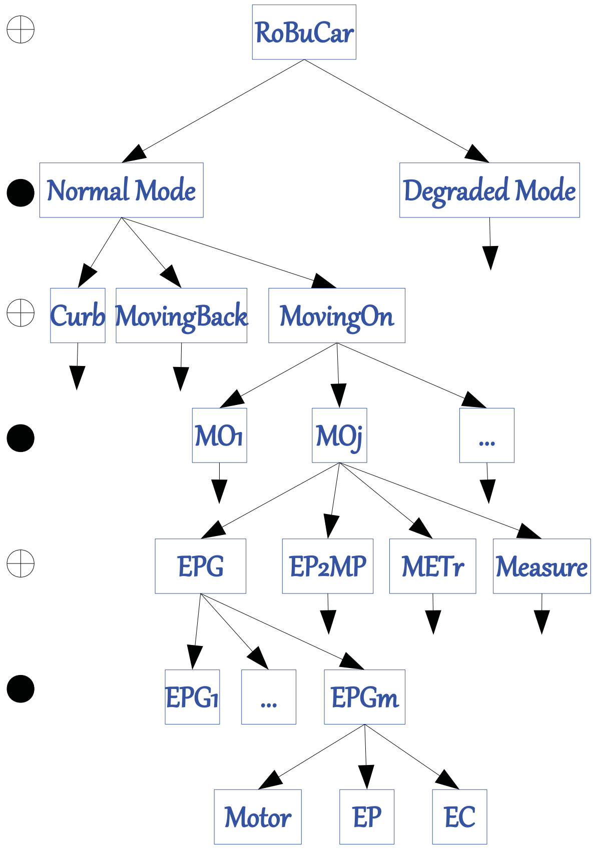

Fig. 4. Simplified version of the graph service of the RoBuCar

Therefore, the method allows to keep IAV continuously operating even with failures. In practice, this is very interesting specially for IAV operating in distant or/and dangerous areas where human cannot operate.

## VI. Conclusions

In this paper we aim at introducing a means to assist and guide the user while carrying the system recovery in case of failure detection. The proposed approach rely on the graph theory. The main advantage of this notation that is formal and thereby, automatic tool using this notation could implemented. Actually, we started by proposing a graph-based description of the study system. Then, we defined an algorithm for the recovery system in case of failure detection. All proposed mechanisms we have developed have been implemented within a software tool. In order to illustrate the developed method an intelligent and automatic vehicle (IAV) case study was presented. First, a textual description of system was given. Then, the service graph is depicted on which the recovery tool is carried. Although, within some critical environments, where the intervention of a human operator is not possible, IAV must be kept continuously operating even with a fault, such as operating in distant and/or dangerous areas. Here we showed how the developped approach could, automatically, be used to detremine alternative exploitation modes.

***Abstract*—Low adhesion in the wheel/rail interface of railway vehicles creates safety and punctuality issues in terms of missed station stops and signals passed at danger. RSSB project T959 is tasked with developing advanced monitoring techniques for the detection of adhesion in this key interface. A number of techniques were developed and initially tested on simplified models of a rail vehicle. The efficacy of these techniques is now being tested with more representative data produced by multi-bodied physics simulation package Vampire. This paper therefore covers the outcomes of the Vampire testing, initial application of a Kalman-Bucy filter creep force estimator to the Vampire data, and application of a data comparison method based upon the Sprague and Geers method, also to the Vampire data.**

## I. Introduction

Low adhesion in the wheel/rail contact of railway vehicles is a current issue occupying the railway industry. This is commonly reported as the ‘leaves on the line’ issue and can create large safety and punctuality issues as rail vehicles fail to stop at stations or pass signals at danger. RSSB managed project T959 [7] is tasked with finding methods of estimating the available adhesion in the wheel/rail interface using modest cost vehicle-mounted sensor sets and advanced filtering applied to in-service vehicles. Knowledge of this would allow numerous commercial benefits such as targeting mitigation methods more efficiently and scheduling rail services to make best potential use of the available adhesion.

Early stages of project T959 investigated a number of low adhesion estimation techniques as applied to simplified plan view dynamics models of typical railway vehicles and were highlighted in [9]. The primary amongst these methods was application of a Kalman-Bucy filter (KBF) [3] which was used to estimate creep forces (longitudinal and lateral forces arising from contact mechanics of the wheel-rail interface), that were then post-processed to imply an adhesion level. Additional techniques were multiple/interacting Kalman filters and data comparison techniques. The efficacy of these methods is now being tested on more representative data produced through a multi-bodied simulation (MBS) package Vampire, success of which will lead to full scale physical testing on a fully instrumented rail vehicle.

This paper therefore covers: brief outcomes of the Vampire simulations and how these compare to the MATLAB/Simulink modelling; initial application of the KBF technique and current issues; and finally a data driven method of non-model based comparison currently being developed using the Sprague and Geers metric [8].

## II. Vampire multi-bodied simulation

The current phase of the project is using data produced by the MBS package Vampire, [1]. The data produced from the package includes the full nonlinearity of the suspension system, as well as the nonlinearity in the wheel/rail contact. It also encapsulates any interaction of the vertical suspension components with the lateral and yaw suspension.

### A. Vehicle selection

The vehicle selected for testing is the British Rail Mk.3 coach. This vehicle was selected due to: vehicle models being readily available; and the physical testing will be likely to take place with this vehicle.

Parameters were interpreted from the MBS model to fit with the simpler plan view lateral and yaw models used for the filter design (Figure 1(a) for the primary suspension and Figure 1(b) for the secondary suspension, with parameter values shown in Table I). The Mk.3 coach is an older form of coach with many features than are no longer incorporated in vehicle design. In particular the secondary yaw damper (that increases the critical speed of bogie instability [11]) is a friction damper rather than the more common viscous damper. Due to the discontinuous nature of this component it adds a significant nonlinearity to the system that cannot be incorporated easily in a state space model.

TABLE I
MK.3 COACH INTERPRETED PARAMETERS

### B. Wheel/rail contact adhesion conditions and test runs

As highlighted in [9] the shape of the creep curves is critical to the detection of areas of low adhesion. It is assumed that the initial slope of the creep curve is constant for all adhesion conditions and that the differentiating factor is the level of creep saturation, [2]. However, as first highlighted in [5] and subsequently verified using the University of Sheffield SUROS twin-disk machine [10], the initial slope of the creep curve reduces as the adhesion conditions reduce, meaning changes in adhesion can be determined in 'normal' running and not just when the contact forces are saturated. Therefore four adhesion condition creep curves were set at dry, wet, low and very low levels for the Vampire simulation testing, Figure 2. These can be thought of as relating to friction coefficients of 0.56, 0.32, 0.072 and 0.038 respectively.

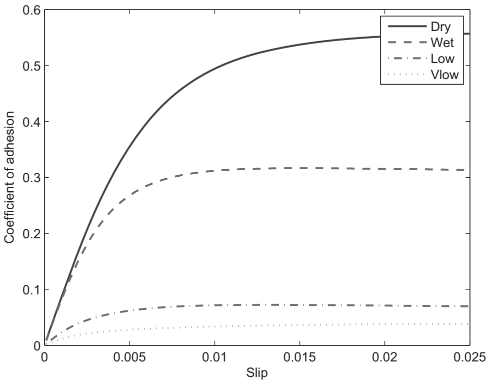

Fig. 2. Creep curves developed from the University of Sheffield SUROS twin disk machine

As with any such form of simulation there are a huge number of potential test combinations. The available variables were narrowed down to: track conditions (straight line, 200 $km/h$ design speed); vehicle speed (100 $km/h$ and 200 $km/h$); track irregularity sizes (full scale and half scale); and adhesion levels (constant, step changes and continuously varying).

### C. Vampire modelling observations

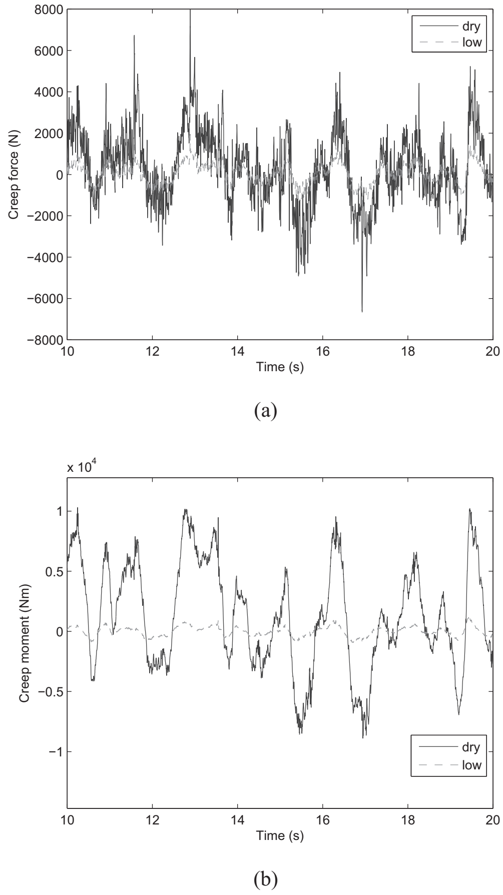
MATLAB/Simulink modelling in [9] demonstrated that the creep forces in the wheel/rail contact reduce as the adhesion level reduces. This trend is repeated with the Vampire simulation, Figure 3(a), for the lateral creep forces of the front wheelset of the front bogie. These tests were performed at a vehicle speed of 200 $km/h$ and with full sized track irregularity where there is a drop in the RMS of the lateral creep force from 1340 $N$ for the dry adhesion case to 300 $N$ for the very low adhesion case. However in the lateral case there is a constant 'gravitational' stiffness force that arises from the profiling of the wheel and varies little with adhesion conditions. This has an RMS value of 1300 $N$, therefore masking changes in the creep forces when estimated in combination. The creep moment demonstrates an even larger change in RMS between the dry adhesion case, 2900 $Nm$, and the very low adhesion case, 310 $Nm$, shown in Figure 3(b). Here gravitational moment is negligible.

## III. CREEP FORCE ESTIMATION

The KBF method of creep force estimation uses a simplified full vehicle model or half vehicle model. The latter approach is favourable due to potential reduction in sensors required and associated reduced order of the model.

### A. Open loop model comparison, half vehicle model

The open loop estimator model is first validated against the Vampire simulation outputs. The creep force estimator model is output only and does not include any terms from the track irregularity that would be costly to measure in practice. In order to test the open loop estimator model the



(a)

(b)

Fig. 3. Vampire modelling creep reductions, (a) lateral, (b) yaw

state space format is subtly modified to include the track irregularities as generated by the Vampire simulation model. The suspension models are linear formations and follow the simplified suspension layouts of Figures 1(a) and 1(b). The lateral and yaw dynamic equations of each wheelset are

$$m_w \ddot{y}_w = F_s + F_g + F_c \tag{1}$$

$$I_w \ddot{\psi}_w = M_s + M_g + M_c \tag{2}$$

where $m_w$ is the mass of the wheelset, $\ddot{y}_w$ is the lateral acceleration of the wheelset, $F_s$ is the lateral primary suspension forces, $F_g$ is the lateral gravitational stiffness, $F_c$ is the lateral creep force, $I_w$ is the moment of inertia of the wheelset, $\ddot{\psi}_w$ is the yaw acceleration of the wheelset, $M_s$ is the primary suspension yaw moment, $M_g$ is the gravitational moment and $M_c$ is the creep moment. For this linear estimator model, the open loop tests use the creep forces and moments of Kalker [2]

$$F_c = 2f_{22}\psi_w - \frac{2f_{22}}{V}\dot{y}_w \tag{3}$$

$$M_c = -\frac{2l\lambda f_{11}}{r_0}\left(y_w - d_r\right) - \frac{2l^2 f_{11}}{V}\dot{\psi}_w \tag{4}$$

where $f_{11}$ is the longitudinal creep coefficient (5770000 $N$ for the dry adhesion case, and 339000 $N$ for the very low adhesion case), $f_{22}$ is the lateral creep coefficient (5770000 $N$ for the dry adhesion case, and 339000 $N$ for the very low adhesion case), $V$ is the vehicle speed (200 $km/h$), $\lambda$ is wheelset conicity (0.131) and $d_r$ is rail lateral irregularity.

| Gain | Phase | $R^2$ | Gain | Phase | Combined |
|---|---|---|---|---|---|
| 0.5 | 0 | 0.75 | -0.5 | 0 | 0.5 |
| 1 | 0 | 1 | 0 | 0 | 0 |
| 2 | 0 | 0 | 1 | 0 | 1 |
| 1 | -90 | -1.09 | 0 | 0.52 | 0.52 |
| 1 | 90 | -0.86 | 0 | 0.48 | 0.48 |
| 1 | 180 | -3 | 0 | 1 | 1 |

TABLE II
SPRAGUE AND GEERS METRIC TEST

Figure 4(a) shows a section of half vehicle open loop model data excited by the track irregularity file compared to the Vampire outputs for the dry adhesion case for the front wheelset yaw, yaw rate and yaw accelerations. Visual inspection shows some differences between the outputs in terms of gain, but that the general trend is that the frequency content is followed. Numerically this is assessed using the Sprague and Geers metric.

*1) Sprague and Geers metric:* This metric was initially used for the comparison of different wave patterns in fluid flows. If $m(t)$ is the measured history and $c(t)$ is the estimated history, then a number of time integrals can be defined

$$\upsilon_{mm} = (t_2 - t_1)^{-1}\int_{t_1}^{t_2} m^2(t)dt \tag{5}$$

$$\upsilon_{cc} = (t_2 - t_1)^{-1}\int_{t_1}^{t_2} c^2(t)dt \tag{6}$$

$$\upsilon_{mc} = (t_2 - t_1)^{-1}\int_{t_1}^{t_2} m(t)c(t)dt \tag{7}$$

where $t_1 < t < t_2$ is the time step of interest, the error in the magnitude is given as

$$M_{SG} = \sqrt{\frac{\upsilon_{cc}}{\upsilon_{mm}}} - 1 \tag{8}$$

the phase error is given by

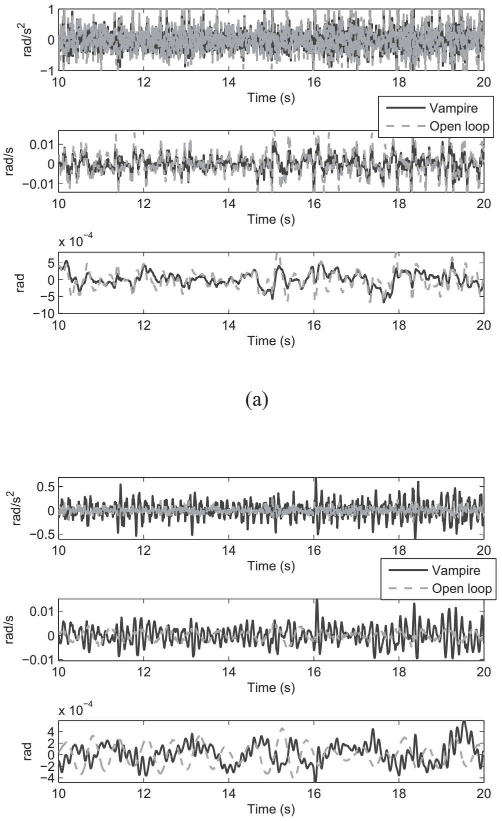
$$P_{SG} = \frac{1}{\pi}cos^{-1}\left(\frac{\upsilon_{mc}}{\sqrt{\upsilon_{mm}\upsilon_{cc}}}\right) \tag{9}$$

these two errors can be combined to give an overall global error

$$C_{SG} = \sqrt{M_{SG}^2 + P_{SG}^2} \tag{10}$$

this is comparable to the $R^2$ method of [4], but is able to cope with a degree of phase lag in the signals. This is illustrated in Table II for a series of sine wave comparison tests where the wave is scaled and phased. This demonstrates that the Sprague and Geers Metric can give information about the size and direction of the gain comparison between the original and estimated value, whereas the $R^2$ metric begins to fail when the scaling is past 2. The Sprague and Geers metric also gives good metrics information when there is phase difference between the signals as will be the case in this application where the signals may not be perfectly aligned, under which conditions the $R^2$ metric fails to see a correlation.

The Sprague and Geers metrics for the open loop model correlation are summarised in Table III. These values show for the acceleration and position signals that they are approximately 1.2 times larger that those from Vampire and the rate signal is 1.5 times larger. There is also mainly agreement in the phase signals of the analysis, with phases of less that $40^0$, though this is more difficult to interpret with more widely spaced spectrum signals. The modelling gives some confidence that the robust properties of the KBF would be able to accommodate model mismatches of this order. Figure 4(b) shows a section of open loop and Vampire output data for the very low adhesion case. This shows that the open loop model now is no longer correlated with the Vampire data, either in terms of gain or phase. This is reflected in the Sprague and Geers metrics shown in Table III, where the phase equivalent is considerably larger for the dry case and gain content is mostly much lower than that observed from the Vampire simulation with the exception of the yaw angle.



(a)

(b)

Fig. 4. Open loop estimator model comparison with Vampire output data, (a) dry case, (b) very low

This therefore represents a significant model mismatch at the lower adhesion levels and may be due to a number of reasons that have not full been understood: stick/slip dynamics in the the secondary yaw damper of the vehicle body and bogie, poor model extraction from the Vampire modelling, etc. Steps are currently being undertaken to understand these dynamics.

| Condition | Parameter | Gain | Phase | Combined |
|---|---|---|---|---|
| Dry | $\ddot{\psi}_{FF}$ | 0.1971 | 0.1332 | 0.2379 |
| Dry | $\dot{\psi}_{FF}$ | 0.5727 | 0.1528 | 0.5928 |
| Dry | $\psi_{FF}$ | 0.1990 | 0.2497 | 0.3193 |
| Very low | $\ddot{\psi}_{FF}$ | -0.5923 | 0.4922 | 0.7701 |
| Very low | $\dot{\psi}_{FF}$ | -0.4603 | 0.5585 | 0.7238 |
| Very low | $\psi_{FF}$ | -0.0390 | 0.5730 | 0.5744 |

TABLE III

SPRAGUE AND GEERS METRIC COMPARISONS FOR THE OPEN LOOP ESTIMATOR MODEL

### B. Creep force estimation example

The open loop suspension modelling from the previous section is now applied to the KBF creep force estimation method. It is noted at the outset that due to the discrepancies in the estimator modelling of the Mk.3 coach at low adhesion levels it is expected that the KBF performance will be affected. The size of this performance deficit requires assessment due to the robust qualities of the KBF.

For this example a full possible measurement vector is used

$$\begin{aligned} y = [&y_{FF}\ \dot{y}_{FF}\ \psi_{FF}\ \dot{\psi}_{FF}\ y_{FR}\ \dot{y}_{FR} \cdots \\ &\cdots\ \psi_{FR}\ \dot{\psi}_{FR}\ y_{BF}\ \dot{y}_{BF}\ \psi_{BF}\ \dot{\psi}_{BF} \cdots \\ &\cdots y_V\ \dot{y}_V]^T \end{aligned} \tag{11}$$

where the subscript $_{FF}$ refers to the front wheelset of the front bogie, subscript $_{FR}$ refers to the rear wheelset of the front bogie, subscript $_{BF}$ refers to the front bogie and subscript $_V$ refers to the vehicle body. It should be noted that this case represents the highest number of measurements possible and will not be practical in a long term application. The state vector is defined as

$$\begin{aligned} x = [&y_{FF}\ \dot{y}_{FF}\ \psi_{FF}\ \dot{\psi}_{FF}\ y_{FR}\ \dot{y}_{FR} \cdots \\ &\cdots\ \psi_{FR}\ \dot{\psi}_{FR}\ y_{BF}\ \dot{y}_{BF}\ \psi_{BF}\ \dot{\psi}_{BF} \cdots \\ &\cdots y_V\ \dot{y}_V\ F_{FF}\ F_{FR}\ M_{FF}\ M_{FR}]^T \end{aligned} \tag{12}$$

where $F$ is the lateral creep force and gravitational stiffness combined, and $M$ is the combined gravitational and creep moment. No physics of the creep forces are included in the estimator model, instead this is defined as

$$\dot{F}_{FF} = \dot{F}_{FR} = \dot{M}_{FF} = \dot{M}_{FR} = 0 \tag{13}$$

The $Q$ and $R$ covariance matrices where selected heuristically through multiple iterations. The Q matrix essentially defines that the state matrix has a high level certainty for the wheelset models, with less certainty assigned to the bogie and vehicle dynamics due to the use of a half vehicle estimator model. The creep force and moment sections are assigned the highest level uncertainty due to the assumptions of Equation 13, where

$$Q = diag[1e^{-10},\ 1e^{-10},\ 1e^{-10},\ 1e^{-10},\ 1e^{-10},\ 1e^{-10},\cdots$$
$$\cdots 1e^{-10},\ 1e^{-10},\ 1e^{5},\ 1e^{5},\ 1e^{10},\ 1e^{10},\cdots$$
$$\cdots 1e^{5},\ 1e^{5},\ 1e^{20},\ 1e^{20},\ 1e^{20},\ 1e^{20}] \tag{14}$$

The measurement covariance $R$ is defined as

$$R = diag[1e^{-3},\ 1,\ 1e^{-3},\ 1,\ 1e^{-3},\ 1,\ 1e^{-3},\cdots$$
$$\cdots 1,\ 1e^{5},\ 1e^{5},\ 1e^{5},\ 1e^{5},\ 1e^{10},\ 1e^{10}] \tag{15}$$

where the wheelset measurement are scaled in relation to their variance. The bogie and vehicle measurements are again treated as a higher level uncertainty due to the use of a half vehicle estimator.

Figure 5(a) shows an example of the creep moment estimation for the front wheelset of the front bogie at the dry adhesion level. Visual inspection shows that the estimator is identifying the correct frequency content of the creep moment but is over estimating the gain of the signal. This is reinforced by the Sprague and Geers metric of the estimation shown in Table IV.

As with the open loop estimator the KBF estimator shows poor convergence to the creep moment of the front wheelset of the front bogie at the very low adhesion level, Figure 5(b). The KBF in this case has failed to account for any discrepancies in the modelling. This is again reinforced by the poor values provided by the Sprague and Geers metric in Table IV.

| Condition | Parameter | Gain | Phase | Combined |
|---|---|---|---|---|
| Dry | $M_{FF}$ | 0.8671 | 0.2493 | 0.9023 |
| Very low | $M_{FF}$ | 6.5419 | 0.3912 | 6.5536 |

TABLE IV
CREEP MOMENT ESTIMATION SPRAGUE AND GEERS METRIC

### C. Development areas

There are clearly discrepancies between the modelling as performed in the MATLAB/Simulink phase of the project and the Vampire simulation package. Currently work is on-going to determine the cause of these differences as it is still hoped that the creep force estimation method of low adhesion estimation offers a high performance and robust solutions once these initial issues are rectified.

## IV. NON-MODEL BASED COMPARISON TECHNIQUE

An alternative method to the model based KBF creep force estimation of the previous section and as proposed in [9] is the use of known adhesion level ‘training’ data sets and real time advanced comparison computational methods. The basic concept of the idea is shown in Figure 6, that of comparing data gathered when the adhesion levels are considered acceptable and comparing this to the current measured data to determine any changes. This method’s success rests upon a number of factors: that the vehicle being tested runs at consistent speed profile down the same section of track on numerous occasions (ideal for service vehicles); that the system excitation (the track irregularity) doesn’t vary too greatly with time; and that spatial data can be stored and recalled in an efficient and accurate manner. The advantage with this type of system is that the processing requirements are much reduced and the limiting computational factor is now essentially one of storage.

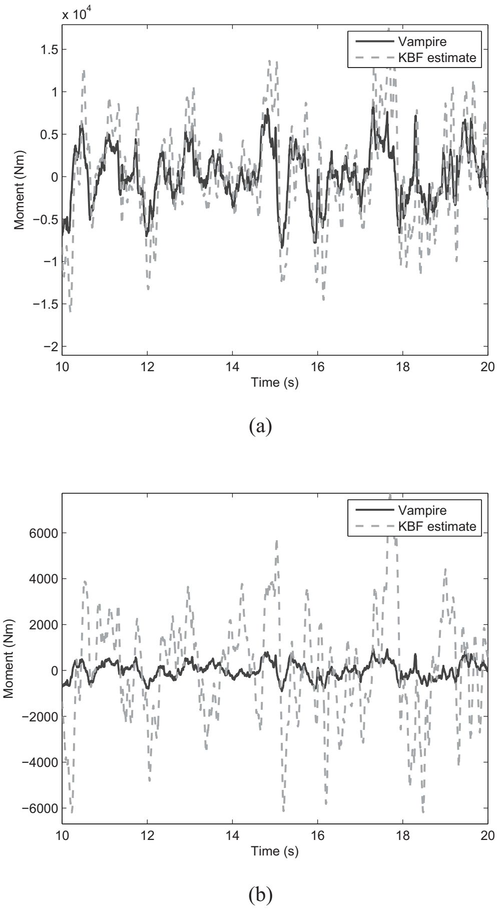


Fig. 5. KBF estimation of the creep moment using a half vehicle estimator for the front wheelset of the front bogie, (a) dry case, (b) very low

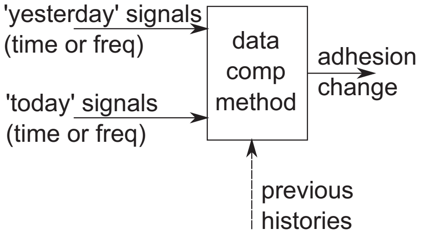

Fig. 6. Sensor signal comparison method

The processing algorithm used is the Sprague and Geers metric, [8]. In this simple demonstration of the method, the signal from an simulated lateral accelerometer mounted on the front bogie frame away from the centre of mass is used. Mounting on the bogie rather than the wheelset is much more advantageous due to the large accelerations (+/-300 $g$) experienced at the wheelset level. A resolution adequate for the application is assumed and the sample rate is 100 $Hz$.

### A. Threshold setting

The 'training' data is defined here as Vampire data run at the constant dry adhesion level and is compared to the constant adhesion data runs performed at the wet, low and very low levels. These are compared in 5-second sections of moving time window data, the size of which was determined in this simulation as to be sensitive enough to identify changes.

Figure 7 demonstrates the clearly defined levels for the gain metric of the Sprague and Geers metric and that they are almost linearly decreasing with the corresponding reduction in adhesion level. Simple thresholds can therefore be set around these levels to determine the current adhesion level.

It should be noted that such high quality data at the lower adhesion levels may not be available in application. However the technique will give a clear indication that the adhesion level has varied for a particular section of track.

### B. Step tests and signal delay

Vampire data was also created for a step change in the adhesion level from the dry condition to the very low at the half way point of the simulation at 30 seconds. The comparison to the 'training' data of the previous section is shown in Figure 7, which shows a clear reduction of the Sprague and Geers metric. Some time lag is evident due to the 5 second time windowing of the data, but this demonstrates that the technique can produce usable comparisons from signal based data alone.

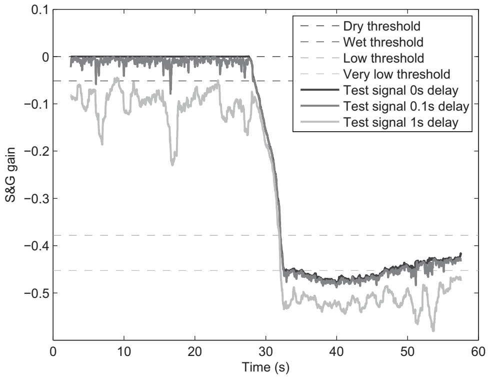

Fig. 7. Data comparison method adhesion threshold setting and step reduction tests at 30 seconds, for 0s time delay, 0.1s time delay and 1s time delay

The method will rely upon precise synchronisation of the 'training' and test data sets. The robustness of the algorithm was checked via delaying the 'training' data. This is also shown in Figure 7 for a 0.1 second and 1 second delay. The first case can be still seen clearly to demonstrate correlation though the quality is reduced. In the second case there is now a significant misalignment in the data, but the algorithm copes, not as clearly defining variations in adhesion but clearly demonstrating changes.

### C. Fuzzy logic reasoning

Multiple signals offer the opportunity for more comparisons of the changes in the dynamics of the vehicle, once thresholds are set this essentially becomes a problem of data fusion. This can be accomplished through simple logic processes or more complex fuzzy logic reasoning the basic architecture of which is a current being developed.

## V. Conclusion

Low adhesion causes punctuality and safety issues to rail operators and users alike due to vehicles failing to stop at stations or vehicles passing signals at danger. The RSSB managed project T959 is developing a number of practical processing options to determine the level of adhesion on in-service vehicles using relative modest cost sensors. The techniques' efficacies are now being tested on more representative modelling data from the multi-bodies physics simulation package Vampire. To date the Kalman-Bucy filtering method of estimating creep forces has proven to work at the higher ends of the adhesion spectrum but fails to converge at the low adhesion levels, which is mostly likely due to a filter model mismatch and research is continuing to resolve the problem. A non-model based pragmatic data comparison method utilising the Sprague and Geers metric has so far proven positive in the estimation of low adhesion provided high quality comparison data is available and that any signal phase is within acceptable limits.

## Acknowledgment

The authors would like to thank RSSB who manage project T959 with funding provided from the Rail Industry Strategic Research Programme. Thanks also goes to DeltaRail for the production of the Vampire simulation data.

*Abstract*— **High-speed train traction power supply system causes serious negative current problem. Railway power conditioner (RPC) is efficient in negative sequence compensation. A novel power quality collaboration compensation system and strategy based on RPC is proposed in this paper. The minimum capacity conducted is 1/3 smaller than traditional single station compensation. Simulation results have confirmed that the collaboration compensation system proposed can achieve a good performance at the negative sequence compensation with capacity and cost efficient.**

***Keywords-RPC; Collaboration compensation; Unbalance compensation; Minimum capacity***

## I. INTRODUCTION

With the rapid development of high-speed railway in China, power quality has become a major concern for traction supply system [1]. Compared with normal electrification railway locomotive load, high-speed locomotive load has some characteristics, such as big instantaneous power, high power factor, low harmonic components and high negative sequence component. A large amount of negative current is injected into grid [2], which causes serious adverse impact on power system, such as increasing motor vibration and additional loss, reducing output ability of transformers and causing relay protection misoperation [3]. These adverse impacts threaten the safety of high-speed railway traction supply system and power system. Therefore, it’s necessary to take measures to suppress negative current.

Many methods and power quality compensators are studied in order to solve the issue of power quality. The traditional methods adopted to suppress negative current are as follows: (1) Connect unbalanced load to different supply terminals;(2) Adopt phase sequence rotation to make unbalanced load distributed to each sequence reasonably;(3) Connect unbalanced load to higher voltage level supply terminals; (4) Use balanced transformers such as Scott transformer and impedance balance transformer [4]. These methods have some effects on reducing unbalance degree, but they are lack of flexibility and can't adjust dynamically.

Recent years, high-voltage, large-capacity Static Var Compensator (SVC), Active Power Filter (APF) and Static Compensator (STATCOM) have become focus on power quality compensation of electrified railway [5]-[7]. However, these methods all need high-voltage transformers which increase cost. APF is effective in suppressing harmonic currents in electrified railway but rarely used in negative sequence compensation [8]. An active power quality compensator (APQC) with a impedance-matching balance transformer or a Scott transformer is proposed in [9] to compensate negative-sequence current, harmonics and reactive current. Reference [10] and [11] put forward a proposal of Railway Power Conditioner (RPC), RPC can make comprehensive compensation of negative sequence components, harmonics and reactive power. Reference [12] carries a dual-loop control strategy in order to improve the control effect and performance of RPC. Taken into account the disturbance and variation of electrified railway environment, a recursive proportional-integral control based on fuzzy algorithm is adopted to realize a fast and smooth tracking to reference current. Reference [13] raises a method of setting up two groups of thyristor control reactors (TCR) and two groups of thyristor control 3rd harmonic wave filter besides RPC. The RPC is used to transfer active power; the reactive power is supplied by the TCR and the filter. These works prove that RPC is a effective way to solve the power quality problems in railway system. But the compensator capacity is still too big to make RPC into practice.

To reduce the high compensator capacity, this paper puts forward a new railway negative unbalance compensation system based on the thought of multiple RPC collaboration compensation. This method realizes a minimum compensation capacity which is strictly proved, which reduces 1/3 capacity compared with traditional single station RPC compensation method. The simulation results have verified the correctness of the method proposed in this paper.

## II. RPC Structure and Analysis of Compensation Principle

The structure of RPC is shown in Fig.1. Three phase 220kV voltage is stepped down into two single-phase power supply voltage at the rank of 27.5kV by V/V transformer. RPC is made of back-to-back voltage source converters and a common dc capacitor, which can provide stable dc-link voltage. Two converters are connected to secondary arms of V/V transformer by step down transformer. Two converters can transfer active power from one power supply arm to another, supply reactive power and suppressing harmonic currents.

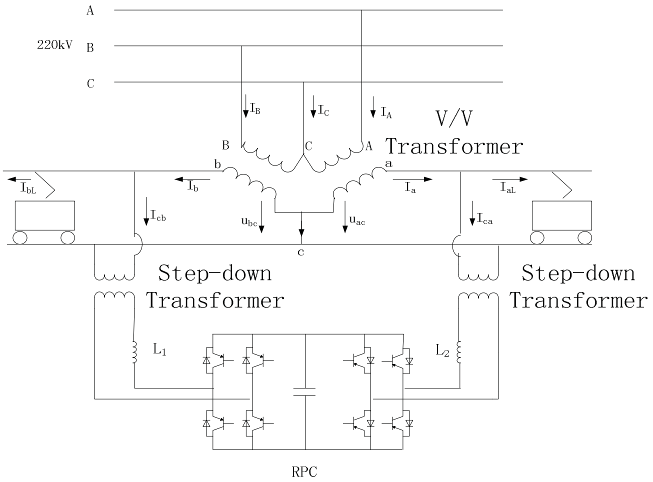

Figure 1. Traction power system with a three-phase V/V transformer and a RPC

The right feeder section in Fig.1 is denoted as *a*-phase power arm, while that the left side is *b*-phase power arm. The corresponding phases on the primary side are denoted as Phase A and Phase B, respectively. Since using four-quadrant pulse rectifiers to feed electrical locomotives, the power factor of high speed electrical locomotive is close to 1. Set $U_A$ as the reference value. Assume that the fundamental current vector of *a*-phase power arm is $\dot{I}_{aL}$ and the fundamental current vector of *b*-phase power arm is $\dot{I}_{bL}$ . $\dot{I}_{aL}$ and $\dot{I}_{bL}$ are shown as follows:

$$\begin{cases} \dot{I}_{aL} = I_{aL} e^{-j30^\circ} \\ \dot{I}_{bL} = I_{bL} e^{-j90^\circ} \end{cases} \tag{1}$$

The turns ratio of V/V transformer is *K*, so the three currents of the high-voltage side are shown as follows:

$$\begin{cases} \dot{I}_A = \dfrac{\dot{I}_{aL}}{K} = \dfrac{I_{aL}}{K} e^{-j30^\circ} \\ \dot{I}_B = \dfrac{\dot{I}_{bL}}{K} = \dfrac{I_{bL}}{K} e^{-j90^\circ} \\ \dot{I}_C = -(\dot{I}_A + \dot{I}_B) \end{cases} \tag{2}$$

Before RPC compensation, *a*-phase power arm has load current $\dot{I}_{aL}$ and the *b*-phase power arm has load current $\dot{I}_{bL}$ . Assume that $I_{aL} \geq I_{bL}$ , the three phase current is shown in Fig.2 .

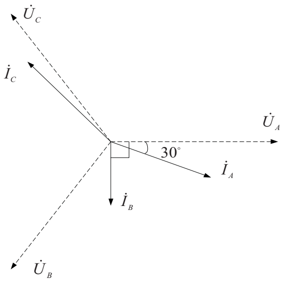

Figure 2. Three-phase current phase diagram without compensation

It is obvious that three phase current is unbalance before compensation. Use RPC to shift $\frac{1}{2}(I_{aL} - I_{bL})$ from *a*-phase to *b*-phase. Then, the current of two power arms are compensated to $I'_{aL}$ and $I'_{bL}$ , and they have an equal amplitude of $\frac{1}{2}(I_{aL} + I_{bL})$ and an angle difference of $\pi/3$ . The unbalance level is 50% now.

On the basis of active power transfer, RPC should compensate a certain quantity of capacitive reactive current $I_{caq}$ on the power arm *a* and a certain quantity of inductive reactive current $I_{cbq}$ on the power arm *b*, which can make the current of *a*-phase power arm lead the corresponding voltage $\pi/6$ . At this point, the reactive current should be calculated as follows:

$$I_{caq} = I_{cbq} = \frac{1}{2}(I_{aL} + I_{bL}) \tan 30^\circ \tag{3}$$

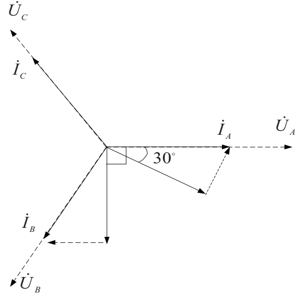

Figure 3. Three-phase current phase diagram after adjusting active and reactive power by RPC

After the compensation, the currents $I_A$ and $I_B$ have the same amplitude, as shown in Fig.3, and their angle difference is $2\pi/3$ . The C phase current $I_C$ can be obtained as $I_C = -I_A - I_B$ . The primary side of traction transformer has a balance three-phase current after active power shift and reactive power compensation. It is similar when $I_{aL} < I_{bL}$ . The common expression of RPC compensation current is:

$$\begin{cases} \dot{i}_{ca} = \dfrac{1}{2}(I_{bL} - I_{aL}) e^{-j30^\circ} + \dfrac{1}{2\sqrt{3}}(I_{aL} + I_{bL}) e^{j60^\circ} \\ \dot{i}_{cb} = \dfrac{1}{2}(I_{aL} - I_{bL}) e^{-j90^\circ} + \dfrac{1}{2\sqrt{3}}(I_{aL} + I_{bL}) e^{j180^\circ} \end{cases} \tag{4}$$

$\dot{I}_{ca}$ , $\dot{I}_{cb}$ --the equivalent current of RPC converters of *a*-phase arm and *b*-phase arm at the voltage of 27.5 kV.

## III. Principle of Collaboration Compensation

Since phase sequence rotation is widely adopted in traction power supply system, 3 stations collaboration compensation is mainly discussed in this paper. The structure of 3 stations collaboration compensation is shown in Fig.4.

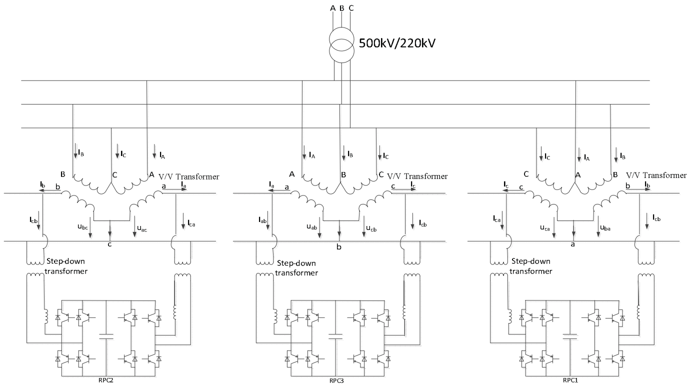

Figure 4. Schematic diagram of collaboration compensation of three stations

The capacity in phase CA, AB and BC is *x,y,z* , which has a relationship of *x>y>z*. The network of *x,y,z* can be divided into two parts, the one is a balanced network of *z,z,z* , the other is an unbalanced network of *x-z, y-z, 0*. Assume that $X = x - z$ , $Y = y - z$ , the original network is simplified as $X, Y, 0$ . Set *X*/2 as the reference value, the p.u. value of the simplified network is 2, $Y'$,0. $Y'$ is varying from 0 to 2.

The extreme case is $Y'$ =0. The optimize compensation strategy is shown below:

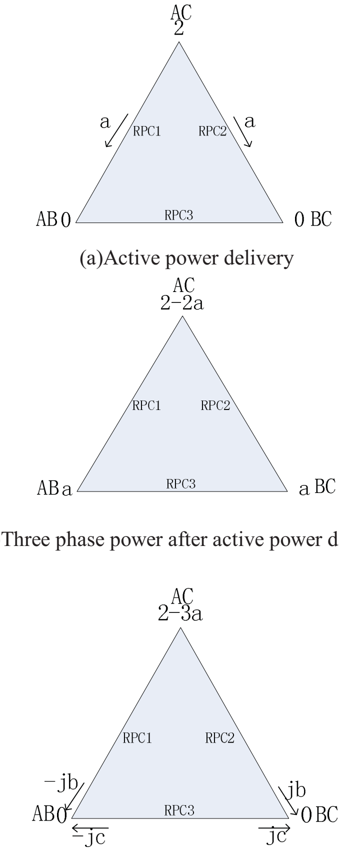
### *A. Single RPC compensation*

Based on the compensation strategy of RPC, when there is a maximum capacity in one of the traction feeder arms, RPC transfers $\frac{1}{2} * \frac{X}{2}$ active power from one traction feeder arm to another. And then compensates $\frac{1}{2\sqrt{3}} * \frac{X}{2}$ reactive power to both traction feeder arms based on Steinmetz theory. So the compensation capacity of single RPC is:

$$S = \sqrt{\left(\frac{1}{2}\right)^2 + \left(\frac{1}{2\sqrt{3}}\right)^2} \frac{X}{2} = 0.2885X \quad (5)$$

### *B. Three stations collaboration compensation*

The simple model of 3 stations structure is shown in Fig.5. Since RPC could transfer a quantity of active power and compensate reactive power, a triangle is applied to illustrate the principle of collaboration compensation: apexes of the triangle are regarded as active load in Phase-AC, Phase-BC and Phase-AB, and edges of the triangle are regarded as three railway power conditioners. The arrows mean the delivery of active power (real part) and compensation of reactive power (imaginary part) . There are three steps to compensate. Firstly, transfer a quantity of active power. Secondly, separate the network into two parts: a balanced network and an unbalanced network. And last, make compensation to the unbalanced network based on the Steinmetz theory.



(a)Active power delivery

(b)Three phase power after active power delivery

(c) Reactive power compensation based on Steinmetz theory

Figure 5. Compensation strategy under the condition of 2,0,0

According to the Steinmetz theory, fully compensation should satisfy the relationship of $b + c \geq \frac{2 - 3a}{\sqrt{3}}$. The capacity of three RPC is $\sqrt{a^2 + b^2}$ , $\sqrt{a^2 + b^2}$ , $c$ , separately. The installed capacity will be the maximum of the three RPC capacities above. So we can obtain the minimum installed capacity when $\sqrt{a^2 + b^2} = c \cdot$

The results can be conducted that $a = \frac{1}{3}, b = \frac{1}{3\sqrt{3}}$ , and the minimum capacity is $S_{\min} = \sqrt{a^2 + b^2} = c = \frac{2}{3\sqrt{3}}$ . This is a fully compensation but the station where RPC2 installed is capacitive. To avoid this condition, RPC1 supply inductive reactive power with the value of *b*, and RPC2 supply capacitive reactive power with the value of *b*, too. So the capacitive condition is avoided and the system keeps balance at the same time.

Working condition of three stations is shown in Fig.6. The ellipses stand for different traction feeder arms, the squares stand for RPC which connect to traction feeder arms. The arrows stand for active power transfer and reactive power compensation.

Figure 6. Working condition of three stations which supply active power and reactive power.

Three stations collaboration compensation minimum capacity is :

$$S_3=\sqrt{\left(1\big/3\right)^2+\left(1\big/3\sqrt{3}\right)^2}\,\frac{X}{2}=\frac{2}{3\sqrt{3}}*\frac{X}{2}=0.1925X\,,\quad(6)$$

which is 2/3 of the capacity of single RPC compensation. Tab.1 shows the compensation capacity of the two strategies.

TABLE I. COMPARISON OF TWO COMPENSATION METHOD

| **Compensation mode** | **Single station** | **Three station collaboration compensation** |
|---|---|---|
| RPC capacity | 0.2885*X* | 0.1925*X* |

It can be proved that this installed capacity (0.1925*X*) can satisfy any condition when *Y'* varying from 0 to 2.

If there is *N* stations connect to one 220kV bus, *N* may be 3*n*, 3*n*+1 or 3*n*+2 (*n*=0,1,2…). When *N*=3*n*, it means there are n sets of 3-stations compensation. When *N*=3*n*+1, it means there are n sets of 3-stations compensation and a single station compensation. When *N*=3*n*+2, it means there are *n* sets of 3-stations compensation and 2 single station compensation.

## IV. SIMULATION RESULTS

Simulation is done to proof the correctness of the theory by MATLAB/Simulink.

### A. Single RPC Compensation

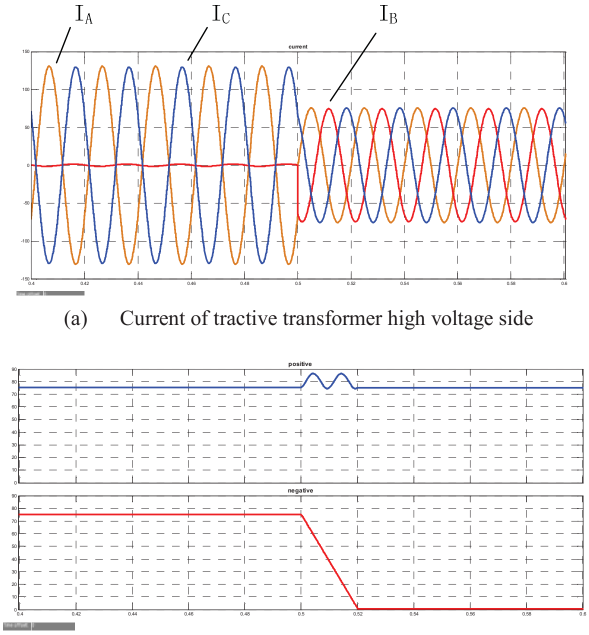
Assume the maximum load capacity appears at *a*-phase power arm, that is $P_{AC}=1$. The base capacity is $P_{base}=20MW$, and the short-circuit capacity is 750MVA. The power of *b*-phase locomotive load is 0. The *a*-phase load was switch on at 0*s*, the compensation system ran at 0.5*s*. The simulation schematic diagram is shown in Fig.1. The simulation parameters are as follows: three phase voltage of the system is 220kV; the frequency is 50Hz; the ratio of V/V transformer is 8:1; the ratio of step down transformer is 40:1; the capacitor of RPC at DC side is 100000 μF, and the value of $L_1$ and $L_2$ is 3mH and 2mH respectively.

Fig.7 (a) is the simulation current waveforms before and after three-phase negative sequence current compensation at 220kV side when locomotive load is under *a*-phase power arm. Fig.7 (b) is sequence analysis of current waveform. It can be seen from Fig.7 that before the compensation the current of Phase B $I_B$ is zero, and the phase current $I_A$ and $I_C$ have the same amplitude and an angle difference of 180° . Meanwhile, the negative sequence component is equal to positive sequence component. The unbalance level is defined :

$$\varepsilon_I=\left|\dot{I}_-\right|\Big/\left|\dot{I}_+\right|\times100\%\qquad(7)$$

$\left|\dot{I}_-\right|,\left|\dot{I}_+\right|$ --modulus of negative and positive current

The unbalance level before the compensation is 100%. The three phase currents become balanced after the compensator was carried out and the unbalance level was reduced to 0.



(a) Current of tractive transformer high voltage side

(b) Positive sequence and negative sequence current

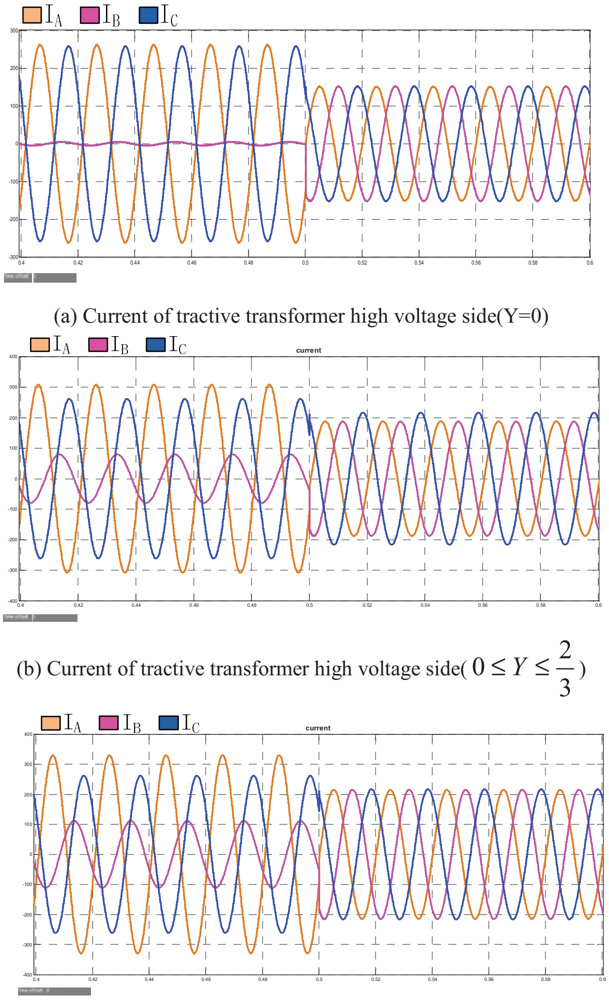
Figure 7. Compensation result under the condition of single station

### B. Three Station Collaboration Compensation

Set three station collaboration compensation for example. Fig.4 shows the schematic diagram of three station collaboration compensation. Three typical conditions are taken into consideration :

$$1)\mathrm{Y}{=}0;\ \ 2)\,0\le Y\le\frac{2}{3};\ \ 3)\,\frac{2}{3}\le Y\le1\,.$$

The simulation parameters are the same as single station compensation. Simulation results are shown in Fig.8. Fig.8 (a) shows the waveform before and after compensation when the maximum locomotive load appears at the Phase-AC at the condition of *Y*=0. The situation before compensation is almost the same as single station compensation, except for that the load is twice as much as single station locomotive load. With the use of compensator, the unbalance level was changed from 100% to 1%.Fig.8 (b) is the waveform when $0 \le Y \le \frac{2}{3}$, $Y$ appears at Phase AB. Compensator was put into operation at 0.5*s*. The unbalance level was reduced from 71% to 7%. The waveform when $\frac{2}{3} \le Y \le 1$ is shown in (c). The unbalance level was reduced from 60% to 2%. It can be seen from the simulation that there is a serious unbalanced condition before the compensation. The collaboration compensation network is effective in reducing the negative current(the unbalance level is reduced below 8%). The error may come from the loss of power electronic components and isolation transformers. The unbalance level before and after the compensation is listed in Tab. 2.



(a) Current of tractive transformer high voltage side(Y=0)

(b) Current of tractive transformer high voltage side( $0 \le Y \le \frac{2}{3}$ )

(c) Current of tractive transformer high voltage side( $\frac{2}{3} \le Y \le 1$ )

Figure 8. Three station collaboration compensation result under the condition of 2,Y,0

Table II. Unbalance Level Before And After Compensation

| | $Y$=0 | $0 \le Y \le \frac{2}{3}$ | $\frac{2}{3} \le Y \le 1$ |
|---|---|---|---|
| **Before Compensation** | 100% | 71% | 60% |
| **After Compensation** | 1% | 7% | 2% |

## V. Conclusion

This paper proposes a new power quality compensation system which is composed of several railway power conditioners. The proposed system can be used to compensate negative sequence current in high speed electrified railway. A minimum installed capacity is conducted which is 2/3 of the traditional single station compensation capacity. A new compensation strategy is raised Simulation results show that the proposed collaboration compensation of railway power conditioners is effective. It can reduce compensation capacity and has a good performance at negative sequence current compensation.

***Abstract*—Isochronal synchronization is a unique phenomenon in which physically distant oscillators wired together relax into zero-lag synchronous behavior over time. Such behavior is observed in natural processes and, recently, has been considered for promising applications in communication. Towards technological development of devices that explore isochronal sync, stability issues of the phenomenon need to be considered, both in the context of a pair or a network of coupled oscillators. This study concerns such stability issues by using the Lyapunov-Krasovskii theorem to propose a framework to study synchronization stability by using accessible parameters of the network coupling setup. As a result, relations between stability and network parameters are unveiled and the comprehension of roads leading to stability is enhanced.**

***Keywords: complex networks, isochronal synchronization, Lyapunov-Krasovskii.***

## I. INTRODUCTION

The communication among physically distant entities is subject to time delays. This is a result of the finite time a signal requires to travel through a physical media the distance from an emitter to a receiver. Curiously, despite of such condition, chaotic oscillators were revealed to overcome time delay and synchronize with zero-lag [1-10]. Under bidirectional coupling and adequate conditions, coupling setups of chaotic oscillators are somehow capable of absorbing coupling delays and synchronize as if no delays were present in the communication process at all [1, 8].

The knowledge of such fact brought promising applications for chaos in communication, such as those presented in [1, 8]. In this context, a fundamental requirement for communication is the stability of isochronal synchronization under small disturbances [6, 7]. This is so because information itself is introduced in the communication process as a disturbance to the synchronous dynamics [1]. As such, the communication process per se is a sequence of desync and resync episodes which can be understood as the transmission of bits through the coupling link between chaotic oscillators [1]. Resync, specifically, is possible if sync is stable, and the need for stability is justified.

In the scenario featuring pairs of delay-coupled oscillators, analytical results may establish frameworks that allow the systematic study of stability of isochronal sync in rather straightforward manners. This paper presents analytical results and their use towards the comprehension of the relations between network sync stability and the network parameters. The phenomenon of isochronal sync is considered, which implies the presence of time delays in the coupling among the oscillators. On this basis, the network parameter space is swept in a search process to map regions of sync stability. The relation between the number of nodes of the network and the number of links among its nodes is shown to be critical to the stability of isochronal sync, as it was observed to be for other types of synchronization as well [12].

The paper is organized as follows: section 2 presents the theoretical basis upon which the developments and explorations are based; section 3 explores the theoretical results towards the understanding of the underlying mechanisms of sync stability; section 4 presents some final remarks.

## II. ISOCHRONAL SYNC STABILITY OVER THE NETWORK PARAMETER SPACE

### *A. Isochronal sync and the network error equations*

Consider the systems

$$\dot{x}_i(t) = Ax_i(t) + g(x_i(t)) + u_i(t) \tag{1}$$

where $x(t) \in R^n$ is a state vector, $A \in R^n \times R^n$ is a constant matrix and $g(.) \in R^n \to R^n$ is a continuous vector field, such that the nodes are coupled exclusively by the control function $u_i(t)$ which is a feedback control function given by

$$u_i(t) = \tfrac{1}{G_{ii}} K \left( G_{ii} x_i(t) - \sum_{\substack{j=1 \\ j \neq i}}^{N} G_{ij} x_j(t-\tau) \right) \tag{2}$$

and $G_{ij}$ are entries of the Laplacian matrix $G$ and $K = K^T$ is a feedback matrix to be designed. The symmetry property of the feedback matrix is desirable as it allows some simplifications later on the development. Note that equation (2) can be rewritten as

$$u_i(t) = KC_{ii} \sum_{j=1}^{N} G_{ij} x_j(t-\tau_{ij}) \tag{3}$$

and the equations for the *ith* node of the network ( $i = 1, 2, ..., N$ ) as

$$\dot{x}_i(t) = Ax_i(t) + g(x_i(t)) + KC_{ii}\sum_{j=1}^{N} G_{ij}x_j(t-\tau_{ij}) \qquad (4)$$

where $\tau_{ij} = \tau$, for $i \neq j$, $\tau_{ij} = 0$, otherwise, and

$$C_{ii} = -\frac{1}{G_{ii}} \qquad (5)$$

for node balance. Alternatively, collecting the *ith* term of the summation (3), the self-coupling, for which $\tau = 0$, and reorganizing the terms of equation (4), it now reads

$$\dot{x}_i(t) = (A-K)x_i(t) + g(x_i(t)) + KC_{ii}\sum_{\substack{j=1 \\ j\neq i}}^{N} G_{ij}x_j(t-\tau) \quad (6)$$

In the following, the state vectors of the network nodes, $x_1(t), x_2(t), ..., x_N(t)$ are collected into the network state vector $X(t) \in \mathbb{R}^{Nn}$, given by

$$X(t) = \begin{pmatrix} x_1(t) \\ x_2(t) \\ \vdots \\ x_N(t) \end{pmatrix} \qquad (7)$$

Thus, the equations of the delay-coupled network can be written in the compact form

$$\dot{X}(t) = I_N \otimes (A-K)X(t) + \bar{G}(X(t)) + CA_d \otimes KX(t-\tau) \quad (8)$$

where $I_N$ is an *N-dimensional* identity matrix, ⊗ is the Kronecker product,

$$\bar{G}(X(t)) = \begin{pmatrix} g(x_1(t)) \\ \vdots \\ g(x_N(t)) \end{pmatrix} \qquad (9)$$

is a nonlinear vector field and $A_d$ is the network adjacency matrix that assigns $A_{d_{ij}} = A_{d_{ji}} = -1$ if nodes $i$ and $j$ are connected, $A_{d_{ij}} = A_{d_{ji}} = 0$ otherwise and, $A_{d_{ii}} = 0$.

At this point, the dynamical equations of the network are available and the formulation of the synchronization problem requires the definition of an error vector function $e(t)$, such that, if $\|e(t)\| \to 0$ as $t \to \infty$, then the $N$ systems of the network are asymptotically synchronized. Towards that end, considering the definition of isochronal synchronization, one can define

$$e(t) = X(t) - X_s(t) \qquad (10)$$

where

$$X_s(t) = SX(t) \qquad (11)$$

being $S \in \mathbb{R}^{Nn} \times \mathbb{R}^{Nn}$ an appropriate vector coordinate transformation defined as $S = T \otimes I_n$ and being $T$ defined as

$$T = \begin{pmatrix} T_{11} & T_{12} & \cdots & T_{1N} \\ T_{21} & \ddots & & \vdots \\ \vdots & & \ddots & \vdots \\ T_{N1} & \cdots & \cdots & T_{NN} \end{pmatrix} \qquad (12)$$

where either $T_{ij} = 1$ or $T_{ij} = 0$ and $\sum_i T_{ij} = \sum_j T_{ij} = 1$, such that $rank(T) = N$ and

$$rank(I_N - T) = N - 1 \qquad (13)$$

It can be verified that (10) yields

$$\begin{aligned} \dot{e}(t) \;=\; & \left(A-K+M_{(X(t),X_s(t))}\right)e(t) + \left(CA_d \otimes K - S[CA_d \otimes K]\right)X(t-\tau) \\ & \left(A-K+M_{(X(t),X_s(t))}\right)e(t) + \left(I_{Nn} - S\right)\left(CA_d \otimes K\right)X(t-\tau) \end{aligned} \qquad (14)$$

where $M_{(X(t),X_s(t))}e(t) = \bar{G}(X(t)) - S\bar{G}(X(t))$. Note that $S\bar{G}(X(t)) = \bar{G}(X_s(t))$.

At this point, note that system (14) depends both on the error states $e(t)$ and the network states $X(t)$, which is undesirable, since the synchronization stability evaluation must be performed in the error equations alone. However, considering equations (10), (11), one can rewrite systems (14) in terms of the error variable $e(t)$ by designing an adequate matrix of coefficients $E$ such that

$$\begin{aligned} (I_{Nn} - S)(CA_d \otimes K)X(t-\tau) &= E\left(X(t-\tau) - X_s(t-\tau)\right) \\ &= E(I_{Nn} - S)X(t-\tau) \\ &= Ee(t-\tau) \end{aligned} \qquad (15)$$

and, finally,

$$(I_{Nn} - S)(CA_d \otimes K) = E(I_{Nn} - S) \qquad (16)$$

Since the matrix $(I_{Nn} - S)$ is singular due to the definition of $S$, the equation cannot be solved for $E$ analytically. However, it is possible to prove that a solution exists, such that equation (14) can be rewritten in the form

$$\dot{e}(t) = I_N \otimes \left(A - K + M_{(X(t),X_s(t))}\right)e(t) + Ee(t-\tau) \qquad (17)$$

which depends only on the error variables $e(t)$. Note that $\|e(t)\| = 0$ implies $x_1(t) = x_2(t) = ... = x_N(t)$, which imply that the network is asymptotically synchronized. In other words, the stability of network synchronization requires that the error system (17) asymptotically establishes at the trivial fixed point.

Towards the determination of conditions for synchronization stability, consider the identity $e(t-\tau) = e(t) - \int_{t-\tau}^{t} \dot{e}(\theta)d\theta$, such that the error equations (17) can be rewritten as

$$\dot{e}(t) = I_N \otimes \left(A - K + M_{(X(t),X_s(t))}\right)e(t) + E\left(e(t) - \int_{t-\tau}^{t} \dot{e}(\theta)d\theta\right) \quad (18)$$

and, one step ahead,

$$\begin{aligned} \dot{e}(t) = & \left[I_N \otimes \left(A - K + M_{(X(t),X_s(t))}\right) + E\right]e(t) + \\ & -E\int_{t-\tau}^{t}\left[I_N \otimes \left(A - K + M_{(X(t),X_s(t))}\right)e(\theta) + Ee(\theta-\tau)\right]d\theta \end{aligned} \qquad (19)$$

such that the error system is obtained.

Notice that according to our formulation, the definition of the error system dismisses the use of reference signals. It follows that the asymptotic stability of the error system (19) means that of the synchronization of the network of oscillators

(8). In the next section, a stability criterion for the trivial fixed point of the error system (19) is derived, by means of the Lyapunov-Krasovskii stability theorem [11].

### B. Criterion for Isochronal sync stability

Consider the upper bound of the Lipschitz constant of the nonlinear vector field $g(.)$ over the invariant set $\Omega$ constituted by the trajectory of $x(t)$ to be given by $\ell$, such that $L=\ell I$ and $I$ is the $n$-dimensional identity matrix. The following result can be established [7]:

***Theorem [Isochronal synchronization of delay-coupled complex networks].*** *If there exists a constant matrix $P=P^T>0$ a positive constant $\varepsilon>0$ and a feedback gain matrix $K$ such that*

$$W=Q-2\varepsilon I_N\otimes A^T A-2\varepsilon E^T E-\frac{\tau}{\varepsilon}E^T P^2 E>0 \qquad (20)$$

*holds for a matrix $Q=Q^T>0$, where $Q$ is given by equation*

$$-Q=\left[I_N\otimes(A-K+L)+E\right]^T P+P\left[I_N\otimes(A-K+L)+E\right] \qquad (21)$$

*then the delay-coupled network whose error system given by equation (19) achieves isochronal synchronization for coupling delay $\tau$.*

## III. Investigating Isochronal Sync Stability

This section explores the relations between (i) synchronization stability and network topology, (ii) synchronization stability and coupling delays, based on the analytical results presented in [7]. The objective is to trace the influence of such network parameters in synchronization stability.

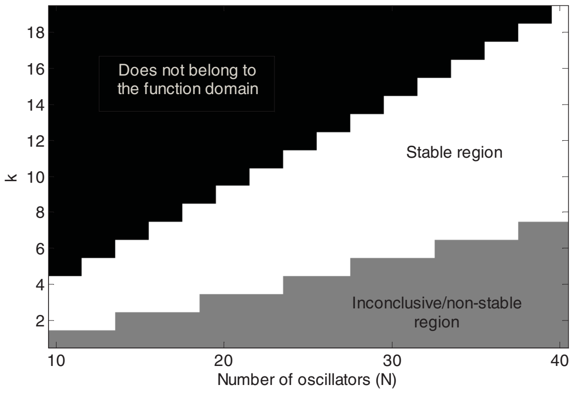

Figure 1 - Example of application of the network isochronal sync stability criterion as a stability function over the parameter domain: stability regions can be mapped from accessible network parameters. Since the stability criterion is sufficient (but not necessary), a the gray region is traced for the parameter values for which (20) is not satisfied.

### A. Sync stability versus network topology

In this example, the regions of stable isochronal synchronization are established for *k-cycle* networks on the basis of the inequality (20). Such regions are subsets of the cartesian product $N\times k$. A similar systematic approach can be used to trace such map for other kinds of network, as other parameters are chosen. To make the visual analysis simple, a $2-$ *dimensional* parameter meshgrid is generated. From Figure 1, Figure 2, Figure 3 and Figure 4, the loss of stability can be traced towards the identification of the parameters that are most influential to its occurrence. It can be recognized that smaller proportions of links among nodes relatively to the number of nodes in the network has negative effect on stability of isochronal sync. This effect is illustrated by arrows which show the direction of the loss of stability. Further analysis and insights into the nature of network stability are possible as other parameters are considered in the generation of the domain for evaluation of other similar stability functions resulting from the analytical results presented in this paper. In the following, similar studies considering stability under different values of coupling delay are considered.

### B. Time-delays versus number of links in k-cycle networks

At first, the form that the delay term appears in the inequality (20) suggests that stability is degraded for larger values of delay. Although this is not a general rule, the qualitative behavior of DDEs is shown to change as delays increase, due to the occurrence of Hopf bifurcations [13], which induce oscillatory and unstable behavior. The stability map in the parameter space $\tau\times k$ shows this relation, and it is illustrated in Figure 4 and Figure 5.

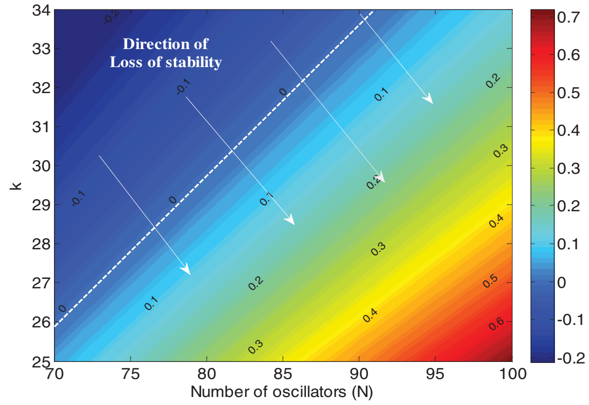

Figure 2 – Stability function over the set $N\times k$ of parameter space of the of the k-cycle network of Lorenz oscillators: the stability region has negative maximum eigenvalue of $-W$ and sync stability is lost as the number of oscillators increases and/or the number of links decreases.

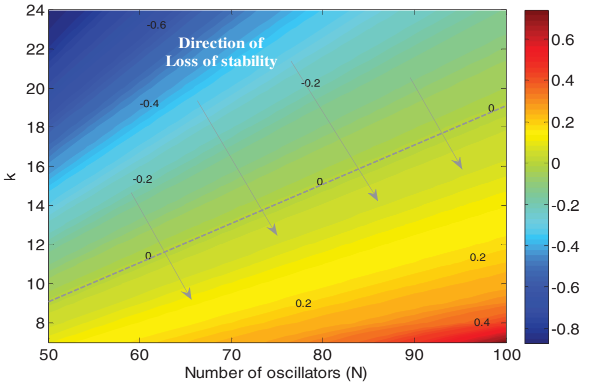

Figure 3 - Stability function over the set $N \times k$ of the parameter space of the k-cycle network of Rössler oscillators: the stability region has negative maximum eigenvalue of $-W$ and sync stability is lost as the number of oscillators increases and/or the number of links decreases.

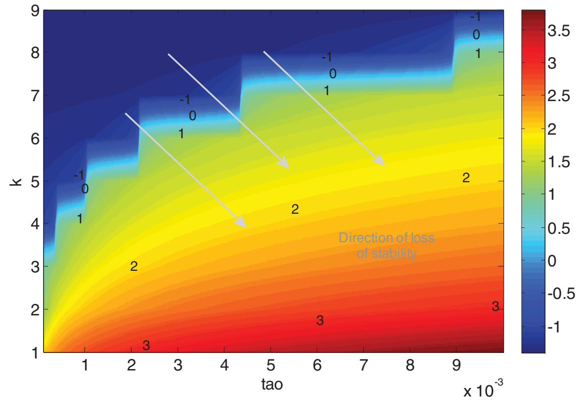

Figure 4 – Stability function over the set $\tau \times k$ of the parameter space of a k-cycle network with N = 20 Rössler oscillators: the region of stable sync has negative maximum eigenvalue of $-W$ . In this case, sync stability is lost as the number of links decreases and the time-delay increases.

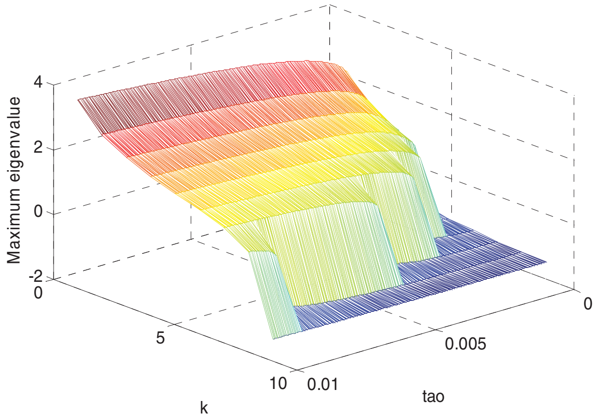

Figure 5 – Mesh of the stability function plotted in Figure 4: few links among nodes and larger values of time-delays render network synchronization less prone to synchronization.

### C. *Sync stability versus individual node dynamics*

A careful observation of the stability criterion (20) reveals that larger values of the Lipschitz $\ell$ constant also contribute negatively to stability. Moreover, it can be concluded that the substitution of the nonlinear terms of the nodes' dynamics with their upper bound, performed in the development of the stability criterion, is a source of restrictiveness, since it considers a worst-case scenario.

From a different perspective, this also illustrates the fact that some chaotic networks are more likely to synchronize than others, depending on the intrinsic dynamics of its nodes. Moreover, larger upper bounds of the nonlinear vector field $g$ over $x(t)$ reflect on the entries of the feedback matrix $K$ , which are supposed to lead the network nodes to isochronal synchronization, and thus counteract the effect of perturbations. Note that the value of $K$ also affects the delay term and, as such, may as well act as a perturbation to stability. Thus, not necessarily larger values of the entries of $K$ imply enhancement of stability, as observed also in non-delayed networks [12].

## IV. Final Remarks

The underlying mechanisms of network synchronization are topics of great interest within the context of complex networks. This paper presented analytical results that allow the determination of stability of isochronal synchronization in complex networks of delay-coupled chaotic oscillators. The relations between stability and the parameters of the network, as developed in this paper, help in the understanding of such mechanisms.

***Abstract*—In this paper, we propose a distributed robust control method for synchronized tracking of multiple Euler-Lagrange systems, where the time-varying reference trajectory is sent to only a subset of the agents. It is assumed that the agents can exchange information with their local neighbors on an undirectionally connected communication graph. The controllers are not only distributed on the network, but also decentralized for each generalized coordinate within each agent. Theoretical analysis is performed. And simulation results are provided to support the theoretical results.**

## I. Introduction

Motivated by applications in physics, biology and engineering the study of synchronized control of collections of locally connected dynamic systems has become an important topic in control theory. Examples of interesting research directions include coverage control, consensus, formation control, flocking, and leader-follower tracking [1]. In recent years, there have been some remarkable works on synchronized tracking problem for multiple multiple Euler-Lagrange (EL) systems when only a portion of the agents can access the leader. In [2], a method of finite time synchronization tracking control of multirobot systems is proposed. The agent models are assumed to be known and each agent's controller requires its neighbors' control signals. In [3], a model-independent sliding mode control algorithm is proposed. However, the algorithm is discontinuous and requires the availability of the information of both the neighbors and the neighbors' neighbors. In [4], an adaptive robust control algorithm is proposed for multiple uncertain EL systems. In [5], the problem of position synchronization of multiple EL systems is studied. However, the proposed method considers the tracking of a stationary leader which sends a piece-wisely constant reference position signal.

In our recent work [6], we proposed a decentralized adaptive robust controller for trajectory tracking of robot manipulators. In this paper, the work of [6] is modified and extended to develop a new distributed robust control method for synchronized tracking of multiple EL systems, where the time-varying reference trajectory is sent to only a subset of the agents. It is assumed that the agents can exchange information with local neighbors on an undirectionally connected communication graph. In the local controller equipped in each generalized coordinate of each agent, a disturbance observer (DOB) is introduced to compensate for the low-passed coupled uncertainties, and a sliding mode control term is employed to handle the uncertainties that the DOB cannot compensate for sufficiently. By some damping terms, the boundedness of the signals of the overall multiple nonlinear systems is first ensured. Then we show how the DOB and sliding mode control play in a cooperative way in each coordinate to achieve an excellent synchronized tracking performance. Simulation results are provided to support the theoretical results.

## II. Background and problem statement

### A. Graph Theory

Consider a graph $\mathcal{G} = (\mathcal{V}, \mathcal{E}, \mathcal{A})$ with a finite set of $N$ nodes $\mathcal{V} = \{v_1, v_2, \cdots, v_N\}$ and a set of edges $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{V}$. Let $i$ denotes the $i$th agent. An edge of $\mathcal{E}$ is denoted as $e_{ij} = (v_i, v_j) \in \mathcal{E}$ where agent $j$ can receive information from agent $i$. In a directed graph, agent $j$ does not send information to agent $i$, whereas in an undirected graph, if $(v_i, v_j) \in \mathcal{E}$, then $(v_j, v_i) \in \mathcal{E}$. A graph is called connected if there exists a path between any two distinct agents. Denote the adjacency matrix as $\mathcal{A} = [a_{ij}] \in \mathcal{R}^{N\times N}$ with $a_{ij} > 0$ if $(v_j, v_i) \in \mathcal{E}$, and $a_{ij} = 0$ otherwise. Note $a_{ii} = 0$. For an undirected graph, we have $a_{ij} = a_{ji}$. The set of neighbors of a node $v_i$ is $\mathcal{N}_i = \{v_j \in \mathcal{V} | (v_j, v_i) \in \mathcal{E}\}$, i.e., the set of nodes with information incoming to $v_i$. The Laplacian matrix $\mathcal{L} = [l_{ij}] \in \mathcal{R}^{N\times N}$ is then defined as $l_{ii} = \sum_{j=1,j\neq i}^{N} a_{ij}$, and $l_{ij} = -a_{ij}, i \neq j$.

### B. EL System models

Consider $N$ agents governed by the following EL vector equations for $i = 1, \cdots, N$.

$$M_i(\theta_i)\ddot{\theta}_i + C_i(\theta_i, \dot{\theta}_i)\dot{\theta}_i + g_i(\theta_i) + f_i(\dot{\theta}_i) = u_i \qquad (1)$$

where $\theta_i = \theta_i(t) \in \Re^n$ is the generalized coordinate vector; $u_i \in \Re^n$ is the input torque vector; $M_i(\theta) = M_i^T(\theta) \in \Re^{n\times n}, M_i(\theta_i) > 0$ is the inertia matrix; $C_i(\theta_i, \dot{\theta}_i)\dot{\theta}_i \in \Re^n$ is the centrifugal and Coriolis torque; $g_i(\theta_i) \in \Re^n$ is the grativity torque; $f_i(\dot{\theta}) \in \Re^n$ is the friction force torque.

We first impose the following assumption.

*Assumption 1:* The reference trajectory $\theta_d(t) \in \mathcal{R}^n$ and the time derivatives $\dot{\theta}_d(t)$ and $\ddot{\theta}_d(t)$ are bounded signals.

Define an auxiliary error vector $r_i = [r_{i1}, \cdots, r_{in}]^T$ as

$$r_i = \dot{e}_i + \phi_i e_i \qquad (2)$$

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

where $e_i = \theta_i - \theta_d$ is the local tracking error vector, $\phi_i = \mathrm{diag}(\phi_{i1}, \cdots, \phi_{in}) > 0$ with constant entries.

Substituting $e_i$ and $r_i$ into (1), we have

$$M_i(\theta_i)\dot{r}_i + C_i(\theta_i, \dot{\theta}_i)r_i = u_i + \xi_i \tag{3}$$

where $\xi_i = [\xi_{i1}, \cdots, \xi_{in}]^T$ is considered to be an uncertain term of (3), and

$$\xi_i = -M_i(\theta_i)(\ddot{\theta}_d - \phi_i\dot{e}_i) - C_i(\theta_i, \dot{\theta}_i)(\dot{\theta}_d - \phi_i e_i) - g_i(\theta_i) - f_i(\dot{\theta}_i) \tag{4}$$

The global dynamics of the multiple EL systems is

$$M(\theta)\ddot{\theta} + C(\theta, \dot{\theta})\dot{\theta} + g(\theta) + f(\dot{\theta}) = u \tag{5}$$

$$\begin{aligned} M(\theta) &= \mathrm{diag}[M_1(\theta_1), .., M_N(\theta_N)] \\ C(\theta, \dot{\theta}) &= \mathrm{diag}[C_1(\theta_1, \dot{\theta}_1), .., C_N(\theta_N, \dot{\theta}_N)] \\ g(\theta) &= [g_1(\theta_1), \cdots, g_N(\theta_N)]^T \\ f(\dot{\theta}) &= [f_1(\dot{\theta}_1), \cdots, f_N(\dot{\theta}_N)]^T \\ u &= [u_1, \cdots, u_N]^T \end{aligned} \tag{6}$$

where $\theta = [\theta_1^T, \cdots, \theta_N^T]^T$.

And the global version of (3) is given as

$$M(\theta)\dot{r} + C(\theta, \dot{\theta})r = u + \xi \tag{7}$$

$$\xi = -M(\theta)(1_N \otimes \ddot{\theta}_d - \Phi\dot{e}) - C(\theta, \dot{\theta})(1_N \otimes \dot{\theta}_d - \Phi e) - g(\theta) - f(\dot{\theta}) \tag{8}$$

where $\Phi = \mathrm{diag}(\phi_1, .., \phi_N)$, $\xi = [\xi_1, \cdots, \xi_N]^T$ is the global uncertain term, $r = [r_1, \cdots, r_N]^T$ is the global auxiliary error vector, and $e = \theta - 1_N \otimes \theta_d$ is the global tracking error vector.

Then the following properties hold [7].

*Property 1:*

$$\mu_{\min}(M)I \leq M(\theta) \leq \mu_{\max}(M)I \tag{9}$$

where $\mu_{\max}(\cdot), \mu_{\min}(\cdot) > 0$ denote respectively the maximal and minimal eigenvalues of a matrix.

*Property 2:*

$$\| C(\theta, \dot{\theta}) \|_2 \leq c_H \| \dot{\theta} \|_2 \tag{10}$$

for some constant $c_H > 0$.

*Property 3:*

$$\| g(\theta) \|_2 \leq c_g, \quad \| f(\dot{\theta}_i) \|_2 \leq c_{f1} + c_{f2} \| \dot{\theta} \|_2 \tag{11}$$

for some constants $c_g, c_{f1}, c_{f2} > 0$.

*Property 4:*

$$x^T \left[ \frac{1}{2}\dot{M}(\theta) - C(\theta, \dot{\theta}) \right] x = 0, \quad {}^{\forall}x \neq 0 \tag{12}$$

### *C. Synchronized tracking problem*

The control objective is to design a controller for each agent to track a time-varying reference trajectory exerted by a leader, with the aid of the neighbor agents' information obtained by certain communication protocol. That is, $\| e_i \|_2$ and $\| \dot{e}_i \|_2$ $(i = 1, \cdots, N)$ should be controlled to be small.

To construct a feedback controller, we define the following local synchronization error vector of agent $i$ which will be used as a feedback signal:

$$e_{si} = \sum_{j \in \mathcal{N}_i} a_{ij}(\theta_i - \theta_j) + b_i(\theta_i - \theta_d) \tag{13}$$

where the scalar pinning gain $b_i \geq 0$. If agent $i$ receives information directly from the leader then $b_i > 0$, otherwise $b_i = 0$. $a_{ij}$ is the $(i, j)$ entry of the adjacency matrix $\mathcal{A}$ which defines the communication topology of the network.

Then the global synchronization error vector is given as $e_s = \mathcal{H}e$, where $\mathcal{H} = (\mathcal{L} + B) \otimes I_n$, $e_s = [e_{s1}^T, \cdots, e_{sN}^T]^T$, $B = \mathrm{diag}(b)$, $b = [b_1, \cdots, b_N]^T$.

We impose the following assumption on the communication topology of the network [4], [3].

*Assumption 2:* The communication graph $\mathcal{G} = (\mathcal{V}, \mathcal{E}, \mathcal{A})$ of the multiple EL systems is undirected and connected.

Then, the following lemma is useful [3], [4].

*Lemma 1:* If the information interchange graph $\mathcal{G}$ is undirected and connected, and if at least one of the elements of $b$ is nonzero, then $\mathcal{L} + B$ is a positive definite symmetric matrix.

According to the aforementioned definitions, the global auxiliary synchronization error vector $r_s$ is given as

$$r_s = \mathcal{H}r = \mathcal{H}(\dot{e} + \Phi e) = \dot{e}_s + \Phi e_s \tag{14}$$

where $r_s = [r_{s1}, \cdots, r_{sN}]^T$, $r_{si} = [r_{si1}, \cdots, r_{sin}]^T$.

For the EL system model (3), it is well known that the uncertainty term is bounded by the following relation [8]:

$$\| \xi \|_2 \leq \alpha_1 + \alpha_2 \| e \|_2 + \alpha_3 \| \dot{e} \|_2 + \alpha_4 \| e \|_2 \| \dot{e} \|_2 \tag{15}$$

where $\alpha_1, \alpha_2, \alpha_3, \alpha_4$ are some positive constants.

For a vector-valued signal $x(t)$, we define a truncated norm for $T > 0$ as $\| x \|_T \equiv \sup_{t \in [0,T]} \| x(t) \|_2$. Then we have [8]

*Lemma 2:* Let Assumption 1 and Properties 1∼4 hold. If there is a constant $T$ such that $\| r \|_T$ exists, then for all $t \in [0, T]$ we have for some $\beta_1, \beta_2, \beta_3 > 0$,

$$\| \xi \|_2 \leq \beta_1 + \beta_2 \| r \|_T + \beta_3 \| r \|_T^2 \tag{16}$$

## III. Controller design

### *A. Introduction of DOB*

Replacing $r$ in (7) by $r_s$, we have

$$\mathcal{H}^{-1}\dot{r}_s = M^{-1}u + M^{-1}(\xi - C(\theta, \dot{\theta})\mathcal{H}^{-1}r_s) \tag{17}$$

For the sake of design a distributed and decentralized controller $u_{ij}$ for each generalized coordinate, we define $\mathcal{H}_0^{-1}$ and $M_0$ as some diagonal nominal matrices of $\mathcal{H}^{-1}$ and $M$ respectively, and then we have

$$\begin{aligned} M_0\mathcal{H}_0^{-1}\dot{r}_s = {} & u + M_0M^{-1}(\xi - C(\theta, \dot{\theta})\mathcal{H}^{-1}r_s) \\ & + (M_0M^{-1} - I)u + M_0(\mathcal{H}_0^{-1} - \mathcal{H}^{-1})\dot{r}_s \end{aligned} \tag{18}$$

Let $M_0\mathcal{H}_0^{-1} = M_{s0} = \mathrm{diag}(m_{s01}, \cdots, m_{s0N})$ with $m_{s0i} = \mathrm{diag}(m_{s0i1}, \cdots, m_{s0in}) > 0$. Then we have the following vector-valued nominal linear system model.

$$M_{s0}\dot{r}_s = u + w \tag{19}$$

where $w = [w_1^T, \cdots, w_N^T]^T$ with $w_i = [w_{i1}, \cdots, w_{in}]^T$ is the global lumped disturbance vector expressed as

$$\begin{aligned} w = {} & M_0M^{-1}(\xi - C(\theta, \dot{\theta})\mathcal{H}^{-1}r_s) + (M_0M^{-1} - I)u \\ & + M_0(\mathcal{H}_0^{-1} - \mathcal{H}^{-1})\dot{r}_s \end{aligned} \tag{20}$$

Writing the dynamics of the $j$th generalized coordinate of the $i$th agent, we have

$$m_{s0ij}\dot{r}_{sij} = u_{ij} + w_{ij} \tag{21}$$

where $w_{ij}$ is considered as a lumped disturbance term. Since calculation of $\dot{r}_{sij}$ by direct differentiation is usually contaminated with high frequency noise, we may pass $w_{ij}$ through a low-pass filter to obtain its estimate as

$$Q_{ij}(s)w_{ij} = Q_{ij}(s)(m_{s0ij}sr_{sij} - u_{ij}) \tag{22}$$

In this paper, for convenience of expression, $s$ denotes not only the Laplace operator, but also a differential operator. This is the so-called DOB studied extensively in the literature. In this a study, we adopt a simple second-order filter

$$Q_{ij}(s) = \frac{1}{(1+\lambda_{ij}s)^2} \tag{23}$$

where $\lambda_{ij} > 0$.

However, we can only expect $Q(s)w_{ij} \approx w_{ij}$ at low-frequencies due to limited pass-band of the DOB. Moreover, the DOBs' outputs $\widehat{w}_{ij}(i = 1, \cdots, n,\ j = 1, \cdots, N)$ may disturb the signals of the other generalized coordinates. To ease the analysis shown later, a straightforward and simple idea is to saturate the output of the DOB as

$$\widehat{w}_{ij} = \begin{cases} \overline{w} & \text{for } |Q_{ij}(s)(m_{s0ij}sr_{ij} - u_{ij})| \geqslant \overline{w} \\ Q_{ij}(s)(m_{s0ij}sr_{ij} - u_{ij}) & \\ & \text{for } |Q_{ij}(s)(m_{s0ij}sr_{ij} - u_{ij})| < \overline{w} \\ -\overline{w} & \text{for } |Q_{ij}(s)(m_{s0ij}sr_{ij} - u_{ij})| \leqslant -\overline{w} \end{cases} \tag{24}$$

where $\overline{w} > 0$ is a selected upper bound of $|\widehat{w}_{ij}|$. Usually, it is recommended to choose a sufficiently large $\overline{w}$. However, even when $\overline{w}$ is not so large such that $\widehat{w}_{ij}$ is really saturated and hence the estimation error $(w_{ij} - \widehat{w}_{ij})$ is not sufficiently small, the control performance is still satisfactory, owing to the sliding mode control term included in the local controller (25) given later. The key point is that the DOB and the sliding mode control term work in a cooperative manner as suggested in [6]. Owing to their cooperative effects, the problems of high-gain or chattering can be avoided. This will be confirmed later by the numerical examples.

### *B. Description of the controller*

Motivated by the aforementioned discussions, we design the following local controller $u_{ij}$ for the $j$th generalized coordinate of agent $i$, using only the neighbor information of agent $i$ to ensure the boundedness of the global system signals and to achieve a satisfactory control performance.

$$u_{ij} = -\rho_a l_1^2 r_{sij} - \rho_b \overline{w} r_{sij} - \rho_c \eta_{\max} r_{sij} - \widehat{w}_{ij} - \eta_{ij}\text{sat}(r_{sij}) \tag{25}$$

where $k, \rho_a, \rho_b, \rho_c, l_1, \eta_{ij} > 0$, $\text{sat}(r_{sij}) = r_{sij}/(|r_{sij}| + \delta_{ij})$, $\delta_{ij} > 0$, $\eta_{\max} = \max(\eta_{11}, \cdots, \eta_{1n}, \cdots, \eta_{N1}, \cdots, \eta_{Nn})$.

The controller is explained as follows.

The damping term $-\rho_a l_1^2 r_{sij}$ is adopted to suppress the effects of neglected uncertainties of the global system model summarized as $\xi$ in (8). The constant $l_1$ is chosen such that $l_1 > \| r \|_2 / \sqrt{Nn}$ for all $t > 0$. It will be shown that there exists such an $l_1$. The term $-\widehat{w}_{ij}$ is a compensation term by DOB for each generalized coordinate. Since the DOBs' outputs $\widehat{w}_{ij}(i = 1, \cdots, N,\ j = 1, \cdots, n)$ may disturb mutually, to suppress the interactions due to $\widehat{w}_{ij}$, we employ the damping term term $-\rho_b \overline{w} r_{sij}$. The last term of $u_{ij}$ is a smoothed version of sliding mode control term. The damping term $-\rho_c \eta_{\max} r_{sij}$ is a term to suppress the interactions among the sliding mode control terms.

The global expression is given as below which will be used for analysis of the global system.

$$u = -\rho_a l_1^2 r_s - \rho_b \overline{w} r_s - \rho_c \eta_{\max} r_s - \widehat{w} - \eta\text{Sat}(r_s) \tag{26}$$

where $\widehat{w} = [\widehat{w}_1, \cdots, \widehat{w}_N]^T$, $\widehat{w}_i = [\widehat{w}_{i1}, \cdots, \widehat{w}_{in}]^T$, $\eta = \text{diag}[\eta_1, \cdots, \eta_N]^T$, $\eta_i = \text{diag}[\eta_{i1}, \cdots, \eta_{in}]^T$, $\text{Sat}(r_s) = [\text{sat}(r_{s1}), \cdots, \text{sat}(r_{sN})]^T$, $\text{sat}(r_{si}) = [\text{sat}(r_{si1}), \cdots, \text{sat}(r_{sin})]^T$.

*Remark 1:* The controller (26) is an extension or modification of the decentralized controller for a single EL system [6]. Compared to the controller in [6] where some nonlinear damping terms with signal dependent gains are used, in the present controller, we have to use some linear damping terms with relatively high constant gains, such as $\rho_a l_1^2 r_s$, $\rho_b \overline{w} r_s$ and $\rho_c \eta_{\max} r_s$. This is mainly due to the presence of the matrix $\mathcal{H}$ in (30) given later. Therefore, as the price of multiple EL system control, the controller design is less flexible as the case of a single agent.

### *C. Comments and guidelines of parameter design*

The guidelines of parameter design are aummarized here based on the theoretical analysis given later.

The constant $l_1$ in (25) should meet the requirement that $l_1 > \| r \|_2 / \sqrt{Nn}$ for all $t > 0$. That is, we have to guess the upper bound of $\| r \|_2$. See Theorem 1 later.

The entries of $\phi_i$ that appeared in (2) should not be very large, since large values of them may lead to a very large $\| r \|_2^2$ which may violate the condition imposed on $l_1$.

A small smoothing factor $\delta_{ij}$ for $\text{sat}(r_{sij})$ in (25) leads to a small ultimate tracking error of the corresponding generalized coordinate. However, as well known in the literature, a less smooth switching function may cause the chattering problem. A high sliding mode control gain $\eta_{ij}$ helps to achieve a small control ultimate tracking error, but it may also cause the chattering problem, and may cause a high gain control term $\rho_c \eta_{\max} r_{si}$.

The saturation level $\overline{w}$ of the DOBs should not be very large to avoid causing a high gain control term $\rho_b \overline{w} r_{si}$.

Usually, a smaller $\lambda_{ij}$ of the DOB filter (23) leads to a better disturbance performance. However, too small a $\lambda_{ij}$ may make $\widehat{w}_{ij}$ sensitive to the noise.

When $l_1^2$, $\overline{w}$, $\eta_{\max}$ and $\eta_{ij}$ meet the aforementioned requirements, the choice of $\rho_a$, $\rho_b$ and $\rho_c$ in (25) is trivial. Some moderate values of these parameters are satisfactory.

## IV. Performance analysis

Since all of the agents interact with their neighbors, we cannot easily see if the signals of the agents are all bounded. We should first ensure the boundedness of the global system signals. Then provided the boundedness of the global system signals, we can analyze the control performance of each agent. Therefore, the performance analysis includes two phases.

### A. Analysis of the global system

The results of analysis are given in Theorem 1. The proof is an extension of [8], [6], but with modifications specified by the newly designed controller in this study.

*Theorem 1:* Let Assumptions 1 and 2 hold. For the multiple EL systems (5) controlled by the proposed distributed robust controller (26), there exists a constant $l_1 > 0$, such that $r$ is bounded as $\| r \|_2 < \sqrt{Nn} l_1$ and hence all the internal signals are bounded, provided the following condition.

$$\sqrt{\frac{\mu_{\min}(M)}{\mu_{\max}(M)}}\sqrt{Nn}l_1 > \left[\frac{2Nn(\beta_1+\beta_2 l_1+\beta_3 l_1^2)}{\rho_a \mu_{\min}(\mathcal{H})}\right]^{1/3} \geq \left(\frac{N^2n^2\overline{w}}{2\rho_a\rho_b\mu_{\min}^2(\mathcal{H})}+\frac{N^2n^2\eta_{\max}}{2\rho_a\rho_c\mu_{\min}^2(\mathcal{H})}\right)^{1/4} \tag{27}$$

*Remark 2:* The first inequality of (27) is easily satisfied for sufficiently large $l_1$, $\rho_a$. The second inequality of (27) can be satisfied for sufficiently large $l_1$, $\rho_b$, $\rho_c$.

**Proof.** According to Assumption 2, we have Lemma 1 and hence $\mu_{\min}(\mathcal{H}) > 0$. We are now ready to show that there exists a constant $l_1 > 0$, such that $r$ is bounded as $\| r \|_2 < \sqrt{Nn} l_1$. The conclusion is proved by contradiction. To this end, according to (27) we first let a positive constant $l_1$ satisfy

$$\begin{aligned}\| r(0) \|_2 &< \left[\frac{2Nn(\beta_1+\beta_2 l_1+\beta_3 l_1^2)}{\rho_a \mu_{\min}(\mathcal{H})}\right]^{1/3}\\ &< \sqrt{\frac{\mu_{\min}(M)}{\mu_{\max}(M)}}\sqrt{Nn}l_1 \leq \sqrt{Nn}l_1\end{aligned} \tag{28}$$

Now assume the signal $r(t)$ is not bounded. Thus there always exists a smallest time $T_1$ such that $\| r(T_1) \|_2 = \sqrt{Nn} l_1$. Consider a Lyapunov function candidate with respect to the global tracking error vector.

$$V(t,r) = \frac{1}{2} r^T M(\theta) r \tag{29}$$

Taking the derivative along the trajectory of the closed-loop system, we have

$$\begin{aligned}\dot{V}(t,r) &= r^T\left(u+\xi-C(\theta,\dot{\theta})r+\frac{1}{2}\dot{M}(\theta)r\right)\\ &\leq r^T u + \| r \|_2 \| \xi \|_2\\ &= -\rho_a l_1^2 r^T\mathcal{H}r - \rho_b\overline{w}r^T\mathcal{H}r - r^T\widehat{w}\\ &\quad -\rho_c\eta_{\max}r^T\mathcal{H}r - r^T\eta\mathrm{Sat}(r_s) + \| r \|_2 \| \xi \|_2\\ &\leq -\rho_a l_1^2\mu_{\min}(\mathcal{H}) \| r \|_2^2 + \| r \|_2 \| \xi \|_2\\ &\quad -\rho_b\overline{w}\mu_{\min}(\mathcal{H}) \| r \|_2^2 + \| r \|_2 \| \widehat{w} \|_2\\ &\quad -\rho_c\eta_{\max}\mu_{\min}(\mathcal{H}) \| r \|_2^2 + \sqrt{Nn}\eta_{\max} \| r \|_2\end{aligned} \tag{30}$$

Here, $\eta_{\max}$ is the maximum diagonal element of $\eta$. Completing the squares, we have

$$\begin{aligned}\dot{V}(t,r) &\leq -\rho_a l_1^2\mu_{\min}(\mathcal{H}) \| r \|_2^2 + \| r \|_2 \| \xi \|_2\\ &\quad + \frac{\| \widehat{w} \|_2^2}{4\rho_b\overline{w}\mu_{\min}(\mathcal{H})} + \frac{Nn\eta_{\max}^2}{4\rho_c\eta_{\max}\mu_{\min}(\mathcal{H})}\end{aligned} \tag{31}$$

By (28), and the assumption that there exists a smallest time $T_1$ such that $\| r(T_1) \|_2 = \sqrt{Nn} l_1$, we have $\| r \|_2 < \sqrt{Nn} l_1$ for any $t < T_1$. Then using Lemma 2, we have for $t < T_1$,

$$\begin{aligned}\dot{V}(t,r) &\leq -\frac{\rho_a\mu_{\min}(\mathcal{H})}{Nn} \| r \|_2^4 + \| r \|_2 \left(\beta_1+\beta_2 l_1+\beta_3 l_1^2\right)\\ &\quad + \frac{Nn\overline{w}}{4\rho_b\mu_{\min}(\mathcal{H})} + \frac{Nn\eta_{\max}}{4\rho_c\mu_{\min}(\mathcal{H})}\\ &= -\frac{\rho_a\mu_{\min}(\mathcal{H})}{2Nn} \| r \|_2 \left(\| r \|_2^3 - \frac{2Nn(\beta_1+\beta_2 l_1+\beta_3 l_1^2)}{\rho_a\mu_{\min}(\mathcal{H})}\right)\\ &\quad -\frac{\rho_a\mu_{\min}(\mathcal{H})}{2Nn}\left(\| r \|_2^4 - \frac{N^2n^2\overline{w}}{2\rho_a\rho_b\mu_{\min}^2(\mathcal{H})} - \frac{N^2n^2\eta_{\max}}{2\rho_a\rho_c\mu_{\min}^2(\mathcal{H})}\right)\end{aligned} \tag{32}$$

We then can say that there exists a time instant $t_2 = T_1 - t_1 > 0,\ t_1 > 0$ such that

$$\begin{aligned}\sqrt{Nn}l_1 > \| r(T_1-t_1) \|_2 &= \left[\frac{2Nn(\beta_1+\beta_2 l_1+\beta_3 l_1^2)}{\rho_a \mu_{\min}(\mathcal{H})}\right]^{1/3}\\ &\geq \left(\frac{N^2n^2\overline{w}}{2\rho_a\rho_b\mu_{\min}^2(\mathcal{H})}+\frac{N^2n^2\eta_{\max}}{2\rho_a\rho_c\mu_{\min}^2(\mathcal{H})}\right)^{1/4}\end{aligned} \tag{33}$$

However, according to (32), we have $d/dtV(t) \leq 0$, for all $t \in [T_1 - t_1, T_1]$. Therefore, for all $t \in [T_1 - t_1, T_1]$, we have

$$\begin{aligned}V[T_1, r(T_1)] &\leq V[(T_1-t_1), r(T_1-t_1)]\\ &\leq \frac{1}{2}\mu_{\max}(M)\left[\frac{2Nn(\beta_1+\beta_2 l_1+\beta_3 l_1^2)}{\rho_a \mu_{\min}(\mathcal{H})}\right]^{2/3}\end{aligned} \tag{34}$$

But the definition of $T_1$ leads to

$$V_1[T_1, r(T_1)] \geq \frac{1}{2}\mu_{\min}(M)Nnl_1^2 \tag{35}$$

Clearly, the last two inequalities are in contradiction, according to (28). This implies that the assumption of $\| r(T_1) \|_2 = \sqrt{Nn} l_1$ is false. Thus the error signal vector $r$ is bounded and satisfies $\| r(t) \|_2 < \sqrt{Nn} l_1$ for all $t \geq 0$.

Furthermore, according to Assumption 1, and (2), (15) and (14), we conclude that $e$, $\dot{e}$, $\theta$, $\dot{\theta}$, $\xi$ and $r_s$ are bounded. And hence each local controller $u_{ij}$ is bounded. Therefore, all the internal signals are bounded. □

*Remark 3:* The condition (27) is always satisfied for a sufficiently large bound $l_1$. The results of Theorem 1 only tell us that $r$ and hence all the internal signals can be made to be bounded. It should be emphasized here that at the present stage our purpose is only to ensure the boundedness of the signals. And hence a conservative bound of the signals is acceptable. Later, we will show that the individual synchronization error $r_{sij}$ can be made sufficiently small by virtue of the corresponding local controller.

### B. Analysis of each agent

We are now ready to analyze how the DOBs and sliding mode control techniques bring improvement in each generalized coordinate. Substituting the local controller (25) into the subsystem (21), the resultant subsystem of the $j$th generalized coordinate of the $i$th agent becomes

$$\begin{aligned} m_{s0ij}\dot{r}_{sij} = &-\rho_a l_1^2 r_{sij} - \rho_b \overline{w} r_{sij} - \rho_c \eta_{\max} r_{sij} \\ &-\widehat{w}_{ij} - \eta_{ij}\frac{r_{sij}}{|r_{sij}| + \delta_{ij}} + w_{ij} \end{aligned} \tag{36}$$

Owing to the results of Theorem 1, $w_{ij}(t)$ and $\widehat{w}_{ij}(t)$ are bounded. Define

$$\eta^*_{ij,0} = \sup_{0\le\tau\le t} |w_{ij}(\tau) - \widehat{w}_{ij}(\tau)| \tag{37}$$

*Theorem 2:* Let the assumptions and results of Theorem 1 hold. The synchronization error of the $j$th generalized coordinate of the $i$th agent satisfies

$$|r_{sij}(t)| \le |r_{sij}(0)| e^{-\frac{c}{m_{s0ij}}t} + \sqrt{\frac{\delta_{ij}\eta^*_{ij,0}}{c}} \tag{38}$$

if $\eta_{ij} \ge \eta^*_{ij,0}$, or

$$|r_{sij}(t)| \le |r_{sij}(0)| e^{-\frac{c}{2m_{s0ij}}t} + \frac{(\eta^*_{ij,0} - \eta_{ij})}{c} + \sqrt{\frac{2\delta_{ij}\eta_{ij}}{c}} \tag{39}$$

if $0 \le \eta_{ij} < \eta^*_{ij,0}$, where $c = \rho_a l_1^2 + \rho_b \overline{w} + \rho_c \eta_{\max}$.

**Proof.** We first consider the case of $\eta_{ij} \ge \eta^*_{ij,0}$, i.e., the sliding mode control gain exceeds the maximum amplitude of $(w_{ij} - \widehat{w}_{ij})$. From (36), we have

$$\frac{d}{dt}\left(\frac{m_{s0ij} r_{sij}^2}{2}\right) \le -c r_{sij}^2 + \delta_{ij}\eta^*_{ij,0} \tag{40}$$

and hence

$$r_{sij}^2(t) \le e^{-\frac{2c}{m_{s0ij}}t} r_{sij}^2(0) + \frac{\delta_{ij}\eta^*_{ij,0}}{c} \tag{41}$$

This leads to (38).

In the case of $0 \le \eta_{ij} < \eta^*_{ij,0}$, we have

$$\begin{aligned} \frac{d}{dt}\left(\frac{m_{s0ij} r_{sij}^2}{2}\right) \le &-\frac{c}{2} r_{sij}^2 - \left(\sqrt{\frac{c}{2}}|r_{sij}| - \frac{\eta^*_{ij,0} - \eta_{ij}}{\sqrt{2c}}\right)^2 \\ &+ \frac{(\eta^*_{ij,0} - \eta_{ij})^2}{2c} + \delta_{ij}\eta_{ij} \end{aligned} \tag{42}$$

and hence

$$r_{sij}^2(t) \le e^{-\frac{c}{m_{s0ij}}t} r_{sij}^2(0) + \left(\frac{(\eta^*_{ij,0} - \eta_{ij})^2}{c_i^2} + \frac{2\delta_{ij}\eta_{ij}}{c_i}\right) \tag{43}$$

This leads to (39). □

However, $\eta^*_{ij,0}$ may not be small since the initial value $\widehat{w}_{ij}(0)$ is often set to be zero. To investigate the performance after a short transient phase of DOB. Let $t_{ij}(\lambda_{ij})$ be an effective time-constant of the DOB depending on $\lambda_{ij}$, until which the initial value of $(w_{ij} - \widehat{w}_{ij})$ has decayed out sufficiently such that for a relatively small constant $\eta^*_{ij,t_{ij}}$ we have

$$\eta^*_{ij,t_{ij}} = \sup_{t_{ij}(\lambda_{ij})\le\tau\le t} |w_{ij}(\tau) - \widehat{w}_{ij}(\tau)| \tag{44}$$

Comparing (37) and (44), it is expected that $\eta^*_{ij,t_{ij}}$ can be much smaller than $\eta^*_{ij,0}$. Then we have

*Corollary 1:* For $t \ge t_{ij}(\lambda_{ij})$, the synchronization error of the $j$th generalized coordinate of the $i$th agent satisfies

$$|r_{sij}(t)| \le |r_{sij}(t_{ij})| e^{-\frac{c}{m_{s0ij}}(t-t_{ij})} + \sqrt{\frac{\delta_{ij}\eta^*_{ij,t_{ij}}}{c}} \tag{45}$$

if $\eta_{ij} \ge \eta^*_{ij,t_{ij}}$, or

$$\begin{aligned} |r_{sij}(t)| \le &|r_{sij}(t_{ij})| e^{-\frac{c}{2m_{s0ij}}(t-t_{ij})} \\ &+ \frac{(\eta^*_{ij,t_{ij}} - \eta_{ij})}{c} + \sqrt{\frac{2\delta_{ij}\eta_{ij}}{c}} \end{aligned} \tag{46}$$

if $0 \le \eta_{ij} < \eta^*_{ij,t_{ij}}$, where $c = \rho_a l_1^2 + \rho_b \overline{w} + \rho_c \eta_{\max}$.

Theorem 2 and Corollary 1 imply that the auxiliary synchronization error $r_s$ is uniformly ultimately bounded (UUB), and hence the auxiliary tracking error $r = \mathcal{H}^{-1} r_s$ is UUB.

## V. Simulation studies

For the sake of comparison, we borrow the example in [3] and carry out the numerical simulations under the same conditions as possible. Consider a group of 6 two-DOF planar robot arms:

$$\begin{aligned} &\begin{bmatrix} m_{i11}(\theta_i) & m_{i12}(\theta_i) \\ m_{i21}(\theta_i) & m_{i22}(\theta_i) \end{bmatrix} \begin{bmatrix} \ddot{\theta}_{i1} \\ \ddot{\theta}_{i2} \end{bmatrix} + \begin{bmatrix} h_{i1}(\theta_i, \dot{\theta}_i) \\ h_{i2}(\theta_i, \dot{\theta}_i) \end{bmatrix} \\ &\qquad + \begin{bmatrix} g_{i1}(\theta_i) \\ g_{i2}(\theta_i) \end{bmatrix} = \begin{bmatrix} u_{i1} \\ u_{i2} \end{bmatrix} \end{aligned} \tag{47}$$

where $i = 1, \cdots, 6$, and

$$\begin{aligned} m_{i11}(\theta_i) &= m_{i1} l_{ci1}^2 + m_{i2}(l_{i1}^2 + l_{ci2}^2) + I_{i1} + I_{i2} \\ &\quad + 2 m_{i2} l_{i1} l_{ci2} \cos(\theta_{i2}) \\ m_{i12}(\theta_i) &= m_{i2} l_{ci2}^2 + I_{i2} + m_{i2} l_{i1} l_{ci2} \cos(\theta_{i2}) \\ m_{i21}(\theta_i) &= m_{i12} \\ m_{i22}(\theta_i) &= m_{i2} l_{ci2}^2 + I_{i2} \end{aligned} \tag{48}$$

$$\begin{aligned} h_{i1}(\theta_i, \dot{\theta}_i) &= -m_{i2} l_{i1} l_{ci2} (2\dot{\theta}_{i1}\dot{\theta}_{i2} + \dot{\theta}_{i2}^2) \sin(\theta_{i2}) \\ h_{i2}(\theta_i, \dot{\theta}_i) &= m_{i2} l_{i1} l_{ci2} \dot{\theta}_{i1}^2 \sin(\theta_{i2}) \\ g_{i1}(\theta_i) &= g(m_{i1} l_{ci1} + m_{i2} l_{i1}) \cos(\theta_{i1}) \\ &\quad + m_{i2} g l_{ci2} \cos(\theta_{i1} + \theta_{i2}) \\ g_{i2}(\theta_i) &= m_{i2} g l_{ci2} \cos(\theta_{i1} + \theta_{i2}) \end{aligned} \tag{49}$$

where $g = 9.807$[m/s$^2$], and the physical parameters are given in Table I.

The network topology for communication among the agents is shown in Fig. 1. It can be verified that agents 1∼6 are undirectionally connected, and only agents 3 and 6 have access

TABLE I

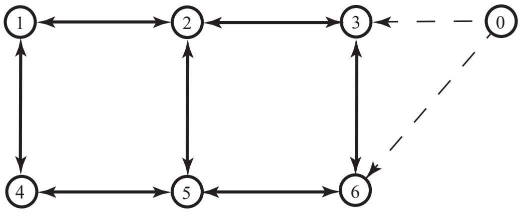

Fig. 1. Information exchange graph of the leader and followers

to the leader (agent 0). The corresponding adjacency matrix and pinning vector are given as follows.

$$\mathcal{A} = \begin{bmatrix} 0 & 1 & 0 & 1 & 0 & 0 \\ 1 & 0 & 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 0 & 1 & 0 \end{bmatrix}, \quad b = [0, 0, 1, 0, 0, 1]^T \tag{50}$$

We investigate the synchronized tracking performance for the following reference trajectory vector and its derivative generated by the leader.

$$\begin{aligned} \theta_d &= \left[\cos\left(\frac{2\pi}{60}t\right),\ \sin\left(\frac{2\pi}{60}t\right)\right]^T \quad \text{[rad]} \\ \dot{\theta}_d &= \left(\frac{2\pi}{60}\right)\left[-\sin\left(\frac{2\pi}{60}t\right),\ \cos\left(\frac{2\pi}{60}t\right)\right]^T \quad \text{[rad/s]} \end{aligned} \tag{51}$$

And to show that the controllers are robust against nonzero initial tracking errors, the initial conditions are given as

$$\begin{aligned} \theta_i(0) &= \left[\frac{\pi}{7}i,\ \frac{\pi}{8}i\right]^T \quad \text{[rad]} \\ \dot{\theta}_i(0) &= [0.05i - 0.2,\ -0.05i + 0.2]^T \quad \text{[rad/s]} \end{aligned} \tag{52}$$

According to the design guidelines, we choose the design parameters of the local controllers (25) as follows.

$$\begin{aligned} &\phi_{i1} = \phi_{i2} = 0.5 \\ &\rho_a = \rho_b = \rho_c = 1,\ \eta_{i1} = \eta_{i2} = 3 \\ &l_1 = 2,\ \delta_{i1} = \delta_{i2} = 0.05 \end{aligned} \tag{53}$$

where $i = 1, \cdots, 6$. The nominal values in (21) are given as $m_{s0i1} = m_{s0i2} = 1$. The time-constants of the DOB filters are given as $\lambda_{i1} = \lambda_{i2} = 0.02$. And the saturation level of the DOBs is chosen as $\overline{\widehat{w}} = 30$ (see (24)).

The simulation results are shown in Fig. 2, where from the top to the bottom are respectively the position-tracking errors $e_{i1}$, $e_{i2}$, auxiliary errors $r_{i1}$, $r_{i2}$, control signals $u_{i1}$, $u_{i2}$ and DOBs' outputs $\widehat{w}_{i1}$, $\widehat{w}_{i2}$, where the lines of magenta, cyan, red, green, black and blue represents the signals of agents 1∼6 respectively. It can be found in Fig. 1 that the proposed distributed controllers deliver a very excellent synchronized tracking performance, owing to the cooperative effects by DOBs and sliding mode control terms.

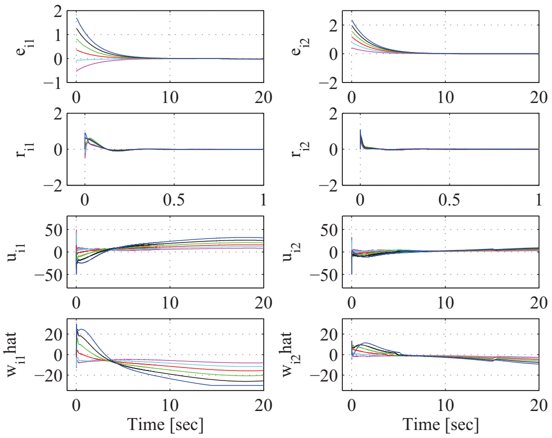

Fig. 2. Synchronized tracking results of 6 two-DOF planar robot arms.

## VI. CONCLUSIONS

In this paper, a distributed robust control method for synchronized tracking of multiple EL systems has been proposed. The problem setting is similar to the works of [3], [4], where the time-varying reference trajectory is sent to only a subset of the agents and the network graph is assumed to be undirectionally connected. The proposed distributed controllers while delivering a very excellent control performance, are model-free and require only the neighbors' information. Therefore the proposed method is considered to be simple and requires moderate computational burden.

***Abstract*—A novel design of two-wheeled double inverted pendulum-like vehicle with a movable payload is presented in this paper. The developed design extends the abilities of the vehicle with five degrees of freedom. The increase of degrees of freedom provides the vehicle with more flexibility in maneuvering in narrow spaces and limited travel distances. The dynamic model of the system is derived using Euler-Lagrange approach and simulated in Matlab Simulink environment. A hybrid fuzzy logic control approach is adopted to control and stabilise the vehicle. Various external disturbances are applied to the system to test the robustness of the control approach. It is demonstrated that the proposed controller successfully stabilises the vehicle in the upright position.**

***Keywords; modelling ; Lagrangian dynamics ; double inverted pendulum ; hybrid control; fuzzy logic control;***

## I. Introduction

An extensive amount of research on inverted pendulum (IP) system is found in the literature due its high nonlinearity and under-actuated nature [1]. It has been used as a platform to test various control algorithms as well as a basis to develop various applications. The applications include, but not limited to, gait of humanoid robots, personal transporters, and self-balancing wheelchairs [2]. The IP system exists in many variations such as mobile inverted pendulum on cart and rotational IP systems. In addition, IP systems have been extended to have multiple links to increase the degrees of freedom (DOF); such as double inverted and triple inverted pendulums [3][4][5]. The increased DOF increase the complexity of the system adding more space for new applications to be developed.

A novel configuration of balancing two-wheeled double inverted pendulum-like vehicle with a movable payload has been presented in [1]. The novelty in the configuration relies in the increased degrees of freedom with the ability to lift a payload to a higher extent. Mathematical model of system dynamics has been derived and presented in [2]. A hybrid fuzzy logic control (FLC) approach is developed to control the vehicle. The vehicle model is used as a basis for an ongoing research of new type of self-balancing wheelchairs with an extended height and ability to maneuver on irregular and uneven surfaces.

## II. System Description and Mathematical Model

A schematic diagram of the designed vehicle is shown in Figure 1. The vehicle is designed based on the double inverted pendulum system model with novel modifications [1]. The vehicle consists of two links and a cart driven by two DC motors that in turn drive the entire system. A third DC motor is used to drive the second link. These motors will help stabilizing the system in the upright position by applying an appropriate control signal. The second link consists of two co-axial rods connected by a linear actuator to enable lifting up the payload to a demanded height. Therefore, the system has five degrees of freedom; translational motion with the right and left wheels, first and second links and linear actuator on the second link. The tilt angles of the first and second links are $\theta_1$ and $\theta_2$ respectively. The linear displacement of the payload designated as Q, while the angular displacements of the left and right wheels designated as $\delta_L$ and $\delta_R$ respectively.

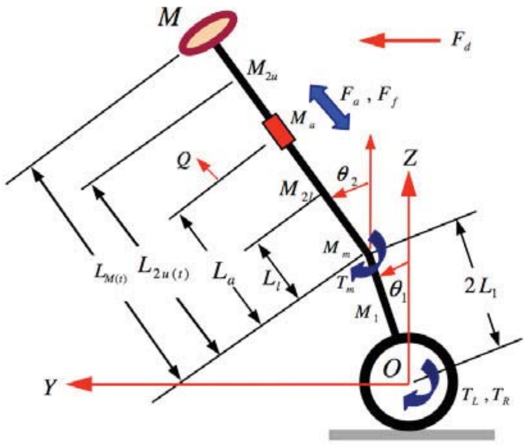

Figure 1. Schematic description of the vehicle

Table 1 describes system model terms and parameters. The system mathematical model consists of five differential equations. The system was modeled using Euler-Lagrange approach because of the system complexity and high coupling nature. System equations of motion were derived in detail in [2] and are presented as in equations (1-5).

Table 1. Nomenclature

| *Variable* | *Description* | *Unit* |
|---|---|---|
| $L_{M(t)}$ | Distance to the COM of the payload | m |
| $L_{2u(t)}$ | Distance to the COM of the upper part link 2 | m |
| $L_a$ | Position of the linear actuator | m |
| $L_l$ | Half length of link 1 | m |
| Q | Displacement of the linear actuator | m |
| $M_1$ | Mass of link 1 | kg |
| $M_m$ | Mass of motor driving link 2 | kg |
| $M_{2l}$ | Mass of the lower part of link 2 | kg |
| $M_a$ | Mass of the linear actuator | kg |
| $M_{2u}$ | Mass of the upper part of link 2 | kg |
| M | Payload mass | kg |
| $T_R$,$T_L$ | Right and left wheels driving torques | N.m |
| $T_m$ | Motor torque | N.m |
| $F_f$ | Frictional force in the linear actuator | N |
| $F_d$ | External disturbance force | N |
| $\theta_1$ | Angular position of link 1 to the positive Z axis | rad |
| $\theta_2$ | Angular position of link 2 to the positive Z axis | rad |
| $\phi$ | Yaw angle of the vehicle around the Z axis | rad |
| $\delta_R$ , $\delta_L$ | Angular position of the right and left wheels | rad |
| $J_l$ | Mass moment of inertia of link 1 | kg.m$^2$ |
| $J_{2u}$ | Mass moment of inertia of the upper rod of link 2 | kg.m$^2$ |
| $J_a$ | Mass moment of inertia of the actuator | kg.m$^2$ |
| $J_M$ | Mass moment of inertia of the payload | kg.m$^2$ |
| $J_w$ | Mass moment of inertia of the wheels | kg.m$^2$ |
| $J_{IB}$ | Mass moment of inertia of the intermediate body | kg.m$^2$ |
| $J_{2L}$ | Mass moment of inertia of the lower rod of link 2 | kg.m$^2$ |

$$\begin{aligned}

\end{aligned}\tag{4}$$

$$\begin{aligned}
&C_8\ddot{Q} - \frac{1}{2}(C_{12}+2C_8Q)\dot{\theta}_2^2 - C_8\frac{R_w}{2}\dot{\theta}_2(\dot{\delta}_L+\dot{\delta}_R)\cos\theta_2\\
&-2L_1C_8\dot{\theta}_1\dot{\theta}_2\cos(\theta_1-\theta_2) + C_8g\cos\theta_2 = F_a - F_{fa}
\end{aligned}\tag{5}$$

## III. Hybrid Fuzzy Logic Control Strategy

Two types of hybrid FLC are designed and implemented to control the novel non-linear two-wheeled vehicle with five degrees of freedom and movable payload. Referring to Figure 2, the block diagram of the system is presented. Proportional-Derivative-like fuzzy logic controller (PD-like FLC) is used to control the angular displacement of the wheels, the first link tilt angle and the payload linear actuator displacement. A PD plus integral fuzzy logic controllers (PD+I FLC) are used to control the links tilt angles to overcome the steady-state error.

The inputs to the PD-like FLC are the error signal and the change of error. While the inputs for the PD+I FLC are the error signal, change of error and the sum of previous errors. Figure 2 presents the Simulink block diagram of the controlled system.

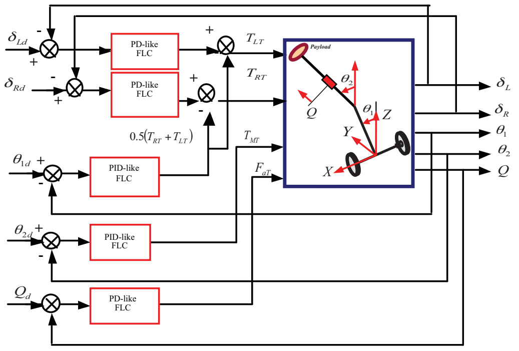

Figure 2. System simulink block diagram

The design of the FLC involves choosing a suitable fuzzy inference engine, defining the fuzzy rules and choosing the membership function type. The FLC developed here is based on Mamdani-type fuzzy inference engine with 25 fuzzy rules presented in Table 2 and Figure 3. The generation of the fuzzy rules-base is based on the required system performance to minimize the system error between the output signal and the desired signal.

Table 2. Fuzzy rule base

## IV. Simulation And Results

In order to test the robustness of the developed control approach, two types of external disturbances were applied to the system. The first simulation scenario incorporates applying disturbances with different amplitudes to the system. The second scenario is to apply disturbances with different durations to the system.

### *A. Variation of disturbance force amplitudes*

Different levels of the applied disturbance force; 0 N, 40 N, 80 N, 160 N, 300 N, were used to examine the robustness of the developed hybrid FLC. The response of the system to the disturbances applied to the centre of the first link and second link are presented in Figures 4 and 5 respectively.

As noted in Figure 4, overshoots resulted in the tilt angle of the first link with a maximum peak amplitude increase of 30% at the maximum disturbance. The average settling time is approximately 5 seconds. The settling time increased by 3% of the initial value with each increase in the disturbance amplitude. Negative peaks at displacements of both wheel motors. Thus explains the opposing movement of the cart to overcome the disturbances and to stabilise the first link at the upright position. The tilt angle of the second link and the displacement of the payload actuator were not affected by this disturbance.

Referring to Figure 5, the effect of applying disturbances to the centre of the second link can be noted. Disturbances resulted in oscillations in the tilt angle of the second link. The tilt angle converges back to the set point within 5 seconds at the maximum applied disturbance force while the rise-time remained unchanged. With every increment of disturbance force amplitude, the peak value increased by an average of 50%. The angular displacements of both wheels, the tilt angle of the first link and the displacement of the payload actuator remained almost unaffected by this disturbance. This is due to the high damping effects caused by the joints of the vehicle and the motor linking the pendulum links.

### *B. Variation of disturbance force duration*

Different durations of the applied disturbance force; 0 sec, 1.25 sec, 2.5 sec, 7.5 sec, 12.5 sec, with a fixed force amplitude of 40 N were used. The response of the system to the disturbances applied to the centre of the first and second links are presented in Figures 6 and 7 respectively.

As noted in Figure 6, oscillations were observed at the tilt angle of the first link with varied amplitudes. The longer the applied disturbance duration the larger the amplitudes of oscillations were noted. The settling-time increased by an average of 6% while the rise-time varied by increasing and decreasing depending on the duration of the applied disturbance. The right and left wheel angular displacements were affected by this disturbance and fluctuations can be noted. The tilt angle of the second link and the payload actuator displacement were not affected by this disturbance.

Figure 7 shows the response of the system for disturbances applied at the centre of the second link. The disturbances resulted in an oscillatory response at the tilt angle of the second link; at disturbance durations up to 7.5 seconds, the controller was able to control the tilt angle of the second pendulum and stabilise the system within an approximate average times of 7 seconds. Settling-time increased by an average of 7% at a time. Finally, The right and left wheel angular displacements, tilt angle of the first link and the payload actuator displacement were not affected by this disturbance.

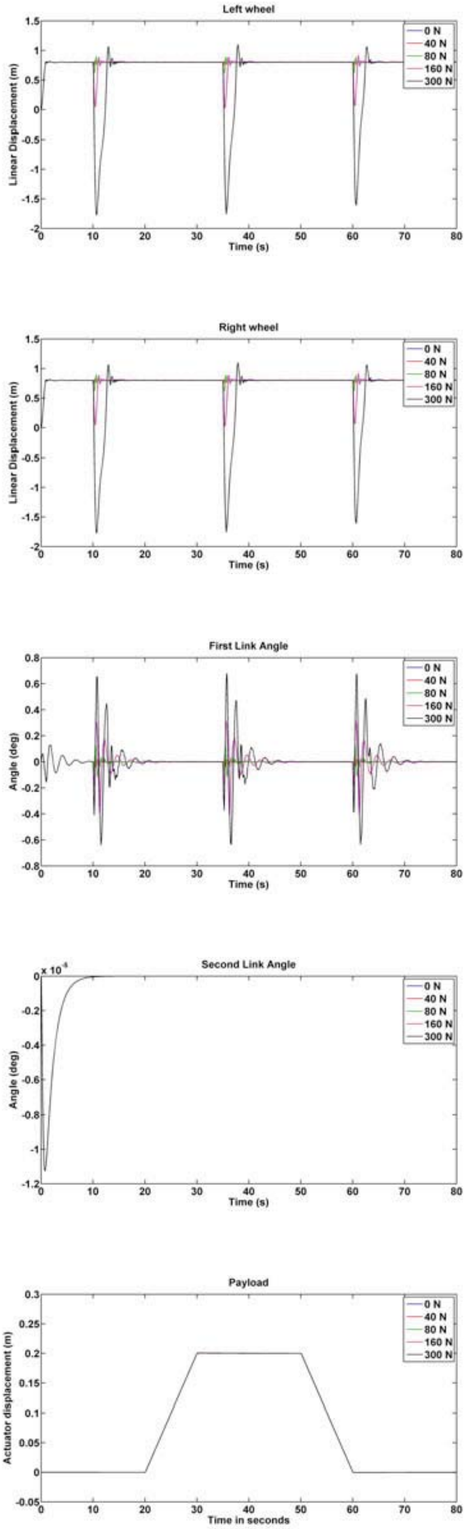

Figure 4. System performance with disturbances
Of different amplitudes applied at the centre of 1st link

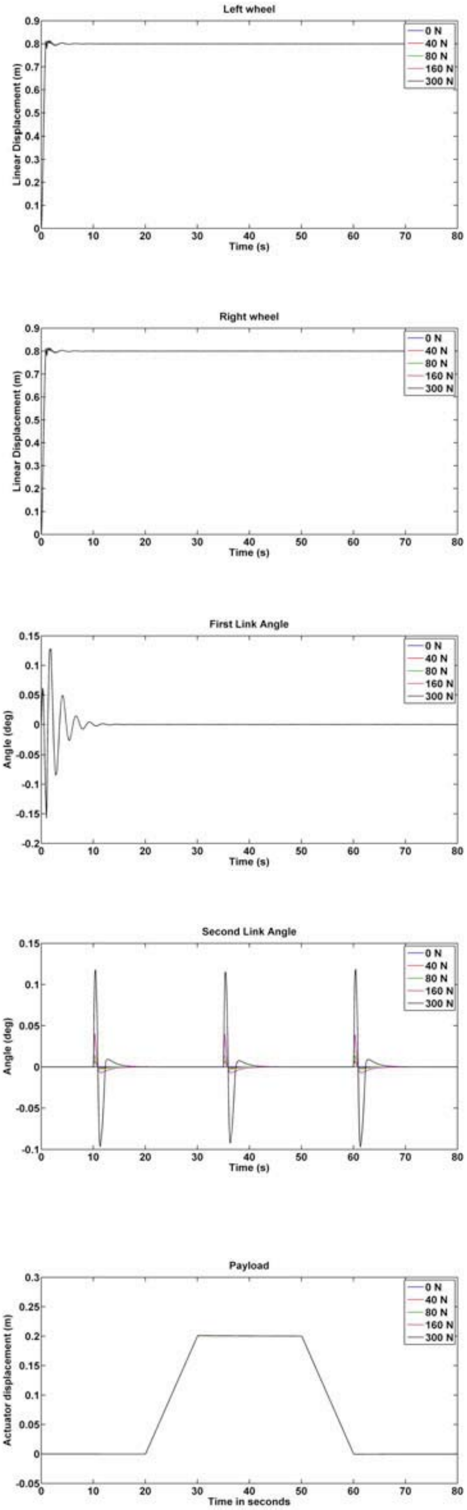

Figure 5. System performance with disturbances
Of different amplitudes applied at the centre of 2nd link

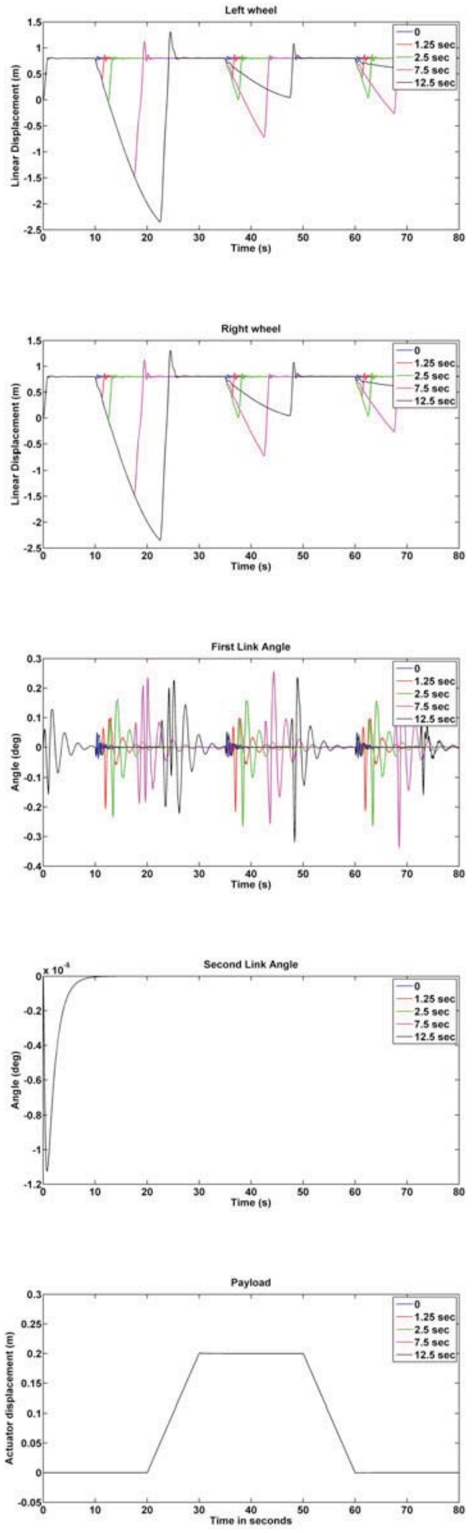

Figure 6. System performance with disturbances Of different durations applied at the centre of 1st link

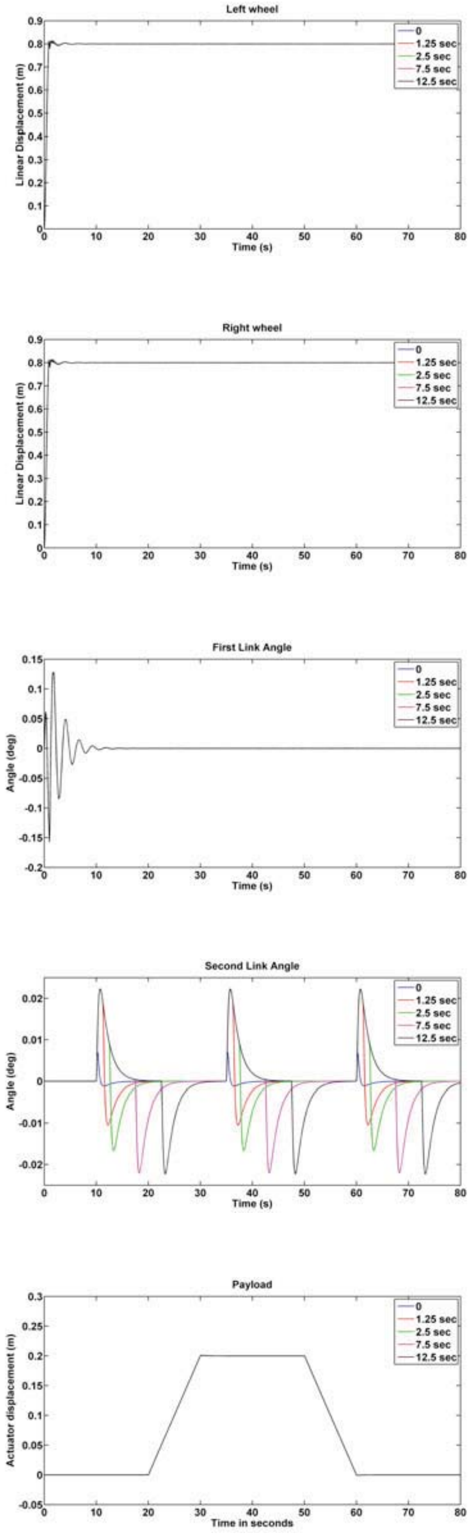

Figure 7. System performance with disturbances Of different durations applied at the centre of 2nd link

## V. CONCLUSION

A hybrid fuzzy logic control approach has been designed and applied on a novel configuration of two-wheeled robotic vehicle. The mathematical model of the vehicle with five degrees of freedom has been derived and equations of motion presented. The model was simulated in Matlab Simulink environment and successfully stabilised. Simulations of the system undergoing different disturbance scenarios have been demonstrated and it has been proved that the controller is able to balance the vehicle in the upright position with various disturbances. The developed hybrid FLC mechanism has been shown to be robust and overcoming external impacts of disturbances.

*Abstract*—**This paper presents a hybrid optimization algorithm, referred to as hybrid spiral dynamics bacterial chemotaxis (HSDBC) algorithm. HSDBC synergizes bacterial foraging algorithm (BFA) chemotaxis strategy and spiral dynamics algorithm (SDA). The original BFA has higher convergence speed while SDA has better accuracy and stable convergence when approaching the optimum value. This hybrid approach preserves the strengths of BFA and SDA and thus has the capability of producing better results. Moreover, it has simple structure, hence reduced computational cost. Several unimodal and multimodal benchmark functions are employed to test the algorithm in finding the global optimum point. Furthermore, the proposed algorithm is tested in the design of PD controller for a flexible manipulator system. The results show that the HSDBC outperforms SDA and BFA in all test functions and successfully optimizes the PD controller.**

***Keywords-Spiral dynamics; bacterial chemotaxis; optimization algorithm; PD control; flexible manipulator.***

## I. Introduction

Metaheuristic optimization algorithms have gained a lot of interest by many researchers worldwide. These algorithms are inspired by biological phenomena or natural phenomena. Some of the newly introduced algorithms include biogeography-based optimization (BBO) [1], firefly optimization algorithm [2], cuckoo search optimization [3], galaxy-based search algorithm [4], and spiral dynamics inspired optimization (SDA) [5]. All these algorithms have gained attention due to their simplicity to program, fast computing time, easy to implement, and possibility to apply to various applications. Each of these algorithms has its own unique features, advantages and also disadvantages. Therefore, there are a lot of possibilities to improve the algorithms from various aspects. Many attempts have been made to improve performances of the algorithms such as developing adaptive approaches or incorporating powerful mathematical functions into the algorithms and mostly hybridizing two or more algorithms.

Hybridisation is a common approach used in metaheuristic to enhance capability of optimization algorithms. It may reduce computational cost by making a simple and better structure to lead to higher performance. Moreover, with the rapidly emerging computing tools and efficiency in current technology, hybrid approaches have become increasingly popular to explore. Various combinations of optimization algorithms have been considered by researchers with the aim to increase system performance. [6] developed a hybrid optimization algorithm combining bacterial foraging optimisation algorithm (BFA) with BBO, and referred to it as intelligent biogeography-based optimization. In the algorithm, chemotaxis behaviour of bacteria is adopted into BBO migration process to determine a valid emigration of an individual from one place to another. This ensures the island that receives the emigrated solution preserves its fitness level by only accepting individuals that contribute to a better fitness value. [7] introduced hybrid version of BFA with differential evolution (DE) algorithm called chemotaxis differential evolution. In the algorithm, chemotaxis strategy of bacteria is combined with the mutation process in DE. [8], [9] and [10] introduced hybrid GA-BF algorithm employing modified mutation and crossover operation in GA while applying variation bacterial chemotaxis step size in BFA. [11] developed cooperative (BF-TS) by combining adaptive bacterial foraging optimization algorithm (ABFA) and adaptive tabu search (ATS). With limited exploration capability of ATS in the search space and complexity of ABFA, the chemotaxis strategy of ABFA is incorporated into ATS to provide suitable exploration at the early stage. On the other hand, [12] used hybrid ABFA and ATS called BTSO, to analyze Lyapunov's stability of linear and nonlinear systems. [13] introduced a hybrid algorithm namely BPSO-DE synergizing BFA, particle swarm optimization (PSO), and DE to solve dynamic economic dispatch problem with valve-points effect. Bacterial chemotaxis strategy with adaptive step-size in BFA is used to perform local search to enhance exploitation while PSO-DE features containing evolutionary operators and velocity update equation are used to perform exploration search over the entire search space. Hybrid BFA and PSO on the other hand, has received the most attention. [14], [15], [16], [17] and [18] employed velocity and position update equation in PSO to act as global search method while utilizing chemotaxis strategy in BFA to serve as local search method. [19] introduced simplified version of BFA employing bacterial chemotaxis strategy and PSO velocity update equation to solve parameter identification problem of heavy oil thermal cracking model. Reproduction and elimination stages were omitted to reduce computational time.

This paper presents hybrid version of bacterial foraging algorithm (BFA) chemotaxis strategy and spiral dynamics algorithm (SDA). The rest of the paper is organized as follows. Section II provides a brief literature review of the original BFA and spiral dynamics inspired optimization. The proposed HSDBC is described in section III. Validation of the proposed HSDBC in comparison to SDA and BFA with uni-modal and multi-modal test functions as well as application of the algorithm in optimizing a PD controller is presented in section IV. Section V presents concluding remarks.

## II. BFA AND SDA

The original versions of BFA and SDA are briefly described in this section.

### A. *Bacterial foraging optimization algorithm*

The BFA is a biologically inspired algorithm introduced in [20]. It is based on adaptation technique of Escherichia Coli (E. Coli) bacteria to find nutrient or food source during their lifetime or alternatively the technique might be called bacterial foraging strategy. Furthermore, E. Coli bacteria use saltatory search technique, which is the combination of cruise and ambush movement. One of the exceptional features of E. Coli is that it has very high growth rate, which is normally exponential. This extraordinary capability of E. Coli has motivated researchers to adopt the strategy as optimization technique. Bacterial foraging strategy consists of three basic cycles namely chemotaxis, reproduction and elimination & dispersal. These cycles are continuing processes and very effective for optimization purposes [21]. Moreover, it offers flexibility for researchers to manipulate the strategy according to a specific application area. When searching for food or nutrient, tumbling and swimming will take place. Tumbling is similar to cruise and it happens when the E. Coli navigates in the search area and once the food source is found, it swims like ambushing a target area with great speed, up to 20μm/s or faster in a rich nutrient medium. This unique movement is called chemotaxis. Reproduction, elimination and dispersal events then happen to bacteria with high fitness or healthier that has capability to reach food source accurately and quickly. The strength of BFA lies in the bacterial chemotaxis strategy adopted by many researchers to improve the optimization algorithm. The details of the original algorithm and pseudocode of BFA can be found in [20]. In this paper, number of bacteria, number of chemotaxis, chemotactic step size, number of swims, number of reproduction, number of elimination & dispersal are represented as *S, Nc, C, Ns, Nre* and *Ned* respectively. The probability that each bacterium will be eliminated and dispersed is defined as *ped* = 0.25 for the problems considered.

### B. *Spiral dynamics inspired optimization algorithm*

The SDA is another metaheuristic algorithm adopted from spiral phenomena in nature [5]. 2-dimensional and N-dimensional [5] logarithmic spiral discrete models have been tested on several benchmark functions. Moreover, comparisons with other optimization algorithms such as PSO and DE have shown that SDA performance is either better or the same as those [5]. This simple and effective strategy retains the diversification and intensification at the early phase and later phase of the trajectory as diversification and intensification are important features of the optimization algorithm. At the early stage, the spiral trajectory explores a wider search space and it continuously converges with a smaller radius providing dynamics step size when approaching the final point, which is the best solution, located at the centre. The distance between a point in a path trajectory and the centre point is varied constantly if the radius of the trajectory is changing at constant rate thus making the radius an important converging parameter for the algorithm. The strength of SDA lies in its spiral dynamics model. An n-dimensional spiral mathematical model that is derived using composition of rotational matrix based on combination of all 2 axes is given as:

$$x(k+1) = S_n(r,\theta)x(k) - (S_n(r,\theta) - I_n)x^* \qquad (1)$$

where

$$S_n(r,\theta)x(k) = rR^n(\theta_{1,2},\theta_{1,3},\ldots,\theta_{n-1,n})x(k).$$

or

$$S_n(r,\theta)x(k) = \prod_{i-1}^{n-1}\left(\prod_{j=1}^{i}(R^n_{n-i,n+1-j}(\theta_{n-i,n+1-j}))\right)$$

and $R^n_{i,j}(\theta_{i,j}) :=$

$$\begin{array}{c|ccccccccc|}
 & & & & i & & j & & & \\
 & 1 & & & & & & & & \\
 & & \ddots & & & & & & & \\
 & & & 1 & & & & & & \\
i & & & & \cos\theta_{i,j} & \cdots & -\sin\theta_{i,j} & & & \\
 & & & & & 1 & & & & \\
 & & & & \vdots & \ddots & \vdots & & & \\
 & & & & & 1 & & & & \\
j & & & & \sin\theta_{i,j} & \cdots & \cos\theta_{i,j} & & & \\
 & & & & & & & 1 & & \\
 & & & & & & & & \ddots & \\
 & & & & & & & & & 1
\end{array}$$

Parameters and descriptions used in equation (1) are similar to those used in HSDBC optimization algorithm, which are shown in Table 1. Since SDA is relatively new, not much work in the literature involving the algorithm has been reported. The details of the original SDA algorithm for 2-dimension and n-dimension can be found in [5]. The hybrid approach of this algorithm and its details are provided in the next section.

## III. HYBRID SPIRAL DYNAMICS BACTERIAL CHEMOTAXIS ALGORITHM

The HSDBC is a combination of bacterial chemotaxis strategy used in BFA and SDA. BFA has faster convergence speed due to the chemotaxis approach but suffers from oscillation problem towards the end of its search process. On the other hand, SDA provides better stability when approaching optimum point due to dynamic spiral step in its trajectory motion but has slower convergence speed. HSDBC algorithm preserves the strengths possessed by BFA and SDA. Moreover, by incorporating only chemotaxis part of BFA simple structure of SDA can be retained, thus reducing computational time and enhancing performance of the algorithm. The parameters and description used in n-dimensional HSDBC optimization algorithm are presented in Table 1 and the algorithm is shown in Fig. 1.

TABLE I. PARAMETERS FOR HSDBC OPTIMIZATION ALGORITHM

| Symbols | Description |
|---|---|
| $\theta_{i,j}$ | Bacteria angular displacement on $x_i - x_j$ plane around the origin |
| $r$ | Spiral radius |
| $m$ | Number of search points |
| $k_{\max}$ | Maximum iteration number |
| $N_s$ | Maximum number of swim |
| $x_i(k)$ | Bacteria position |
| $R^n$ | n x n matrix |

An n-dimensional hybrid spiral dynamics bacteria chemotaxis optimization algorithm.

```
Step 0: Preparation
    Select the number of search points (bacteria) $m \geq 2$ , parameters
    $0 \leq \theta < 2\pi, 0 < r < 1$ of $S_n(r,\theta)$ , maximum iteration number,
    $k_{\max}$ and maximum number of swim, $N_s$ for bacteria chemotaxis.
    Set $k = 0, s = 0$ .
Step 1: Initialization
    Set initial points $x_i(0) \in R^n$, $i = 1,2,...m$ in the feasible region
    at random and center $x^*$ as $x^* = x_{i_g}(0)$ ,
    $i_g = \arg\min_i \ f(x_i(0)), i = 1,2,...,m$ .
Step 2: Applying bacteria chemotaxis
    (i) Update $x_i$
        $x_i(k+1) = S_n(r,\theta)x_i(k) - (S_n(r,\theta) - I_n)x^*$
        $i = 1,2,...,m$ .
    (ii) Bacteria swim
        (a) Check number swim for bacteria i.
            If $s < N_s$ , then check fitness,
            Otherwise set $i = i+1$ , and return to step (i).
        (b) Check fitness
            If $f(x_i(k+1)) < f(x_i(k)$ , then update $x_i$ ,
            Otherwise set $s = N_s$ , and return to step (i).
        (c) Update $x_i$
            $x_i(k+1) = S_n(r,\theta)x_i(k) - (S_n(r,\theta) - I_n)x^*$
            $i = 1,2,...,m$ .
Step 3: Updating $x^*$
    $x^* = x_{i_g}(k+1)$ ,
    $i_g = \arg\min_i \ f(x_i(k+1)), i = 1,2,...,m$ .
Step 4: Checking termination criterion
    If $k = k_{\max}$ then terminate. Otherwise set $k = k+1$ ,
    and return to step 2.
```

Figure 1. HSDBC optimization algorithm.

In the proposed hybrid approach, bacterial chemotaxis strategy is employed in step 2 to balance and enhance exploration and exploitation of the search space. The bacteria move from low nutrient location towards higher nutrient location, placed at the centre of a spiral. The most important factor of HSDBC algorithm is the respective diversification and intensification at the early phase and later phase of the spiral motion. In the diversification phase, bacteria are located at low nutrient location and move with larger step size thus producing faster convergence. On the other hand, in the intensification phase, bacteria are approaching rich nutrient location and move with smaller step size hence avoiding oscillation around the optimum point. Another factor contributing to better performance of the algorithm is the swimming action in bacterial chemotaxis. Bacteria continuously swim towards optimum point if the next location has higher nutrient value compared to previous location until the maximum number of swim is reached.

## IV. VALIDATION TEST AND RESULTS

In this section, the proposed algorithm is validated through simulation tests on two 3-dimensional uni-modal and two 2-dimensional multi-modal benchmark functions. Moreover, the HSDBC algorithm is tested in optimizing PD controller of a flexible manipulator system. Comparison with the original version of SDA and BFA tested on the four benchmark functions is also given to show the improved performance of HSDBC. The parameters used in the simulation are chosen heuristically for all test functions.

### A. *Uni-modal sphere function*

The sphere function is defined as:

$$f(x) = \sum_{i=1}^{n} x_i^2 \qquad (2)$$

The function has a global minimum at $x_i$ = [0, 0, 0] with fitness *f(x)* = 0. In this simulation, the sphere function is considered to have dimension n = 3 and variable $x_i$ is in the range [–5.12, 5.12]. Number of search points, m = 30, iteration number, 80, angular displacement, θ = π/4, and spiral radius, *r* = 0.96 were used for both algorithms. Number of swims with for HSDBC was defined as $N_s$ = 5. BFA parameters for this function were *S* = 30, *Nc* = 30, *C*=0.01, *Ns* = 4, *Nre* = 4 and *Ned* = 2. The convergence plot for 3 dimensional sphere function thus achieved is shown in Fig 2.

### B. *Uni-modal Ackley function*

The Ackley function is mathematically defined as:

$$\begin{aligned} f(x) = -20\exp(-0.2\sqrt{(\frac{1}{n}\sum_{i=1}^{n} x_i^2)} \\ -\exp(\frac{1}{n}\sum_{i=1}^{n}\cos(2\pi x_i) + 20 + e \end{aligned} \qquad (3)$$

The function has a global minimum at $x_i$ = [0, 0, 0] with fitness *f(x)* = 0. The Ackley function is considered with dimension n = 3 and variable $x_i$ in the range [–32.768, 32.768]. Number of search points, m = 30, iteration number

200, angular displacement, θ = π/4, and spiral radius, $r$ = 0.96 were used in both algorithms. Number of swims for HSDBC with swim radius, $r$ = 0.6 was defined as $N_s$ = 1. BFA parameters for this function were $S$ = 20, $Nc$ = 20, $C$ = 0.02, $Ns$ = 4, $Nre$ = 4 and $Ned$ = 2.The resulting convergence plot for 3-dimension Ackley function is shown in Fig 3.

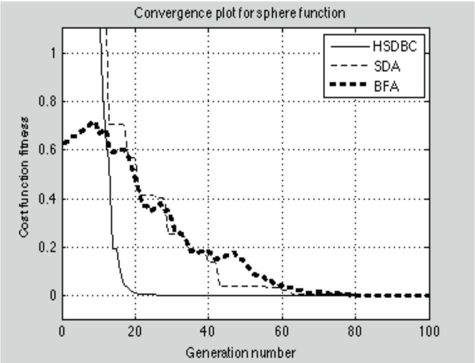

Figure 2. Convergence plot for 3D sphere function.

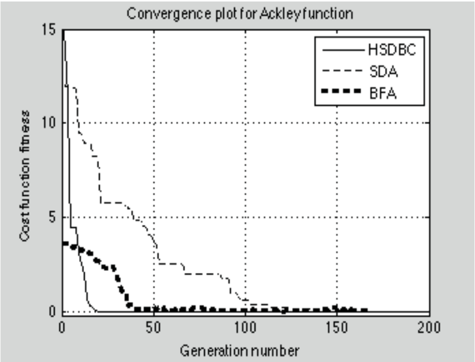

Figure 3. Convergence plot for 3D Ackley function.

### C. Multi-modal Rastrigin function

The Rastrigin function is defined as:

$$f(x) = \sum_{i=1}^{n} [x_i^2 - 10\cos(2\pi x_i) + 10] \qquad (4)$$

The function has a global minimum at $x_i$ = [0, 0] with fitness $f(x)$ = 0. The Rastrigin function is considered with dimension n = 2 and variable $x_i$ in the range [–5.12, 5.12]. The number of search points, m = 50, iteration number 120, angular displacement, θ = π/4, and spiral radius, $r$ = 0.96 were used in both algorithms. Number of swims for HSDBC with swim radius, $r$ = 0.65 was defined as $N_s$ = 2. BFA parameters for this function were $S$ = 30, $Nc$ = 20, $C$ = 0.01, $Ns$ = 4, $Nre$ = 4 and $Ned$ = 2. The resulting convergence plot for the 2-dimensional Rastrigin function is shown in Fig 4.

### D. Multi-modal Griewank function

The Griewank function is defined as:

$$f(x) = \frac{1}{4000}\sum_{i=1}^{n} x_i^2 - \prod_{i=1}^{n}\cos\left(\frac{x_i}{\sqrt{i}}\right) + 1 \qquad (5)$$

The function has a global minimum at $x_i$ = [0, 0] with fitness $f(x)$ = 0. The Griewank function was considered with dimension n = 2 and variable $x_i$ in the range [–600, 600]. The number of search points, m = 50, iteration number 200, angular displacement, θ = π/4, and spiral radius, $r$ = 0.96 were used for both algorithms. Number of swims for HSDBC with swim radius, $r$ = 0.55 was defined as $N_s$ = 1. BFA parameters for Griewank function were $S$ = 30, $Nc$ = 10, $C$ = 0.1, $Ns$ = 4, $Nre$ = 4 and $Ned$ = 2. The resulting convergence plot for the 2-dimensional Griewank function is shown in Fig 5.

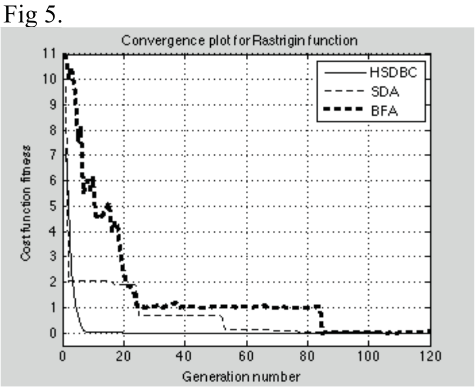

Figure 4. Convergence plot for 2D Rastrigin function.

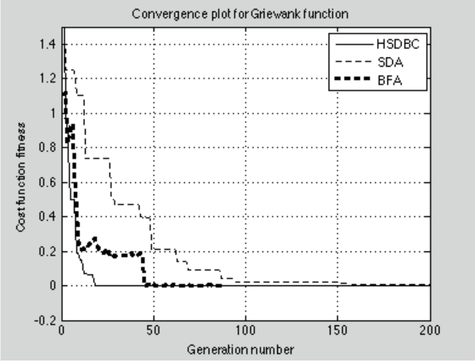

Figure 5. Convergence plot for 2D Griewank function.

It can be clearly seen in the plots, in Figures 2-5 that the HSDBC outperformed SDA and BFA in terms of convergence speed and improved accuracy. Numerical results of HSDBC, SDA and BFA performance tests with the benchmark functions are shown in Tables II, III and IV respectively. It is noted that HSDBC has achieved better performance than SDA and BFA with the test functions in terms of convergence speed and accuracy.

TABLE II. HSDBC PERFORMANCE ON BENCHMARK FUNCTIONS

### *E. Controller design optimization*

The HSDBC algorithm is employed here to optimize PD controller of a flexible manipulator system (FMS). Schematic diagram of the flexible manipulator system is shown in Fig. 6. $X_oOY_o$ and XOY represent the stationary and moving coordinate frames respectively. $\tau$ represents the applied torque at the hub. Young modulus, area moment of inertia, mass density per unit volume, cross-sectional area, hub inertia, displacement and hub angle of the manipulator are represented by $E, I, \rho, A, I_h$, $v(x,t)$ and $\theta(t)$ respectively [23].

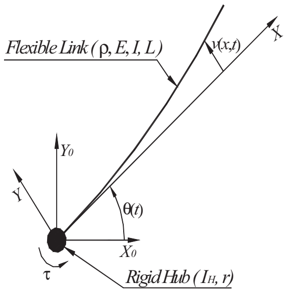

Figure 6. Schematic diagram of flexible manipulator system.

Mathematical model of FMS adopted here is that derived using Lagrange method in [22]. The FMS model has been used by many researchers in testing various types of controller for flexible systems [23], [24]. The dynamic equation of motion of FMS can be represented as:

$$M\ddot{Q}(t)+D\dot{Q}(t)+KQ(t)=F(t) \qquad (6)$$

where $M$, $D$ and $K$ are mass, damping and stiffness matrices respectively. $F(t)$ and $Q(t)$ are vectors of external forces and modal displacement respectively;

$$F(t)=[\ \tau \quad 0 \quad 0 \quad \cdots \quad 0\ ]^T \qquad (7)$$

$$Q(t)=[\ \theta \quad q_1 \quad q_2 \quad \cdots \quad q_n\ ]^T=[\ \theta \quad q^T\ ]^T \qquad (8)$$

More details of the derivation and parameters of FMS can be found in [22], [23]. A state-space model of FMS is obtained by linearizing (6) and it is used to design PD controller through HSDBC. The control strategy of FMS is adopted from [23] and [24] where PD feedback of collocated sensor signals is employed. A block diagram of the control structure is shown in Fig. 7, where $K_p$, $K_v$ and $A_c$ are the proportional, derivative and motor amplifier gains respectively. The input of the system is reference hub angle, $R_f$ and the outputs of the system are hub angle, θ and hub angle velocity, $\dot{\theta}$. In this simulation, number of search points, m = 30, iteration number 100, angular displacement, θ = π/4, and spiral radius, $r$ = 0.96, and number of swim $N_s$ = 3 were used to optimize the PD controller.

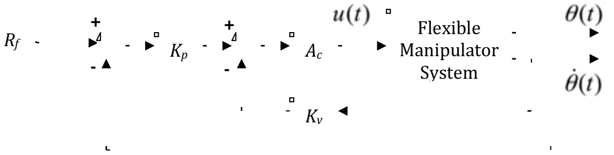

Figure 7. Collocated PD control structure of FMS.

Integral square error (ISE) of hub angle was chosen as cost function for the optimization algorithm. As a means of examining the proposed algorithm, this paper is only dealing with step input tracking capability of FMS. Step input was defined to have final value at 0.8 radians, which is the final location of hub angle. Graphical plot of the hub angle achieved is shown in Fig. 8.

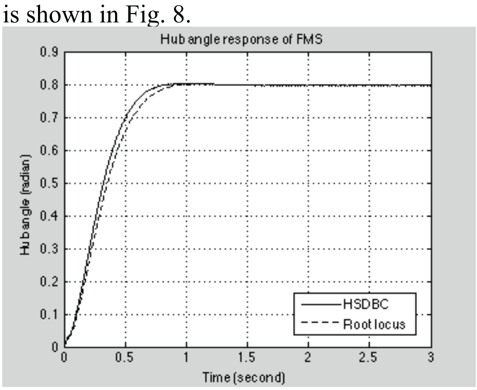

Figure 8. Hub angle response of FMS.

In this plot, for the purpose of comparison, the hub angle response with PD controller designed using root locus approach from [24] is also shown. Simulation with HSDBC optimization algorithm on the FMS gave $K_p$ =72.3459 and $K_v$ =20.6227 while $K_p$ =60 and $K_v$ =19 using root locus technique [24]. It is clear from Fig. 8, that hub angle response of FMS using HSDBC was better than hub angle response using root locus technique in terms of speed of response. Numerical results of the hub angle response are shown in Table V. It is noted that the HSDBC approach resulted slightly larger overshoot within acceptable range. However, the response rise time with HSDBC was better, which indicates that the algorithm can perform faster with satisfactory response overshoot and no error at steady state.

TABLE V. PERFORMANCE SPECIFICATION OF HUB ANGLE RESPONSE

| Tuning Method | Performance Specification | | | |
|---|---|---|---|---|
| | *Overshoot, %os (%)* | *Settling time, ts (s)* | *Rise time, tr (s)* | *Steady state error, ess* |
| HSDBC | 0.84 | 1.47 | 0.44 | 0 |
| Root locus | 0.53 | 1.47 | 0.50 | 0 |

## V. CONCLUSION

A novel hybrid spiral dynamics bacterial chemotaxis optimization algorithm has been proposed. Validation with uni-modal and multi-modal benchmark functions and comparison with standard SDA and BFA have been carried out. Moreover, the HSDBC has been used in controller design of a flexible manipulator in comparison with root locus design approach. Simulation results have shown that the proposed algorithm outperformed its counterpart in all test functions and it successfully optimized PD controller of flexible manipulator system in terms of convergence speed and accuracy.

***Abstract*—This article develops and evaluates state–dependent parameter (SDP) control systems for the hydraulically actuated dual–manipulators of a mobile nuclear decommissioning robot. A unified framework for calibration, data collection and SDP model identification is proposed, in which the state–dependent variable is a delayed voltage signal associated with the time–varying gain of the system. The latter can cause undesirable joint movements when the device is regulated using linear control algorithms. By contrast, the present article develops a novel nonlinear pole assignment algorithm based on the SDP model. Closed–loop experimental data shows that the SDP design more closely follows the joint angle commands than the equivalent linear algorithm, offering improved resolved motion.**

## I. Introduction

The UK nuclear legacy comprises a number of facilities that are significantly contaminated by radioactivity and non–radiological toxins, are sometimes in a relatively poor state of repair and for which knowledge of their use can be incomplete. In fact, the regulatory requirements were very different when first constructed, with the result that many facilities were not designed with decommissioning strategies in mind. In areas of significant contamination, it is necessary to resort to the use of remote and teleoperated mobile robots. These provide an invaluable option for the safe retrieval and disposal of contaminated materials in high–hazard legacy facilities [1].

Mobile robots are used in many hazardous environments, including explosive ordnance disposal, military reconnaissance, natural disaster search and rescue, and in the nuclear decommissioning sector. In the early stages of nuclear clean–up, expensive, bespoke machines were designed, built and commissioned. However, these have suffered from reliability problems and are usually restricted to specific tasks. More recently, off–the–shelf remote solutions are striven for but these lack the ease of control afforded by high–specification bespoke solutions. The research described in this article aims to alleviate this unsatisfactory situation by developing optimized, widely applicable control architectures, that are being tested on an off–the–shelf robotic platform.

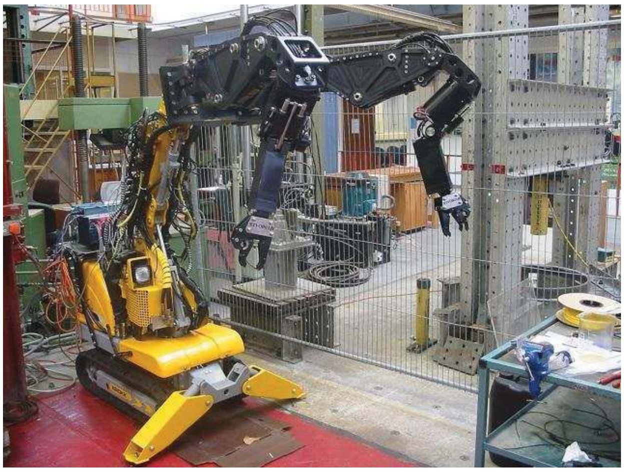

Fig. 1. Brokk–40 and dual HydroLek–7W manipulators.

The research utilizes a Brokk–40 demolition robot, consisting of a moving vehicle with a single manipulator. Two seven–function HydroLek–HLK–7W robotic arms have been attached to the Brokk, as shown by Fig. 1. Such dual–arm mobile robots now offer a powerful and versatile tool for various types of decommissioning activity [2]. Unfortunately, devices initially developed for heavy lifting are not necessarily suitable for 'soft touch' duties such as picking up relatively fragile objects or accurately aligning the end effectors. Indeed, the manipulator can suffer from a relatively slow control action because of limitations in existing linear methods.

Since the behaviour of hydraulically–driven manipulators is dominated by the nonlinear, lightly–damped dynamics of the actuators, high performance control depends on the introduction of some type of nonlinear model structure. Research embraces approaches such as sliding mode [3], adaptive [4], quasi–linear parameter varying [5] and state–dependent parameter (SDP) design [6], among others. An earlier article considered SDP control of the HydroLek but was limited to simulation and did not consider resolved motion [7].

By contrast, the present article utilises open and closed–loop experimental data to investigate potential state dependencies and resolved motion. Here, the nonlinear system is modelled using the quasi–linear SDP structure [8]. For the HydroLek, a novel non–minimal state variable feedback 'regulator' is adapted from the nonlinear pole assignment algorithm of [9]. The data collection and kinematics are described in sections II and III, followed in section IV by an overview of the control design method. Finally, the experimental results and conclusions are discussed in sections V and VI.

## II. Mobile Robot Platform

The hardware arrangement was developed at Lancaster University from components supplied by Brokk UK Ltd and HydroLek Ltd [2]. The Brokk–40 base machine is 650mm wide, allowing for access through narrow doorways. The five Degrees–Of–Freedom (DOF) manipulator is usually equipped with a variety of tools, including percussive breakers, hydraulic crushing jaws, excavating buckets and concrete milling heads. The unit is electrically powered to facilitate internal use, with an onboard hydraulic pump to power the caterpillar tracks and, by means of several hydraulic pistons, the manipulator.

For decommissioning tasks, accessing the robot on–site to change tools could be a slow, laborious and potentially hazardous task. A more flexible system with the ability to perform multiple tasks without a tool change has been achieved with the mounting of two HydroLek–HLK–7W, seven DOF manipulators, each consisting of six rotational joints and a gripper. The combined system is shown in Fig. 1, whilst Fig. 2 illustrates the azimuth yaw, shoulder pitch, elbow pitch, forearm roll and wrist pitch joints. These are fitted with potentiometer feedback sensors, allowing the position of the end–effector to be determined during operation. The joints are actuated via hydraulic pistons, which are powered via an auxiliary output from the hydraulic pump of the Brokk unit.

A standard input device, such as a joystick, is connected to a PC running a graphical user interface developed for the NI Labview software environment. The PC transmits information to a NI Compact Fieldpoint Real–Time controller (cFP) via an Ethernet networking connection. The cFP is a stand alone device running a real–time operating system, allowing for the precise sampling rates needed for discrete–time control. The hydraulic pistons are controlled by seven pairs of control valves, where each pair has an input for both positive and negative flow. Output modules convert the digital cFP signal to a varied voltage fed to the control valves.

The present authors have developed a semi–automated system for calibrating and initialising the robot for open–loop data collection [10]. Here, the robot is manipulated into a suitable configuration using ‘de–tuned’ proportional control systems. The operator selects from classical step experiments or pseudo–random signals for the estimation of nonlinear models. Figure 3 summarises the basic control system for a single joint. The system input $u_k$ is scaled to lie in the range -100, representing the maximum power in a negative ‘closing’ direction, through to +100, representing the maximum power in a positive ‘opening’ direction. The dead–band of the system is eliminated by the input calibration step, hence an input of zero represents no movement. The output $y_k$ is the potentiometer voltage, representing a scaled joint angle.

## III. Inverse Kinematics

Since it has no bearing on the end–effector location, the gripper is neglected from the kinematic solution illustrated in Figure 4. Gripper control will be considered separately on the basis of pressure feedback and is beyond the scope of the present article. Hence, each manipulator is described as a kinematic model with six solid links and rotational joints. In fact, the manipulator is over–specified in terms of end–effector positioning, with the additional degrees–of–freedom potentially utilised to allow the end–effectors orientation to be set and to reach past obstacles (for example, to pick up a contaminated object from a container/skip). The system is non–trivial to solve for a closed–form, hence incremental steps in complexity are utilised for testing control performance.

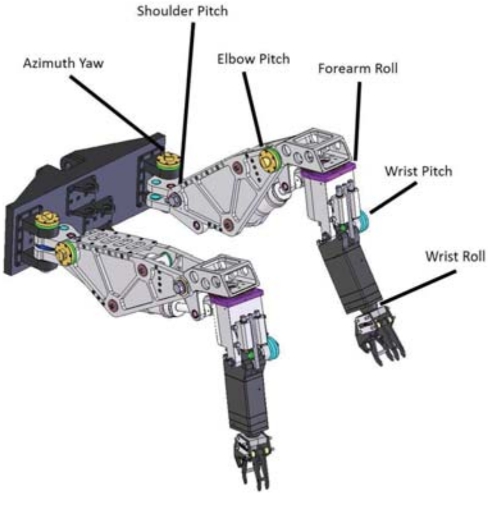

Fig. 2. HydroLek–7W rotational joints.

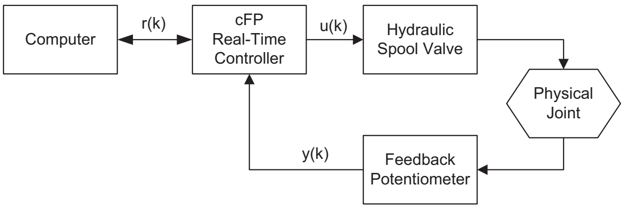

Fig. 3. Control system overview for a single joint.

The present research concentrates on the development of novel joint control systems and initially evaluates these using a reduced 2–DoF system that allows for straightforward movement of the end–effector in a plane. Figure 5 shows how the manipulator is limited to a straightforward 2–DoF system for Joints 2 and 3, with the remaining joints locked off. Equations (1) and (2) describe the forward kinematic relationship of $P_x$ and $P_z$ to the joint angles $\theta_1$ and $\theta_2$, for a generic 2–DoF planer robot, where $P_x$ and $P_z$ represent the horizontal and vertical positions of the end–effector respectively.

$$P_x = l_2 c_{12} + l_1 c_1 \tag{1}$$

$$P_z = l_2 s_{12} + l_1 s_1 \tag{2}$$

Here, $c_1$ and $s_1$ denote $\cos(\theta_1)$ and $\sin(\theta_1)$ respectively, $c_{12}$ and $s_{12}$ represent $\cos(\theta_1 + \theta_2)$ and $\sin(\theta_1 + \theta_2)$, while $l_1$ and $l_2$ are link lengths. Equations (3) and (4) show how this description is applied to the manipulator geometry in Figure 5,

$$P_x = Rc_{23-r} + a_2 c_2 + a_1 \tag{3}$$

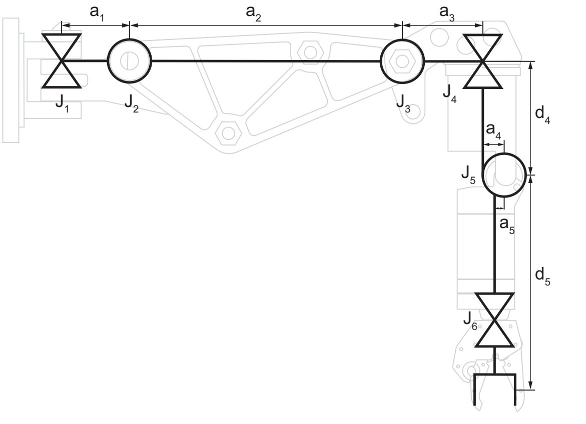

Fig. 4. 6–DOF kinematic description of HydroLek–7W Manipulator.

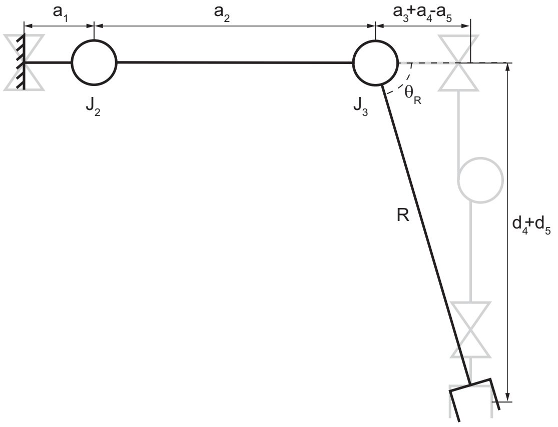

Fig. 5. 2–DOF description of HydroLek–7W Manipulator.

$$P_z = Rs_{23-r} + a_2 s_2 \tag{4}$$

in which $\theta_2$ and $\theta_3$ represent the shoulder pitch and elbow pitch respectively (Figure 2), $\theta_R = \text{atan2}(a_3+a_4-a_5, d_4+d_5)$, $R = \sqrt{(a_3+a_4-a_5)^2+(d_4+d_5)^2}$ and $c_{23-r}$ represents $\cos(\theta_2+\theta_3-\theta_R)$. The inverse kinematics are subsequently derived as follows [11],

$$c_3 = \frac{(P_x-a_1)^2+P_z^2-R^2-a_2^2}{2a_2R} \tag{5}$$

$$s_3 = \pm\sqrt{1-c_3^2} \tag{6}$$

$$\theta_3 = \text{atan2}\,(s_3, c_3) + \theta_R \tag{7}$$

Similarly,

$$c_2 = \frac{(P_x-a_1)(Rc_3+a_2)+P_zRs_3}{d} \tag{8}$$

$$s_2 = \frac{P_z(Rc_3+a_2)-(P_x-a_1)Rs_3}{d} \tag{9}$$

where $d = (Rc_3+a_2)^2 + (Rs_3)^2$. Hence, $\theta_2$ is solved by,

$$\theta_2 = \text{atan2}\,(s_2, c_2) \tag{10}$$

## IV. Nonlinear pole assignment

Consider the deterministic form of the SDP model:

$$y_k = \mathbf{w}_k^{\mathrm{T}}\mathbf{p}_k \tag{11}$$

where $\mathbf{w}_k^{\mathrm{T}}$ is a vector of lagged input and output variables and $\mathbf{p}_k$ is a vector of SDP parameters, defined as follows,

$$\begin{aligned}\mathbf{w}_k^{\mathrm{T}} &= \begin{bmatrix} -y_{k-1} & \cdots & -y_{k-n} & u_{k-1} & \cdots & u_{k-m}\end{bmatrix}\\ \mathbf{p}_k &= \begin{bmatrix} a_1\{\chi_k\} & \cdots & a_n\{\chi_k\} & b_1\{\chi_k\} & \cdots & b_m\{\chi_k\}\end{bmatrix}^{\mathrm{T}}\end{aligned}$$

Here $y_k$ is the output and $u_k$ the control input, while $a_i\{\chi_k\}\,(i=1,2,\ldots,n)$ and $b_j\{\chi_k\}\,(j=1,\ldots,m)$ are $n$ and $m$ state dependent parameters. The latter are assumed to be functions of a non–minimal state vector,

$$\chi_k^{\mathrm{T}} = \begin{bmatrix}\mathbf{w}_k^{\mathrm{T}}\ \mathbf{U}_k^{\mathrm{T}}\end{bmatrix} \tag{12}$$

in which $\mathbf{U}_k = [U_{1,k}, U_{2,k}, \ldots, U_{r,k}]$ is a vector of measured variables, potentially including other joint angles. Any pure time delay $\tau \geq 1$ is represented by setting the leading $b_1\{\chi_k\}\ldots b_{\tau-1}\{\chi_k\}$ terms to zero. To identify and estimate this model from experimental data, the authors have used the back–fitting approach of references [8] and [12].

Using this model, the first author and colleagues have developed a novel method for nonlinear pole assignment of SDP systems that guarantees closed–loop stability at the design stage: see references [6] and [9] for details. The approach is based on the definition of a suitable non–minimal state space (NMSS) form. For the present research, the algorithm has been modified to handle the integrating joint angle dynamics. In particular, the dead–zone calibration routine ensures that there is no movement when $u_k = 0$, hence external integral action is not required. In fact, the destabilizing nature of integral action has a negative impact on the control performance. For this reason, the following 'regulator' NMSS form is utilised:

$$\mathbf{x}_{k+1} = \mathbf{F}\{\chi_k\}\mathbf{x}_k + \mathbf{g}u_k \quad ; \quad y_k = \mathbf{h}\mathbf{x}_k \tag{13}$$

where the $n+m-1$ dimensional state vector is,

$$\mathbf{x}_k = \begin{bmatrix} y_k & \cdots & y_{k-n+1} & u_{k-1} & \cdots & u_{k-m+1}\end{bmatrix}^T \tag{14}$$

and the state matrices are defined to satisfy the SDP model (11), as shown by the example in section V. The state variable feedback control algorithm is,

$$u_k = -\mathbf{v}\{\chi_k\}\mathbf{x}_k + k_0\{\chi_k\}r_k \tag{15}$$

where,

$$\mathbf{v}\{\chi_k\} = [f_0\{\chi_k\}\ldots f_{n-1}\{\chi_k\}\,g_1\{\chi_k\}\ldots g_{m-1}\{\chi_k\}]$$

is a vector of scheduled control gains, $r_k$ is the command input and $k_0\{\chi_k\} = f_0\{\chi_k\} + \ldots + f_{n-1}\{\chi_k\}$. A vector $\mathbf{c}\{\chi_k\}$ is defined with a similar structure to $\mathbf{v}\{\chi_k\}$ but in which $\bar{g}_i\{\chi_k\}\,(i = 1\ldots m-1)$ differ from $g_i\{\chi_k\}$ as follows,

$$g_i\{\chi_k\} = \frac{b_\tau\{\chi_{k+\tau-i}\}}{b_\tau\{\chi_{k+\tau}\}}\cdot\bar{g}_i\{\chi_k\} \tag{16}$$

Here, $\mathbf{c}\{\boldsymbol{\chi}_k\}$ is determined by defining a suitable matrix $\Sigma_k\{\boldsymbol{\chi}_k\}$ of model coefficients and solving,

$$\Sigma\{\boldsymbol{\chi}_k\}\cdot\mathbf{c}\{\boldsymbol{\chi}_k\}=\mathbf{d}-\mathbf{p}\{\boldsymbol{\chi}_k\} \tag{17}$$

in which $\mathbf{p}\{\boldsymbol{\chi}_k\}$ and $\mathbf{d}$ are the open–loop and desired (time–invariant and stable) closed–loop coefficients respectively [6]. For brevity, full definitions of the above matrices are omitted but illustrative solutions for the HydroLek manipulator are presented in section V. The scaling (16) is necessary in order to achieve the desired stable closed–loop response and imposes a clear limitation on $b_\tau\{\boldsymbol{\chi}_{k+\tau}\}$. In fact, $b_\tau\{\boldsymbol{\chi}_{k+\tau}\}\neq 0$ corresponds directly to the pole assignability condition [6].

## V. Results

Preliminary open–loop step experiments (not shown) suggest that a first order linear difference equation, i.e.,

$$y_k=-a_1y_{k-1}+b_\tau u_{k-\tau} \tag{18}$$

provides an approximate representation of individual joints, with time–invariant parameters $\{a_1,b_\tau\}$ and the time delay $\tau$ depending on the sampling interval $\Delta t$. Such models have previously been utilized for the development of linear control systems for large scale hydraulic machinery in the construction industry [13]. However, further analysis quickly reveals limitations in the linear model. For the HydroLek, it is readily apparent that the numerical values of $\{a_1,b_\tau\}$ are not repeatable for different step experiments. Most notably, the value of $b_\tau$ depends on the magnitude of the applied voltage utilized for these step experiments, i.e. it is a SDP.

### A. System identification

Various candidate SDP structures have been investigated for open–loop movement of the right hand side manipulator shoulder and elbow pitch, moving in air with no additional loading terms, i.e. no objects are held by the gripper. For these conditions, trial and error experimentation suggests that a sampling interval of $\Delta t=0.07$ seconds yields a satisfactory compromise between a fast response and the following low–order model for control system design,

$$y_k=-a_1\{y_{k-1}\}\,y_{k-1}+b_2\{u_{k-2}\}\,u_{k-2} \tag{19}$$

The model is based on equation (11) with $n=1$, $m=\tau=2$, $b_1\{\boldsymbol{\chi}_k\}=0$ and initially $\boldsymbol{\chi}_k=[y_{k-1}u_{k-2}]$. In fact, the statistical estimates suggest that $a_1\{\boldsymbol{\chi}_k\}$ is relatively constant over time, with the pole close to unity. Assuming $a_1=-1$, the system essentially behaves as an integrator. In this case, $b_2\{\boldsymbol{\chi}_k\}$ represents the state–dependent angular velocity, approximated by the following second order polynomial,

$$b_2\{u_{k-2}\}=p_1u_{k-2}^2+p_2u_{k-2}+p_3 \tag{20}$$

The coefficients in equation (20) are optimized from open–loop experiments using fminsearch in Matlab®, yielding the estimates shown in Table I. The model responses (18) and (19) are compared with measured data for an illustrative open–loop shoulder joint experiment in Fig. 6. The SDP model is far superior, typically explaining over 95% of the output variance, compared with only 20–60% for the linear model.

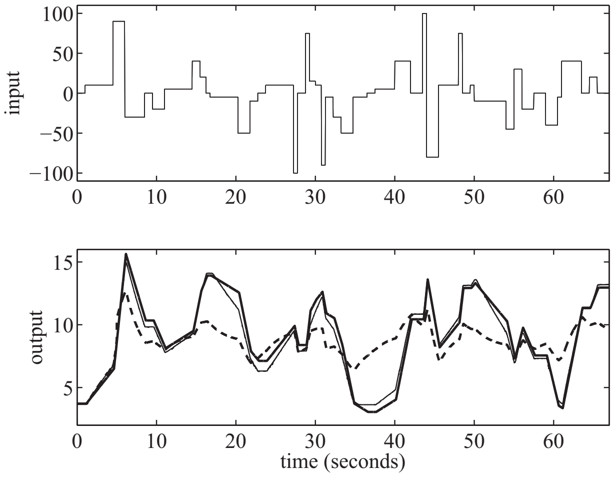

Fig. 6. Upper subplot: applied input voltage plotted against time. Lower subplot: potentiometer voltage, showing the optimized SDP model response (thick trace), experimental data (thin) and linear model (dashed).

TABLE I
Optimized polynomial coefficients

| Joint | $p_1$ | $p_2$ | $p_3$ |
|---|---|---|---|
| $\theta_2$ | $-2.2898e^{-007}$ | $1.2576e^{-005}$ | 0.0055 |
| $\theta_3$ | $-1.9290e^{-007}$ | $1.8214e^{-005}$ | 0.0051 |

### B. Control system design

The NMSS/SDP (13) representation of equation (19) is,

$$\mathbf{x}_k=\begin{bmatrix}y_k\\u_{k-1}\end{bmatrix}=\begin{bmatrix}-a_1 & b_2\{u_{k-2}\}\\0 & 0\end{bmatrix}\mathbf{x}_{k-1}+\begin{bmatrix}0\\1\end{bmatrix}u_{k-1} \tag{21}$$

and $y_k=\begin{bmatrix}1 & 0\end{bmatrix}\mathbf{x}_k$. For $b_2\{u_{k-2}\}>0$, the matrix $\Sigma\{\boldsymbol{\chi}_k\}$ in equation (17) can always be inverted, i.e.,

$$\begin{bmatrix}f_0\{\boldsymbol{\chi}_k\}\\\bar{g}_1\end{bmatrix}=\begin{bmatrix}0 & 1\\b_2\{u_{k-2}\} & a_1\end{bmatrix}^{-1}\begin{bmatrix}-p_1-p_2-a_1\\p_1p_2\end{bmatrix} \tag{22}$$

in which $(z-p_1)(z-p_2)=z^2-(p_1+p_2)z+p_1p_2$ is the desired closed–loop characteristic polynomial, with the poles $\{p_1,p_2\}$ chosen to lie within the unit circle of the complex $z$–plane. For the illustrative results considered in Figures 7, 8 and 9, $p_1=0.9$ and $p_2=0.94$ are chosen by trial and error simulation. Utilising (16), the control algorithm (15) is,

$$u_k=-f_0\{\boldsymbol{\chi}_k\}\,y_k-\frac{b_2\{u_{k-2}\}}{b_2\{u_{k-1}\}}g_1u_{k-1}+k_0\{\boldsymbol{\chi}_k\}\,r_k \tag{23}$$

where $f_0\{\boldsymbol{\chi}_k\}=k_0\{\boldsymbol{\chi}_k\}=(p_1p_2-g_1)/b_2\{u_{k-2}\}$ and $g_1=-p_1-p_2-a_1$. Note that $g_1$ is time–invariant in this case. For the HydroLek, $a_1=-1$ and $b_2\{u_{k-2}\}$ is defined by equation (20). Finally, three linear control systems are also considered. Experimental results suggests that the most robust linear algorithm is based on an operating level of $u_k=0$, hence utilising equation (20) and Table I, $b_2=0.0055$ and $b_2=0.0051$ for the shoulder and elbow joints respectively. For comparison, linear controllers are also developed for the maximum input signal each direction, i.e. equation (20) with $u_k=-100$ and $u_k=100$. In each case, equation (22) is solved off–line for these time–invariant coefficients.

### C. Experimental results

Typical practical results for the NMSS/SDP controller are illustrated by Fig. 7, showing a satisfactory response across a range of operating levels. The linear controller based on an operating level of $u_k = 0$ or 100 yields a slower response (not shown), since the model utilised tends to 'overestimate' the steady state gain of the system. By contrast, the linear controller based on $u_k = -100$ works adequately for large negative steps in the command (since these are associated with large negative values of the input) but tends to overshoot the set point at other times, as illustrated by Fig. 8.

Here, it should be emphasized that the control objective is to follow the particular response specified by the design poles. Although arbitrarily chosen for the present article, which focuses on the low–level joint control problem, the poles and command sequences are generally determined by the higher–level control module for optimising tasks using the attached tools. Hence, the faster speed of response and overshoot for the linear design in Fig. 8 represents an undesirable deviation from the required behaviour of the system.

Fig. 9 shows this error between the experimentally observed joint angle and the ideal or 'design' response. The latter is obtained by simulating a transfer function with the design poles in open–loop. In Fig. 9, the grey and black shading highlights the errors for the SDP and linear controllers respectively. Hence the black colour represents the *additional* errors associated with the linear controller in each case, demonstrating the improved performance of the NMSS/SDP design against all three linear controllers. The mean absolute errors between the joint angle and ideal response for each of the controllers (i.e. SDP and the linear controllers associated with each operating level) are summarised in Table II, for experiments similar to Fig. 7 and Fig. 8.

Finally, Figures 10 and 11 illustrate a resolved motion experiment based on the kinematic equations discussed in section III. Here, the end–effector is programmed to trace a circle in a clockwise motion, followed by a second lower circle in an anticlockwise direction, with point–to–point motion between. In fact, the circular movement is also based on point–to–point motion, with the trajectory defined by a series of small steps in the positional set point for $[p_x, p_z]$. The speed of response is determined by the number of iterations and the waiting time for each point. This straightforward approach to positional trajectory planning appears to work well in practice for hydraulically operated robotic manipulators [13].

Although the linear and nonlinear responses in Figure 10 are visually very similar, small joint angle errors are propagated in relation to the position of the end–effector for these resolved motion experiments. Once the experimental data are displayed in Cartesian form on the work–plane, as in Figure 11, the potential benefits of high performance nonlinear control become more apparent, particularly when relatively fast movement is required. For the illustrative results shown, each circle was programmed to be completed in 6 seconds, with the experiment repeated three times in Figure 11.

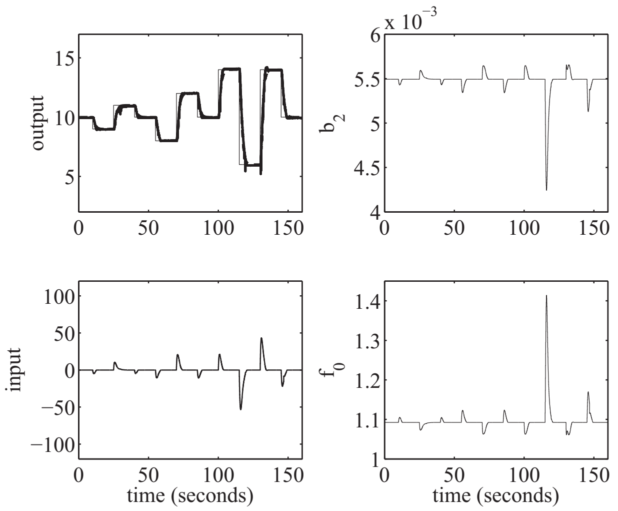

Fig. 7. Clockwise from upper left: closed–loop experiment showing the response of joint angle (thick trace) to a sequence of step changes in the command (thin), $b_2\{\chi_k\}$, $f_0\{\chi_k\}$ and $u_k$, all plotted against time.

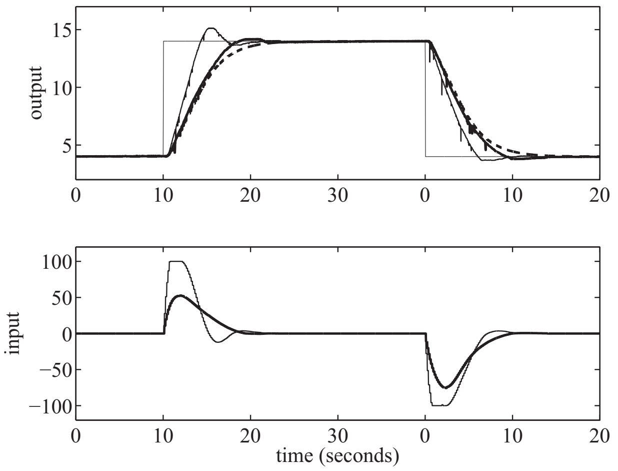

Fig. 8. Closed–loop response of joint angle to positive (joint opening) and negative (closing) step changes in the command input, showing experimental data obtained using the linear (thin trace) and nonlinear (thick) controllers, compared to the simulated design response (dashed), all plotted against time. Upper subplot: potentiometer voltage. Lower subplot: applied input voltage.

## VI. Conclusions

This article has considered state–dependent parameter (SDP) models and non–minimal state space (NMSS) control design for the hydraulically actuated joints of a mobile robot designed for nuclear decommissioning. The analysis suggests that a univariate SDP model with state–dependent gain, representing the angular velocity, is adequate for fast and smooth control of the manipulators. However, the authors are presently investigating other configurations and settings with a view to identifying additional state variables and potential multivariable state–dependencies.

To illustrate the modelling approach and typical closed–loop results, the analysis has concentrated on experimental data associated with the shoulder and elbow pitch of one

manipulator. The authors are now investigating the remaining joints, with a view to the development of a high–level control algorithm for resolved control of the dual–manipulators. In the future, these algorithms are intended to be part of a self–calibrating and self–tuning automatic control system.

## ACKNOWLEDGMENT

The authors are grateful for the support of Brokk UK Ltd. and HydroLek Ltd., who supplied the base robotic systems, and the Nuclear Decommissioning Authority (NDA), who have part–funded this research. The statistical tools have been assembled as the CAPTAIN toolbox within the Matlab® software environment and may be obtained from the second author [12].

*Abstract*—**Automated guided vehicle (AGV) is used widely in many industrial applications to transport materials. A long-travel material transport system is designed and controlled in this paper for a unit load AGV to transfer the material pallet from AGV to the load stand and back, including a both-side three-level push-pull load-transfer mechanism and a programmable logic controller (PLC). AGV follows the path of the magnetic tapes in the floor, and locates itself according to the RFID tags beside the load stand. The PLC detects the docking position of AGV and the load stand, and controls the horizontal and vertical movement of the load-transfer mechanism by using a stepper motor and an electric push rod. The load transfer experiments of our AGV testify the performance of this material transport system.**

***Keywords-automated guided vehicle; material transport; load transfer; mechanism control***

## I. Introduction

Automated guided vehicle (AGV) is a driverless, steerable, wheeled industrial vehicle that follows markers or wires in the floor, or uses vision or lasers. The largest consumer of AGVs is the automotive industry, yet AGVs are also common in other industries, including warehouses and distribution centers, paper, printing, textiles, and steel industries [1]. In these applications, AGVs have been found to increase routing flexibility, improve space utilization, ensure safety, and reduced overall operational cost [2].

According to the means of load transfer, AGVs can be classified as towing AGV, unit load AGV, pallet truck AGV, and fork truck AGV [3]. Towing AGV was the first type introduced and is still a very popular type today. It can tow single or multiple trailers by using hooks to provide traction. It has a simple structure and a capability of several times more materials than conventional unit load AGV. However, it has a difficulty to control the trailer position and has a larger turning radius. Unit load AGV is equipped with decks, which permits unit load transportation and often automatic load transfer. The decks can either be lift and lower type, powered or non-powered roller, chain or belt decks or custom decks with multiple compartments. Pallet truck AGV is designed to transport palletized loads to and from floor level, and it can eliminate the need for fixed load stands. Fork truck AGV is ideal for applications where automatic load pickup or delivery is required from floor or various height elevations. It has counterbalanced or straddled leg configurations depending on application requirements.

Initially, AGV paths are specified by electric wires placed approximately 1 inch below the ground [4]. It requires the expense of cutting the floor for the entire travel route, and it can not be easily removed and relocated if the course needs to change. Due to these disadvantages, Many AGVs begin to use tape in the floor as the guide path. The tapes can be magnetic, colored or other media. AGV uses the magnetic sensor to detect the magnetic tape and then follow the path [5], or uses the vision sensor (e.g. camera) to identify the colored tape [6-7]. In order to measure the position of AGV on the path, magnetic and visual coded signs can be used as artificial landmarks to express its absolute coordinates. Additionally, radio frequency identification (RFID) is regarded as a promising technology suitable for location and navigation of robot that can achieve a pervasive automation [8]. It can contain a large amount of data coded information compared to magnetic and visual signs.

We intend to design and develop an intelligent AGV guided by the magnetic tapes and located by the RFID tags to achieve the pervasive automation of materials transport and transfer, by combining the high guidance accuracy and setting convenience of magnetic taps with the high information capacity of RFID tags. The pervasive automation requires a close collaboration between vehicle guidance and material transport. This paper presents a long-travel material transport system for a unit load AGV having been equipped with the guidance control system. Section II proposes a material transport control methodology containing docking, retrieving and depositing for the unit load AGV. Section III designs a push-pull load-transfer mechanism that can pick up and down the material pallet in both sides. Section IV develops a PLC-based control system to detect the position of executive mechanisms and control their movements in the load transfer process. Section V presents the load transfer experiments, and a conclusion is given in section VI.

## II. Load Transfer Methodology

Unit load AGV has many kinds of decks (e.g. lift, roller, chain, etc) to transport materials. In the consideration of the transfer requirements of automobile assembly production lines, we suggest a material transport control methodology to locate AGV beside the load stand accurately and retrieve and deposit the pallet automatically.

### A. Docking

A load stand is the fixed port where the material pallet is transferred from the AGV to the workstation and back. AGV movement near the load stand is controlled differently to its movement on the path since both a higher accuracy and a different obstacle avoidance technique are needed. In the close proximity to the load stand, AGV needs to navigate closer to obstacles and it must reach the designated point with greater precision. In order to achieve the accurate docking distance between AGV and the load stand, the real-time position of AGV needs to be updated continuously and AGV pose needs to be adjusted accurately.

Our AGV navigates on the specified paths by following the magnetic tapes, as shown in Fig.1. A magnetic guide sensor is mounted in the lateral center of AGV body, and it can detect the lateral deviation between AGV and the desired paths. Path tracking control is used to eliminate this deviation and keep AGV on the path. When the load stands are placed accurately beside the paths, the lateral position between AGV and the load stand can be guaranteed by controlling the lateral deviation. On the other aspect, the longitudinal position from AGV to the load stand is also very important to the docking process. It can be controlled by dead reckoning that accumulates the traveling distance by supposing pure rolling of AGV wheels. In fact, dead reckoning data tends to drift due to wheel slippage. It is necessary to reset the dead reckoning counters according to some artificial landmarks before AGV enters the docking area. Here we put several RFID tags on the path near the load stands, as shown in Fig.1. The longitudinal position begins to sum up by using dead reckoning after AGV reads the RFID tags. The RFID sensor is installed in the head of AGV, which is designed as a semi-open structure in order to avoid the shielded metal environment that may block the RFID signals.

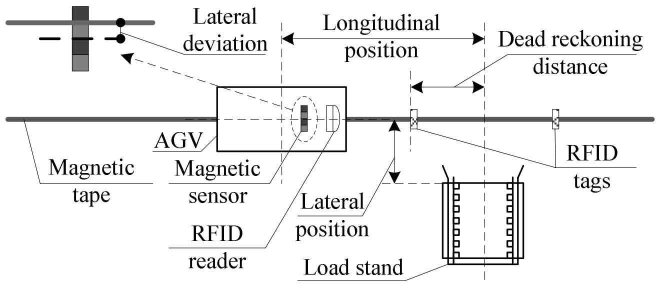

Figure 1. Materials transport path

### B. Retrieving

Retrieving means AGV picks up the material pallet from the load stand. After AGV arrives at the accurate docking spot, it should check whether there is the designated pallet in the load stand. If it exists, AGV begins to pull it by using its load-transfer mechanism. AGV locates itself by making its side facing the front of the load stand, and the pallet needs to be pulled to AGV from its side. AGV should dock in the close proximity to the load stand in the lateral direction to reduce the transfer distance, as shown in Fig.2. Since the width of the load-transfer mechanism is no more than that of AGV body, the retrieving process is proposed as following actions.

(1) The mechanism moves downwards to make its convex blocks below the sockets of the pallet in the vertical direction.

(2) The mechanism moves towards the pallet to make its convex block 2 aligned with socket 1 in the lateral direction.

(3) The mechanism moves upwards to make its convex block 2 inserted into socket 1. At this time the load-transfer mechanism has grasped the pallet.

(4) The mechanism moves backwards to pull the pallet on AGV gradually. At this time block 2 (shown as the dashed lines) has aligned with the initial position of block 1 (shown as the solid lines) in the lateral direction.

(5) The mechanism moves downwards to release the pallet. At this time, the pallet has been placed on AGV.

(6) The mechanism moves towards the pallet to make its convex block 1 and 2 aligned with socket 1 and 2 respectively in the lateral direction. Note that at this time they are aligned on AGV.

(7) The mechanism moves upwards to make its convex block 2 inserted into socket 2 (block 1 also inserted into socket 1). So the load-transfer mechanism can hold the pallet firmly when the pallet is carried in the travel.

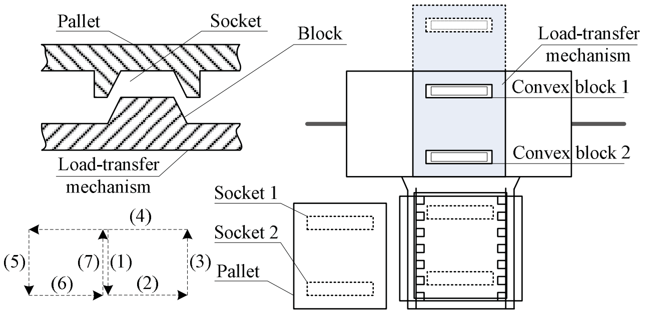

Figure 2. Load pickup approach

### C. Depositing

Depositing means AGV puts down the material pallet to the load stand. AGV should contact the workstation and verify the load stand is free before the material delivery process starts. The pallet is pushed to the load stand from the side of AGV. It is a similar process of retrieving as following actions, shown in Fig.3.

(1) The mechanism moves downwards to depart from its initial position, shown as step (1) in Fig.3.

(2) The mechanism moves away from the pallet to make its convex block 2 aligned with socket 1 in the lateral direction, shown as step (2) in Fig.3.

(3) The mechanism moves upwards to make its convex block 2 inserted into socket 1. At this time the load-transfer mechanism has grasped the pallet, shown as step (3) in Fig.3.

(4) The mechanism moves towards the load stand to push the pallet on it gradually, shown as step (4) in Fig.3.

(5) The mechanism moves downwards to release the pallet. At this time, the pallet has been placed on the load stand, shown as step (5) in Fig.3.

(6) The mechanism moves backwards to align itself with AGV body in the lateral direction, shown as step (6) in Fig.3.

(7) The mechanism moves upwards to return its initial position that is always kept when AGV follows the paths.

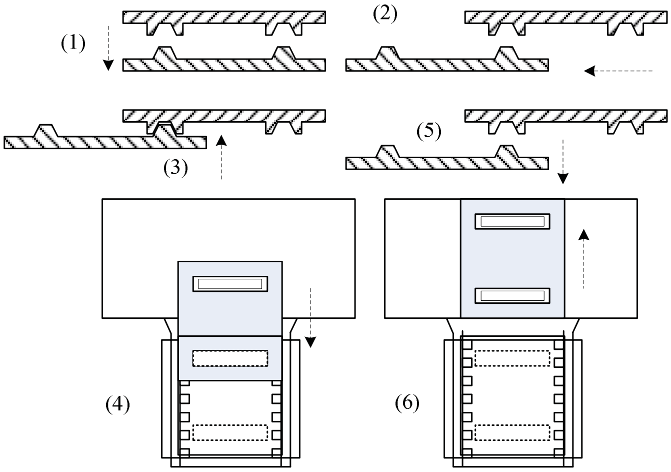

Figure 3. Load putdown approach

## III. LOAD-TRANSFER MECHANISM DESIGN

In order to execute the retrieving and depositing behaviors required in the long-travel materials transport process, a both-side three-level push-pull load-transfer mechanism is designed. This mechanism contains a lifting module and a translational module, as shown in Fig.4.

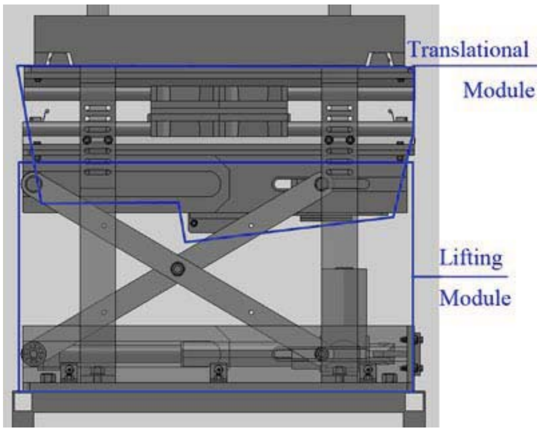

Figure 4. Load-transfer mechanism

### A. *Lifting module*

Lifting module is able to change the vertical height of the platform by using a cross-shaped mechanism, as shown in Fig.5. Two rods are linked at the middle point by using a hinge 3 to form a cross shape. Hinge 1 and rail 1 are fixed on the upper surface of AGV body. Hinge 2 and rail 2 are fixed on the lower surface of the platform. An electric push rod mounted on AGV surface impels slider 1 to make it move forwards and backwards along rail 1. When slider 1 moves forwards, hinge 3 is pulled to move along arc 1, slider 2 to move along arc 2, and hinge 2 to move downwards in the vertical direction, shown as dashed shapes in Fig.5. As a result, the platform follows their movements and lowers itself. When slider 1 moves backwards, these parts moves in reverse trajectories, and their movements lift the platform consequently. In order to control two limit positions of the platform in the vertical direction, two travel switches can be placed at two ends of rail 1 accurately.

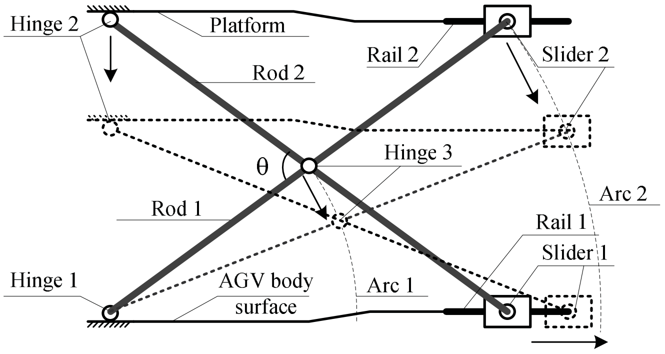

Figure 5. Lifting module

### B. *Translational module*

Translational module is fixed on the platform and moved by lifting module upwards and downwards. This module is responsible for the lateral movement of their convex blocks by using a three-level planar mechanism, as shown in Fig.6. The low-level plane is the platform, and a stepper motor is installed on its lower surface. Gear 1 is linked with the motor shaft by using a key, and gear 2 is supported by a stationary mandrel. On its upper surface, rail 1 is fixed near the right border, and rack 2 is in its middle line. The middle-level plane (plane 2) has slider 1 and slider 2 fixed on its upper and lower surfaces symmetrically, and has gear 3 supported by another stationary mandrel in the center of its upper surface. The high-level plane (plane 3) has rail 2 mounted near the right border on its lower surface, and rack 3 in its middle line. Convex block 1 and 2 are located on its upper surface, as shown in Fig.2.

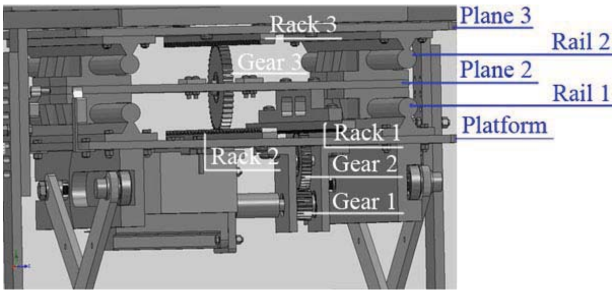

Figure 6. Translational module

The stepper motor drives gear 1 via the connecting key, and then gear 1 makes gear 2 roll on rack 1 by engaging tooth. Since the platform is fixed with lifting module, plane 2 moves relatively to the platform in the lateral direction. Gear 3 is pushed forwards by plane 2, and it rolls on the lower rack 2 of the platform and on the upper rack 3 of plane 3 simultaneously. If plane 2 is selected as the reference coordinate system, plane 2 and plane 3 have an opposite translational movement with the same speed rate. Therefore, when the platform is stationary, if plane 2 has a translational speed and displacement in one direction, plane 3 will have a double speed and displacement in the same direction. It is the basic principle on which the large-travel translational movement is implemented based by using the three-level planar mechanism with gears and racks. In order to control two limit positions and one initial position of plane 3 in the lateral direction, three travel switches can be placed at two ends and in the middle of rail 1 accurately.

## IV. Control System Development

A Siemens PLC S7-224XP CN is adopted as the controller of the material transport system, in charge of controlling the lateral movement of translational module by using the stepper motor, regulating the vertical movement of lifting module by using the electric push rod, and communicating with the on-board controller of AGV, as shown in Fig. 7.

The PLC has two high-speed impulse output ports Q0.0 and Q0.1, which can generate a PWM pulse or a PTO pulse. PWM means the duty cycle is variable by fixing pulse cycle and changing pulse width. They are accumulated by counters with the maximum value of 65535 and based on time unit of micro-second or millisecond. PTO is a pulse sequence of square wave with a fixed duty cycle of 50%. Their pulse number can change in the range of 10~65535μs or 2~65535ms. The stepper motor is controlled by a PTO pulse from Q0.0 and a direction signal from Q0.1. The PLC sends a pulse to make the stepper motor rotate over a step angle, and then checks whether the switch is triggered by the translational module.

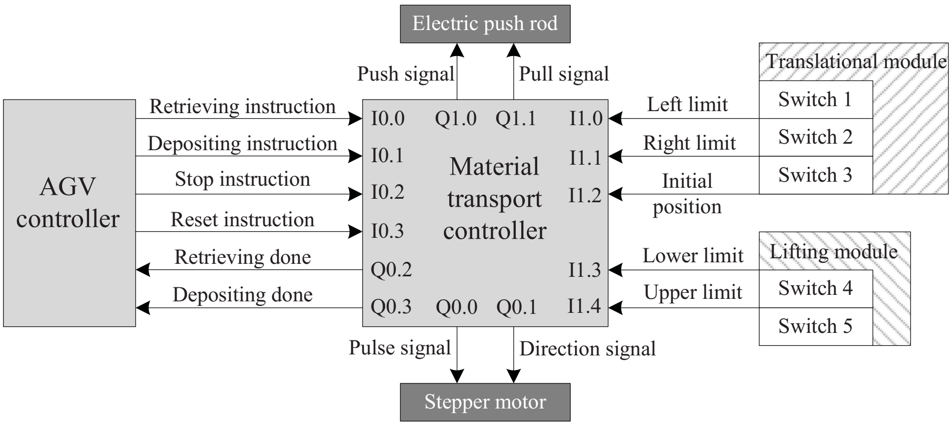

Figure 7. Material transport control system

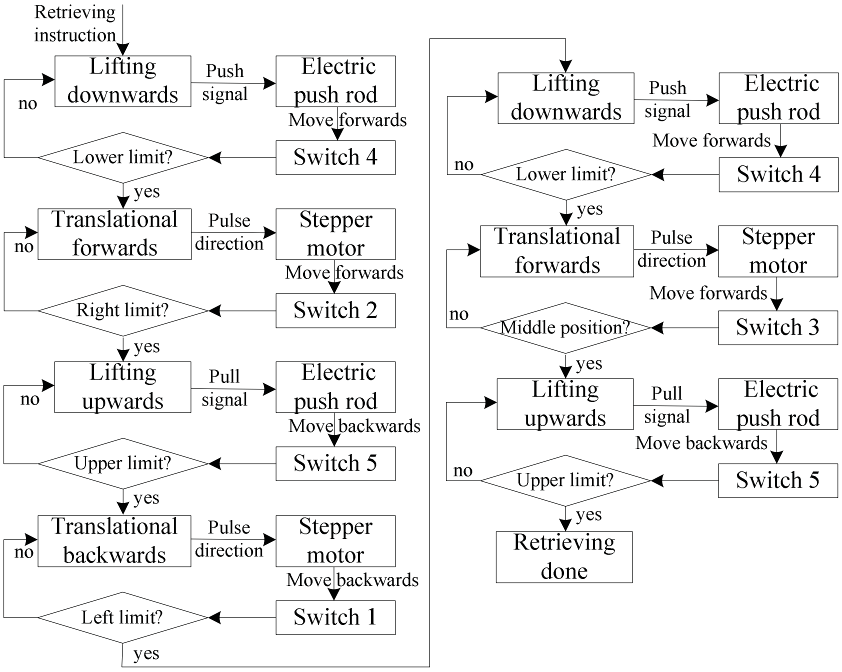

Figure 8. Retrieving control diagram

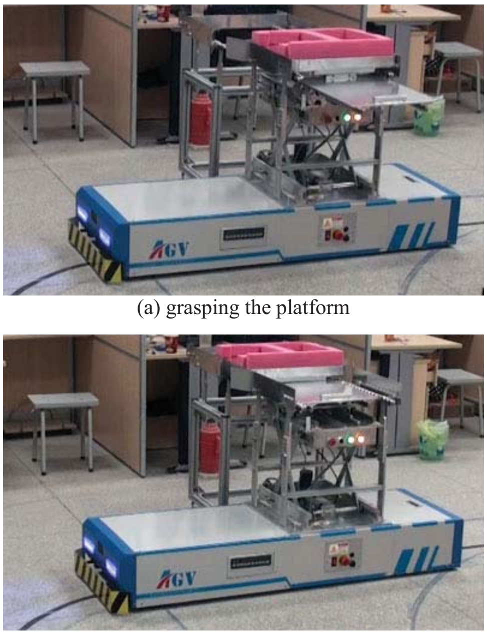
After AGV arrives at the accurate docking spot and checks its pallet target, AGV controller sends a retrieving instruction to the PLC that starts the entire control process, as shown in Fig8. Firstly, the PLC gives a push signal to the electric push rod, and it pushes sliders forwards to lower lifting module. When switch 4 sends a lower limit signal back to the PLC, it stops the push rod, and the convex blocks have moved below the sockets. Secondly, the PLC gives a forward pulse sequence to the stepper motor. The motor drives plane 2 and 3 towards the load stand. When switch 2 sends a right limit signal back to the PLC, it stops the stepper motor, and convex block 2 has aligned with socket 1. Thirdly, the PLC gives a pull signal to the electric push rod, and it pulls sliders backwards to raise lifting module. When switch 5 sends an upper limit signal back to the PLC, it stops the push rod, and convex block 2 has inserted into socket 1. Fourthly, the PLC gives a backward pulse sequence to the stepper motor. The motor drives plane 2 and 3 backwards AGV. When switch 1 sends a left limit signal back to the PLC, it stops the stepper motor, and block 2 has aligned with the initial position of block 1 in the lateral direction. Fifthly, the PLC gives a push signal to the electric push rod until switch 4 feeds back a lower limit signal. Convex block 2 has retracted from socket 1 and plane 3 has released the pallet. Sixthly, the PLC gives a forward pulse sequence to the stepper motor until switch 3 feeds back a middle position signal. Convex block 1 and 2 has aligned with socket 1 and 2 respectively in the lateral direction. Lastly, the PLC gives a pull signal to the electric push rod until switch 5 detects an upper limit signal. Convex block 1 and 2 has inserted into socket 1 and 2, and plane 3 has grasped the pallet again.

## V. Load Transfer Experiments

In order to test the material transport system of AGV, the load transfer experiments are carried out in our laboratory. A ring closed path is laid out in the floor by using magnetic tapes. One load stand is placed on a designated spot accurately beside the path, which is used as a load pickup workstation as well as a load delivery workstation. Firstly, AGV starts at an arbitrary point of the path and moves towards the load stand. After it arrives at the accurate docking spot, it picks up the pallet from the load stand automatically. Then it continues to run on the ring path and comes back to the load stand when it finishes the circle of path. After it checks the load stand is free, it delivers the pallet to the load stand automatically, as shown in Fig.9. Fig.9.(a) shows the grasp operation that plane 3 holds the platform by inserting convex block 2 into socket 1 when the electric push rod pulls sliders backwards to raise lifting module. Fig.9.(b) shows the push operation that plane 3 pushes the platform to the load stand when the stepper motor drives rack 1 and 3 move forwards.

In the load transfer experiments, retrieving and depositing operations of AGV are executed continuously in a periodic way up to 8 hours. This satisfactory experiment result can only be achieved when the material transport system already has two control capacities at the same time. One is that AGV can locate itself accurately on the same spot beside the load stand at each time. So the longitudinal position and the lateral position between AGV and the load stand can be guaranteed strictly. Usually, the longitudinal position error is less than ±15mm, and the lateral position error is less than ±10mm. The other is that the load-transfer mechanism can arrive at the precise position to grasp the platform, push the platform to the correct position of the load stand, and pull the platform back to itself accurately. The experiments show that the translational module has a position error less than ±1mm, and the lifting module has a position error less than ±3mm. It is seen that the performance of the material transport system can be guaranteed by the high repeatable accuracy of AGV and its load-transfer mechanism.



(a) grasping the platform

(b) pushing the platform

Figure 9. Load transfer experiments

## VI. Conclusions

This paper designs a long-travel material transport system for a unit load AGV. AGV follows the path of the magnetic tapes in the floor, and locates itself according to the RFID tags beside the load stand. A load transfer methodology containing docking, retrieving and depositing is proposed firstly. A push-pull load-transfer mechanism is then designed to pick up and down the pallet in both sides, including a lifting module that changes the vertical height of the platform and a translational module that moves their convex blocks in the lateral direction. Thirdly, a PLC-based control system is developed to detect the position of executive mechanisms and control their movements. Lastly, the load transfer experiments of our AGV testify the performance of this material transport system.

# A Novel Adaptive Approach for Home Care Ambient Intelligent Environments with an Emotion-Aware System

Sherief Mowafey and Steve Gardner
Glamorgan Intelligent Home Care
Faculty of Advanced Technology, University of Glamorgan
Pontypridd, United Kingdom
smowafey@glam.ac.uk and sgardner@glam.ac.uk

*Abstract*— **The elderly population worldwide has an increasing expectation of well-being and life expectancy. The monitoring of elderly people on an individual basis, in a medical sense, will not be a viable proposition in the future. The infrastructure available is not adequate to meet all expectations and subsequently people will continue to live at home with inadequate care. Prior research has shown an accelerated need for the expansion in the Ambient Intelligence (AmI) domain and to that end we present a novel learning technique for intelligent agents that are embedded in Ambient Intelligent Environments (AIEs). A novel agent that combines an emotion recognition system with a fuzzy logic based learning and adaptation technique provides for an automated self-learning system that constantly adapts to individual requirements. This agent, entitled Health Adaptive Emotion Fuzzy Agent (HAOEFA), has the ability to model and learn the user behaviour in order to control the environment on their behalf with respect to his/her emotional preferences. In addition, the agent incorporates temporal adaption in order to facilitate changing behaviour and preferences within the environment. The results show that such architecture can both provide monitoring and ambient environmental control features such that users with limited physical or cognitive functions can have their well-being advanced with limited external resources.**

## I. INTRODUCTION

The world is being overtaken by different demographic trends that will affect the human life over the coming years. One of these trends is labelled as global ageing where in the next few decades it promises to affect everything from business psychology and workforce productivity to the shape of the family and the direction of global capital flows [1]. For instance, according to the Office for National Statistics (ONS) [2] the percentage of the population aged 65 and over within the UK has increased from 15% in 1984 to 16% in 2009, which is an increase of 1.7 million people. More important is in the same period of time, the percentage of the population aged under 16 decreased from 21% to 19%. Future estimation were calculated where it presents that by the year 2034, 23% of the population is projected to be aged 65 and over compared to 18% aged under 16. Also, a chart presented by the HelpAge International [3, 4] showed in Fig. 1 shows different world countries in different regions ageing around the globe as years pass. The vertical axis measures the percentage of each country's population between 65-79 years, the horizontal axis measures shows the countries' population get "older" as they move upwards and across the years [4].

Fast ageing of populations is presenting different challenges for developed and developing countries. These challenges include economic challenges, strains on pension and social security systems, bigger demand on long-term care as well as health care, and bigger demand for trained-health workforce. To address such challenges computer scientists attempted to develop a variety of interactive systems that can communicate with humans as well as helping people through their daily life activities. So, the use of new technologies such as ambient sensors can help doctors to monitor certain activities of elderly people within their houses in order to collect more information about the person. It can help them to understand the alteration of the human well-being status.

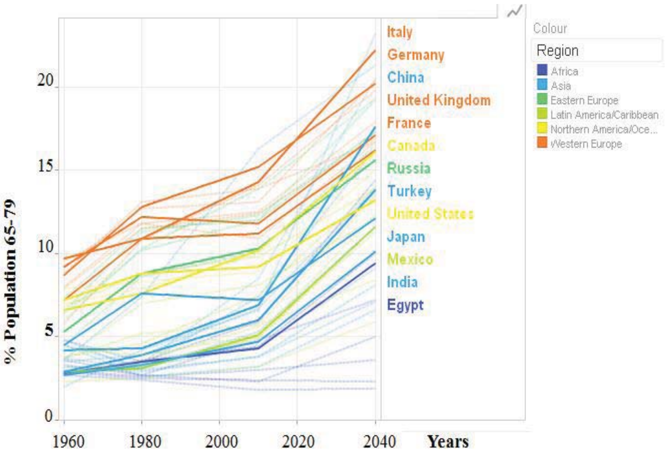

Figure 1. World population over the years [4]

With intelligent home care assistance, care providers can use these aspects and functionalities of sensors (such as kitchen sensor activated, fridge door opened, cold water run for 20 seconds, kettle switched on for 60 seconds) in order to clearly understand the individual's wellbeing current state, as well as answering judgmental questions (such as “is occupant sleeping regularly”, “has the occupant any repeating eating disorder in the last few months”, etc.) [5].

Such techniques of intelligent data monitoring, information clustering and analysis can enable doctors to make accurate diagnosis before it is “late”, and by “late” it is meant the doctor was able to identify accurately the current situation before it reaches a critical state [6]. These efforts of advancing technology to pervade everyday life and to foster wide availability and acceptance was yielded in 1991 when Mark Weiser [7] introduced his vision of ubiquitous computing in his famous article "The Computer for the 21st Century" [7]. Thus, different approaches developed have attempted to help decreasing the global ageing trend where applications such as Tele-care systems developed by Martin et al. [5] tries to produce emergency alerts system that helps in critical situations. Also, research scientists in the Ambient Intelligent Center (AMIC) located in the German University in Cairo [8] have developed an AIE that can learn, and model the user behaviour as well as adapt to the changes of his needs, habits, and gestures in an invisible none interrupting way. In Essex, the Computational Intelligence Centre research team [9] used a soft computing approach based on computational intelligence techniques in order to control the environment on the user behalf and adapt to his/her needs. According to Riva [10] the Intelligent Mixed Reality (IMR) is the most determined illustration to ambience intelligence where it can be invasively integrated and embedded into physical real life environments. It will allow the user to interact with other persons and the environment itself in a usual way. The Research group in University of Bristol identified the three generations of telecare as the first generation systems are typically for “panic alarms situations” such as falling on the ground, the second generation systems are more complicated where they use sensors to detect needed assistance in certain situations and send alarm to family members, friends or to a monitoring agency. Finally, the third generation vision where it tries to predict early warnings for possible emergency situations by observing intrusively significant changes in the person’s “well-being” [5, 11].

Most of the research in the intelligent environments field is focused on controlling and adapting the environment to its user according to their behaviour preferences [12], less focus has been given to the user emotional state within the environment. Therefore, this paper aspect is to show a developed embedded intelligent agent that has the ability to understand the user behaviour in a real-life physical environment pervasively. In addition to, the emotions recognition that take place over time in order to understand the domain of the word well-being and how does it affect the user behavioural actions within the environment. For instance, a person notices that his house has been burglarised. The person assesses the situation, which triggers anger. His heart rate, respiration rate starts to increase rapidly. Consequently, the person contacts the police. Such a situation handling strategy shapes the emotional reactions by adjusting the link between a person and their environment [13].

Various experiments had took place in which the intelligent agent has learned the user behaviour and their emotions during an extended experiment of 14 consecutive days in Glamorgan intelligent home care (Glam i-HomeCare) that acts like a real world AIE test bed. The rest of this paper is structured as follows. In Section II, we will introduce our test bed for AIEs which is the Glam i-HomeCare. Section III presents a description of the life-long learning and adaptation agent entitled HAOEFA. Section IV presents the experiments and results obtained while testing HAOEFA in the environment. Finally, Section V provides the conclusion and future work.

## II. Glamorgan i-HomeCare Overview

The Glam i-HomeCare is one of the real physical AIE test beds shown in Fig. 2, located in the University of Glamorgan. It aims at Home Care AIEs where it looks like any other ordinary room containing furniture. However, it consists of a big number of embedded actuators, processors and sensors that are connected to each other through an assorted network [14]. The Glam i-HomeCare is a single user space that can be used in a wide range of activities such as reading books, watching TV, and eating dinner, etc.

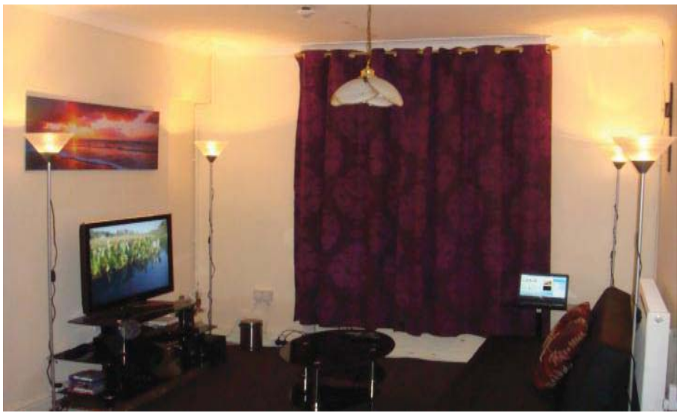

Figure 2. The Glam i-HomeCare Environment

Any networked computer that can run a standard Java process can access the Glam i-HomeCare easily. Thus, this multimedia PC shown in Fig. 2 can also act as an interface controlling the actuators inside room wirelessly. The Glam i-HomeCare Network Infrastructure shown in Fig. 3 is equipped with various embedded actuators and sensors that consists of: date, time of day, internal light level sensor, external light level sensor, internal temperature sensor, external temperature sensor and an occupancy sensor. The developed agent can control four dimmable floor standing up lights and the TV inside the room. These actuators and sensors are embedded within the room infrastructure in order to keep the user completely unaware of the intelligent infrastructure developed, which is required to reach the main aim of AIEs [15].

Although the Glam i-HomeCare environment looks like any other room, the walls and the celling hide numerous networked embedded devices residing on two different networks. Since, it is essential to manage the access of the devices, gateways between different networks critical components in such systems, while combining appropriate granularity with security. Glam i-HomeCare network architecture provides the diverse infrastructure present in ubiquitous computing environments that allow us to improve network independent solutions [16].

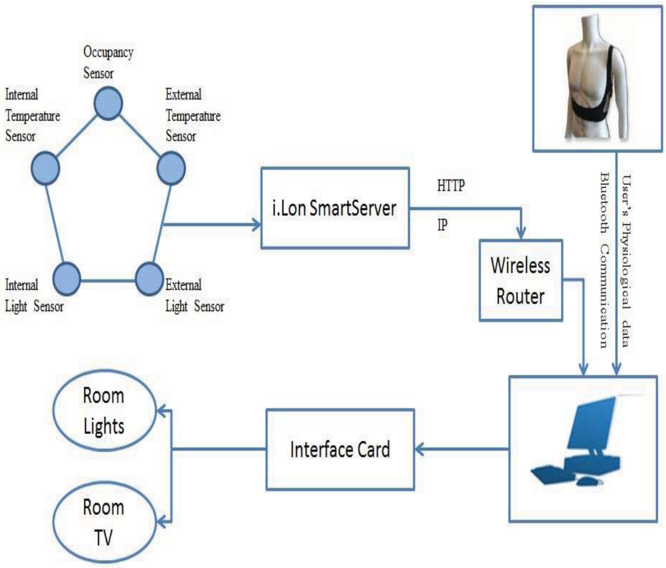

Figure 3. Glam i-HomeCare Network Infrastructure

Fig. 4 shows photos of the various sensors located in the Glam i-HomeCare where its values are displayed on our fuzzy agent interface shown in Fig. 7(b) that operates from the standard multimedia PC in the room presented in Fig. 2.

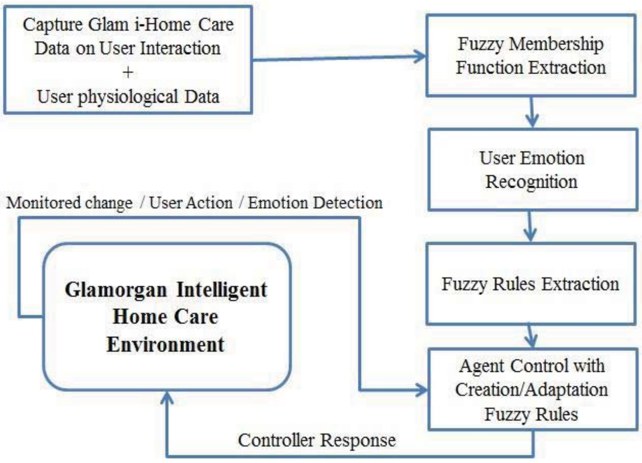
## III. The Health Adaptive Online Emotion Fuzzy Agent (HAOEFA)

The proposed agent, entitled as Health Adaptive Online Emotion Fuzzy Agent (HAOEFA), is a Type-1 Fuzzy Logic Controller (FLC). HAOEFA uses an unsupervised methodology to extract fuzzy membership functions and fuzzy rule sets from the data gathered during the learning process, in order to build a fuzzy logic controller that will be capable of learning and modelling the user's behaviour while taking in consideration his/her emotional preferences. These data are gathered by monitoring the user interaction inside the real life environment over a certain period of time. HAOEFA allows its interface to take controls actions in the Glam i-HomeCare environment based on the present situation (state of inputs) and the user emotional state. Additionally, the adaptive agent have the ability to control and manage the room on behalf of the user as well as allowing the rules set to be extended online and adapted over time, achieving a life-long learning technique that adjust to environmental changes and user's behaviour adjusting to it. The HAOEFA consist of the five following phases as shown in Fig. 5:

1. Monitoring the user's behavior and capturing the input/output data that are associated with user's actions with in the environment.
2. Extraction of fuzzy membership functions from the data.
3. Extraction of the user emotional states.
4. Extraction of the fuzzy rules from the captured data.
5. The agent controls the AIE on behalf of the user
6. Life-long learning and adaptation mechanism.



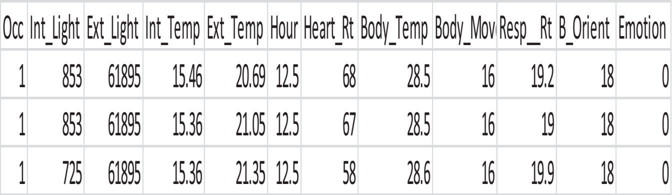
Capture Glam i-Home Care Data on User Interaction + User physiological Data
Fuzzy Membership Function Extraction
User Emotion Recognition
Monitored change / User Action / Emotion Detection
Glamorgan Intelligent Home Care Environment
Fuzzy Rules Extraction
Agent Control with Creation/Adaptation Fuzzy Rules
Controller Response

Figure 5. HAOEFA Flow Diagram.

As presented in Fig. 5, the last two phases of this algorithm are control loops that once started, it receives the environment inputs as changes of sensor values. Subsequently, HAOEFA produces the right control response based on the set of learned rules. Moreover, if the user is not satisfied by the agent control, he/she can take over with a simple change to the system Graphical user interface (GUI) that will lead to a modification in their environment behavioural actions. Therefore, the rules learned by the system will be adapted to the new preference instantly.

### A. *Input/Output Data Capture*

In the learning process the agent displays the different sensor values shown in Fig. 7(b) and monitors the user actions in the room. Every five minutes the agent records a "snapshot" of the current sensor values. For instance, a snapshot of the Glam i-HomeCare environment would look like the following statement:



| Occ | Int_Light | Ext_Light | Int_Temp | Ext_Temp | Hour | Heart_Rt | Body_Temp | Body_Mov | Resp_Rt | B_Orient | Emotion |
|---|---|---|---|---|---|---|---|---|---|---|---|
| 1 | 853 | 61895 | 15.46 | 20.69 | 12.5 | 68 | 28.5 | 16 | 19.2 | 18 | 0 |
| 1 | 853 | 61895 | 15.36 | 21.05 | 12.5 | 67 | 28.5 | 16 | 19 | 18 | 0 |
| 1 | 725 | 61895 | 15.36 | 21.35 | 12.5 | 58 | 28.6 | 16 | 19.9 | 18 | 0 |

where Occupancy will be equal to 1 if the user is in the room, else it's going to be 0, the internal and external light levels are measured in LUX, internal and external temperatures are measured in degree Celsius (°C), the hour is the time of the day. In addition, the agent captures the measurements of the heart rate, skin temperature, respiration rate, and body posture using a wireless belt that that user wears around his chest. In the learning process the system won't be able to detect the user emotional state, but once the adaptation process takes place, HAOEFA will be able to interpret the emotions of the user such as happy, angry and Neutral.

It also observes the outputs (actuator states with new values of which any actuators were modified by the user). For instance, the output or the action of the user that took place for the input or the situation discussed previously in the snapshot taken is:

| ACTION_Light_value | Action_TV_value |
|---|---|
| 0 | 0 |
| 0 | 0 |
| 0 | 0 |

where the ACTION_Light_value are the control light values of the lights in the room where they range from 0 to 100 (0 equals off, 50 equals to halfway, and 100 is on). The TV value is either 0 or 1 (0 equals off, and 1 is on). All these inputs are recorded by the agent in order to model the user behavior, detect his/her emotional state while living in the Glam i-HomeCare.

### *B. Extraction of Fuzzy Rule Sets*

The proposed agent combines the set of membership functions with the input/output data so that it can model the behavior of the user in order to extract the fuzzy rules. This fuzzy rule extraction methodology used by the HAOEFA extracts multi-input multi-output rule that describe the relation between y = $(y_1, ..., y_k)$ and x = $(x_1, \dots, x_n)^T$ as in (1):

$$if\ x_1\ is\ A_1^{(l)}\ and\ ...\ and\ x_n\ is\ A_n^{(l)} then\ y_1 \text{ is } \mathrm{B}_1^{(l)}\text{and ... and } \mathrm{y_n} \text{ is } \mathrm{B}_n^{(l)} \tag{1}$$

where l = 1, 2, ... , M, and M is the number of rules and l is the index of rules. There are V fuzzy sets $A_s^q$, q = 1, ... , V, defined for each input $x_s$. There are W fuzzy sets $B_c^h$, h = 1, ... , W defined for each output $y_c$ [9].

### *C. The Emotion Recognition System*

Emotion recognition computing systems should operate in a similar way to how humans recognize emotions during communication. Thus, detecting people emotions during conversations could lead to an intelligent human to human interaction. For example, a person notices that a friend is feeling sad so he turns off the music being played instantly. Inspired by this idea the intelligence of HAOEFA is not only limited to the environment conditions, weather, time, etc. but it also includes the recognition of the user emotional state as it tries to achieve a certain level of comfortably within the environment by controlling it on the user's behalf. In addition, it monitors the user's health indicators as an attempt to better understand the user's well-being over time.

During Glam i-HomeCare experiments, the user wears the equivital belt which uses Bluetooth communication to measure the physiological conditions of the human body. Following the learning period and the extraction of the fuzzy membership functions for the FLC, HAOEFA is able to identify the user emotions by monitoring the user physiological data where it detects any changes that occurs in a real-time mode. Consequently, the agent starts controlling the environment on the user behalf. For instance, play some music while the user is happy. Currently, only "angry", "happy" and "neutral" emotions are being considered since more differentiated emotion recognition would lead to lower accuracies [14, 17].

### *D. The Agent Controller*

The proposed agent uses singleton fuzzification, max-product composition, product implication and height defuzzification, as it maps a crisp input n into a crisp output y = f(x) where it applies as in (2) as follows:

$$\mathrm{y(x)} = \mathrm{f_s(x)} = \frac{\sum_{l=1}^{M} y^{-l} \prod_{i=1}^{n} \mu_{F_i^l}(x_i)}{\sum_{l=1}^{M} \prod_{i=1}^{n} \mu_{F_i^l}(x_i)} \tag{2}$$

where M is the total number of rules in the rule base, y-l is the maximum membership value point in the ith rule output fuzzy Bl, $\prod_{i=1}^{n} \mu\, F_i^l\, (x_i)$ set is the product of the membership values of each rule's input fuzzy sets, and n is the number of inputs. As to get multiple outputs, equation (2) is repeated for each output parameter. Consequently, after extracting the membership function and building the set of rules from the user's environment multi-input/output data. The agent has learned and modeled the user behavior. Consequently, HAOEFA starts controlling the environment on the user's behalf with respect to their needs and emotional state by monitoring the Glam i-HomeCare environment input values (such as sensors and emotional state) and as a result it controls the actuators based on the rule model built before from the user interactions that have been made during the learning process in the intelligent environment.

### *E. Life Long Learning and Online adaptation*

In the above subsection, we have explained how the agent can learn the user behaviors. Nevertheless, HAOEFA is a flexible system, where the initially learned rules can be easily extended to change both existing rules as well as adding new rules as user's behavior might alter or change over time. The agent allows capturing wide range of various values for each input and output constrains. This methodology offers a continuous operation even if a gradual change in the environment exists (such as temperature drop off in winter). If, however, a significant alteration in the environment or the user's behavior acquires, that has not been introduced to the system during the learning phase. Consequently, the agent will intelligently create new rules that satisfy the current state in an unobtrusive way in order to extend its behavior to satisfy the user [14].

In other words, that the rule fired, and would therefore have contributed to the overall control response generated by the agent's FLC. The consequent membership functions that give the highest membership values to the user defined actuator values are selected to replace the consequent sets of all fired rules in the rule base [15]:

$$\mu_{B_c^{h*}}(y_c) \geq \mu_{B_c^h}(y_c) \tag{3}$$

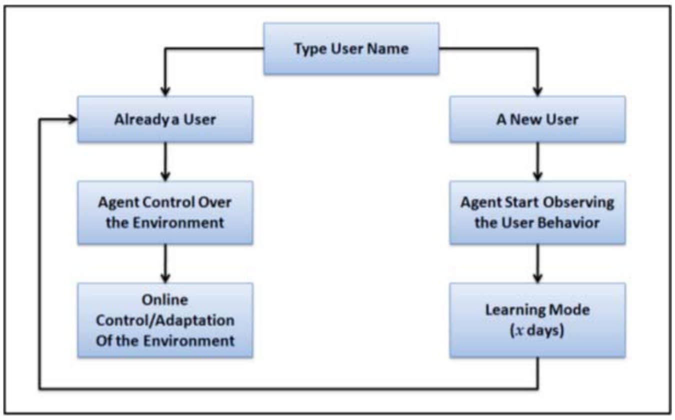
where $h = 1, 2, \dots, W$, and W is the number of fuzzy sets, $B_c$ is chosen as $B_c^{h*}$, where $c = 1, 2, \dots, k$. The fired rules are therefore adapted to better reflect the user's updated actuator preferences given the current state of the environment and this leads to a grid of identified fuzzy set(s) for each input parameter. From this grid, new rules are constructed based on each unique combination of consecutive input fuzzy sets [15]. The consequent fuzzy sets for each of the new rules are determined as in (3). This allows new rules to be gradually added to the rule base. The agent will also add new rules when the currently monitored environmental state is undefined by the existing rules in the rule base; i.e., none of the existing rules fired. In this case, the agent will create new rules where the antecedent sets reflect the current input states of the environment and the consequent fuzzy sets are based on the current state of the actuators. The agent adopts life-long learning, where it adapts its rules as the state of the environment and the preferences of the user change over a significantly long period of time [14, 15].

## IV. Experiments and Results

This section demonstrates the results obtained by the HAOEFA in the Glam i-HomeCare which is a real AmI test bed. In the beginning, we are going to introduce the scenario performed during experiments. Consequently, the HAOEFA results obtained in the Glam i-HomeCare will be presented, where the agent has learned and modeled the user behavior through a certain period of time. Afterwards, the agent controls the environment on the user behalf with respect to the user emotion preferences. The results were examined where the rules are compared with the readable format rules with user's journal parameters to guarantee that the agent has successfully learned the behavior the user was anticipating.

### *A. Glam i-HomeCare Scenario*

The experiments scenario takes the following route: whenever a user enters the Glam i-HomeCare, there are several steps to be maintained as shown in Fig. 6. Firstly, the user enters the username and password in order to authenticate with an online server as shown in Fig. 7(a) as well as for the system to identify the user in action. Subsequently, on one hand, if the user is already registered with the Glam i-HomeCare, HAOEFA will start immediately to control the environment on the his/her behalf accordingly to the behavior learned and the emotion preference. It can be easily adapted online to whatever changes could happen wither in the environment or in the user behavior. On the second hand, if he/she is a new user to Glam i-HomeCare, the HAOEFA will start monitoring the user for x days as it enters the learning mode. The experiments presented in this section take a period of 14 days while the first day is the learning day then the agent start computing in order to build the rule base. Subsequently, HAOEFA will enter the live adaption online control phase for 13 more days where the agent controls the environment and whenever the user is unsatisfied with agent control he can easily adapt it using the Glam i-HomeCare GUI shown in Fig 7(b).



Type User Name
Already a User
A New User
Agent Control Over the Environment
Agent Start Observing the User Behavior
Online Control/Adaptation Of the Environment
Learning Mode ($x$ days)

Figure 6. The Glam i-HomeCare Scenario

In addition, the user uses HAOEFA's GUI installed on the multimedia PC to monitor the real-time physiological body changes and the emotions recognized with it, as well as the display of the environment's sensors data while the agent the environment control taken as shown in Fig. 7(b). In order to test the agent capabilities a history record of the user decisions was saved in a journal and using a parsing tool that convert the .csv file containing the fuzzy rules sets into a readable format.

The complete dataset of 2880 instances acquired from the user's interactions in the Glam i–Home Care over the initial period of one day was used by HAOEFA to learn an initial FLC set of rules. The membership functions were built using fuzzy c-means and the results are shown in Fig. 8 (a) and (b). The agent then runs online for a further 13 days, during which it monitors the user's activities and controls the environment on their behalf. During this time, the user is allowed to override and adapt the agent's learned control responses, if it was necessary to modify and tune them further. As mentioned previously, one of the main characteristics of the Glam i-HomeCare System is that the user is always in control of the environment and capable of overriding the agent's control at any time and his instructions are executed immediately, in order to achieve the responsive property implied in the ambient intelligence vision.

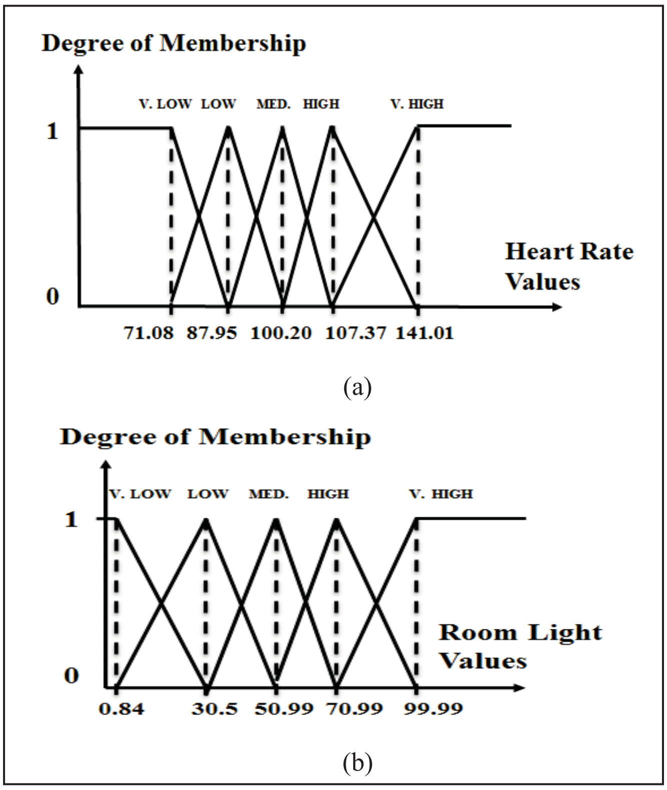
Figure 7. (a) User Login Screen (b) Glam i-Home Care Graphical User Interface

Thus, whenever changes to controls were made by the user, the agent received the request, generated new rules or adjusted previously learned rules, and allowed the action through. The performance of the agent could be gauged on the number of occasions when the user had to override the agent's control responses and adapt the rules over time, as this can reflect how satisfied the user is with the agent control actions.



(a)

(b)

Figure 8. (a) User Heart Rate Membership Function (b) User Heart Rate Membership Function

The success of HAOEFA could be measured by the ability of understanding human dialogue words such as very low, low, medium, high, etc. as presented in the built membership of different attributes like heart rate and the control indoor room light shown in Fig. 8(a) and Fig. 8(b) respectively. In addition to, the monitoring of how efficient the agent adjusted the environment to the user's preferences where the user intervention was reduced over time. Fig. 9 shows a graph plotting the number of online rule adaptations against time measured in hours. The agent initially learned 16764 rules in the first 24 hours from the user's dataset and over the course of the subsequent rest of the days. It also demonstrates the number of the user's induced rule adaptations that occurred over the duration of the experiment, where 341 rules were added in the second day, and then 11 rules were added in the third day. Later, a total of 729 new rules were added by end of the seventh day. At that time, no more adaptations occurred which illustrate that HAOEFA was able to fully stabilize by the end of the first week. Moreover, given the theoretical maximum number of rules which is 15625000 rules, the agent generated a total of 17493 rules. This shows that HAOEFA was able model the user's behaviour within Glam i-HomeCare using 0.001% of the actual theoretical number using a nonintrusive technique to learn most of the user's preferences for various weather and environmental conditions over the duration of the first day of the experiment, including behavioural changes associated with user emotion changes.

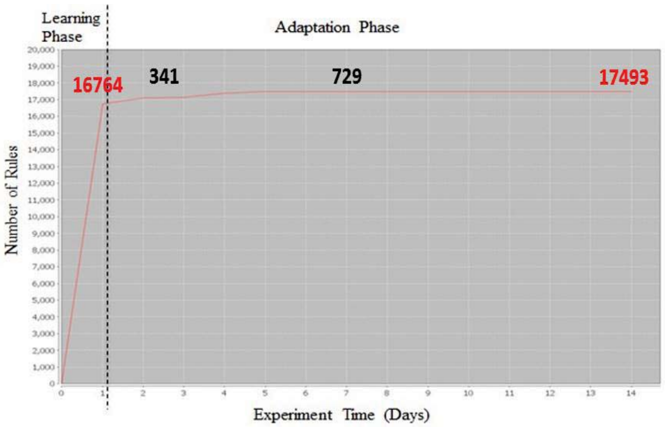


Figure 9. HAOEFA rules learned plotted against the experiment time.

## V. CONCULISION AND FUTURE WORK

In Conclusion, the Glam i-HomeCare agent succeeded in interacting within a real life physical environment. HAOEFA has effectively produced the appropriate control responses based on its learned rules and the emotion preference of the user detected at a time. In the Future, more experiments will take place in order to enhance the emotional model and to add more emotions such as sadness, and fear to the agent. Over and above that, a more efficient Type-2 Fuzzy Logic agent will be developed in order to enhance the FLC to model the user behavior with respect to his emotional preference as an attempt to define the word "Well-Being" in order to help the elder people to live a better life in their homes with care they deserve.

***Abstract*—ILC is an emerging technique for learning control. The D-ILC algorithm is the generic ILC scheme which captures the error trend of a batch to update the control input for the next batch or batches. The 2-dimensional nature requires in-depth convergence analysis of the algorithm. This paper addresses these issues in detail. This paper deals with the convergence properties of ILC algorithms with emphasis on control input. Discrete-time linear state space representation of a linear time-invariant system has been considered along with usual assumptions which ensure D-type ILC algorithm converges in terms of output error. The convergence for control input sequence is investigated up to component level.**

***Keywords: Iterative Learning Control; Rate of Convergence;***

## I. Introduction

Iterative Learning Control (ILC) is one of the Intelligent Control schemes. The transient performance is improved for systems which operate in a repetitive manner. The repetitions occur after fixed intervals of time. ILC has achieved better performance of control systems especially when dealing with uncertain/stochastic systems[1]. The concept of learning through repeated trials evolved in late 1970s for improving the motion control of mechanical arms [2, 3]. The D-type algorithms for Iterative Learning Control for linear time-varying systems with application to robotic manipulators were developed [4-6]. However, the D-type ILC suffered with the problem of differentiation of high frequency noise. Later, the P-type ILC improved upon by using only the error instead of its derivative [7].

Current Iteration Tracking Error (CITE) was introduced which formulated ILC in line with feedback control paradigm and helped to overcome large overshoot thus convergence could be accelerated [8]. The discrete-time version of D-type ILC was formulated for MIMO linear systems which possessed global robustness against state disturbances, measurement noise and re-initialisation error at the beginning of each iteration[9]. The ILC law has been employed for non-linear time varying systems having affine input and linear output. Uniform convergence of input and state was achieved when there were no disturbances [10].

In real world applications, the plants are usually non-linear with higher order dynamics and can not be modelled accurately. The mathematical model is linearised around a known equilibrium point for LTI systems. It then becomes easier to design the controllers. However, the model uncertainties restrict the controller from achieving optimal solutions.

Iterative Learning Controllers provide an adaptive solution. These controllers utilize the error information of each batch/iteration and update the control input accordingly for the next batch or batches. The control input signal using ILC converges to the desired value of the control input which is the inverse solution. Hence, it is also termed as Iteration Inversion Process.

The error information at each time instance can be used in a variety of ways to generate the update for control input. Hence, there are D, PD, PI, PID, Gradient based etc. many types of ILC controllers in which the output error, its derivative, integral or some combination of these is added to the current control input to generate input for the same time instant in next batch [7, 9-19]. The rate of convergence up to component level inside batches has not been covered in earlier works. This has been carried out in this paper.

## II. Discrete-time System with ILC

The discrete-time LTI system having one relative degree is considered as follows:

$$\begin{aligned} x(i+1,k) &= A\,x(i,k) + B\,u(i,k) \\ y(i,k) &= C\,x(i,k) \end{aligned} \tag{1}$$

where $k$ denotes the Batch/iteration/trial number having $M$ number of samples in each trial, $i \in [1, M]$ is the time index or sample number during each batch, state vector $x \in \mathbb{R}^n$, input $u(i,k) \in \mathbb{R}^r$ and output of the system is $y(i,k) \in \mathbb{R}^p$. $A, B$ and $C$ are the real-valued state, input and output matrices respectively, having appropriate dimensions. The initial conditions have been selected as follows:

- $x(1,k) = x_0$ is same at the start of each batch. Hence zero initial error is maintained.
- $u(i,1) = u_0(i)$ is the control input vector for first batch which may be externally specified or left to be zero [9, 10, 19, 20].

Here the control input for the first batch is assumed zero.

### *A. D-ILC Control Input Update*

Control input is updated using D-ILC as follows:

$$u(i,k+1) = u(i,k) + K_d\{e(i+1,k) - e(i,k)\} \tag{2}$$

where $K_d$ is the real-valued learning gain matrix and the derivative of error $\dot{e}(i,k)$ has been approximated using forward difference:

$$\dot{e}(i,k) = e(i+1,k) - e(i,k) \tag{3}$$

where $e(i,k)$ is the error between the desired/reference and the actual outputs:

$$e(i,k) = y^*(i) - y(i,k) \quad \text{for } 1 \le i \le M \tag{4}$$

Furthermore, using the zero initial error assumption we have $e(1,k) = 0$ i.e., $y^*(1) = y(1,k)$.

Thus, the objective of the D-type ILC algorithm is to find the sequence $u(i,k)$ so that:

$$\lim_{k\to\infty} u(i,k) = u^*(i) \quad \text{for } \forall i = 1,2,\ldots,M \tag{5}$$

For a linear system, the convergence of input sequence corresponds to the convergence of the output sequence:

$$\lim_{k\to\infty} y(i,k) = y^*(i) \quad \text{for } \forall i = 2,3,\ldots,M+1 \tag{6}$$

### *B. Convergence of Control Input Sequence using D-ILC*

In this section, the component-level relationship for $u(i,k+1)$ at $(k+1)^{\text{th}}$ batch is presented in terms of static and dynamic components as well as the control input $u(i,k)$ from previous batch *k*. Convergence of control input $u(i,k)$ approaching the desired input $u^*(i)$ is investigated. So that the desired output sequence $y^*(i)$ is generated when sequence $u^*(i)$ is applied to the system:

$$y^*(i) = G(z)u^*(i) = \left\{C\,(zI - A)^{-1}\,B + D\right\}u^*(i) \tag{7}$$

The convergence condition for control input and rate of convergence for individual components of the control input have been derived, where bounds for the convergence rates have been formulated as well.

#### *1) Batch to Batch Control Input Sequence*

The D-type ILC algorithm generates the batch to batch control input sequence, i.e. from $1,2,\ldots,k,k+1,\ldots$ for each time index $i$. In this section a recurrence relationship is derived to perform a convergence analysis on $u(i,k)$. The control input sequences for individual time indices are derived using (2) as follows:

$$u(1,k+1) = u(1,k) + K_d\{e(2,k) - e(1,k)\} \tag{8}$$

Using the zero initial error, i.e., $e(1,k) = 0$, we get:

$$\begin{aligned} u(1,k+1) &= u(1,k) + K_d\{e(2,k)\} \\ &= u(1,k) + K_d\left\{y^*(2)\right\} - K_d C \begin{Bmatrix} Ax(1,k) \\ +Bu(1,k) \end{Bmatrix} \\ &= \left(I - K_d CB\right)u(1,k) + K_d\left\{y^*(2)\right\} - K_d CAx_0 \end{aligned} \tag{9}$$

It can be further expressed as follows:

$$\begin{aligned} u(1,k+1) &= \left(I - K_d CB\right)u(2,k) + K_d\left[y^*(3) - y^*(2)\right] \\ &\quad + K_d C\,(I - A)\,x(2,k) \end{aligned} \tag{10}$$

The sequence in (10) can be generalized as follows:

$$u(i,k+1) = \begin{pmatrix} \left(I - K_d CB\right)u(i,k) + K_d \begin{bmatrix} y^*(i+1) \\ -y^*(i) \end{bmatrix} \\ + K_d C\,(I - A)\,x(i,k) \end{pmatrix} \tag{11}$$

Solution for (11) is expressed as a recurrence relation:

$$\begin{aligned} u(i,k) &= \left(I - K_d CB\right)^{k\text{-}1} u(i,1) + \\ &\sum_{j=1}^{k\text{-}1}\left(I - K_d CB\right)^{k\text{-}j\text{-}1} \begin{bmatrix} K_d\left\{y^*(i+1) - y^*(i)\right\} \\ +K_d C\,(I - A)\,x(i,k) \end{bmatrix} \end{aligned} \tag{12}$$

For zero control input at first batch, (i.e. $u(i,1) = 0$), (12) can be reduced as follows:

$$u(i,k) = \sum_{j=1}^{k\text{-}1}\left(I - K_d CB\right)^{k\text{-}j\text{-}1} \begin{bmatrix} K_d\left\{y^*(i+1) - y^*(i)\right\} \\ +K_d C(I - A)x(i,k) \end{bmatrix} \tag{13}$$

As batch number $k$ increases, the control input components achieve convergence one after the other with increasing time index $i$ inside a batch. From re-writing the sequences in (11) to show the dependency of $u(i,k+1)$ on $u(i,k)$ from previous batch including all the other previous control input components $u(i-1,k)$, $u(i-2,k),\ldots,u(1,k)$ occurring in the same batch as follows:

$$\begin{aligned} u(i,k+1) &= \left(I - K_d CB\right)u(i,k) + K_d C \begin{pmatrix} (I - A) \\ Ax(i-1,k) \end{pmatrix} \\ &\quad + K_d C \begin{pmatrix} (I - A) \\ Bu(i-1,k) \end{pmatrix} + K_d\left[y^*(i+1) - y^*(i)\right] \end{aligned} \tag{14}$$

On further simplification, we have:

$$
\begin{aligned}
u(i,k+1) = \left(I - K_d CB\right) u(i,k) + \ K_d C\,(I - A)\,Bu(i-1,k) \\
+ \cdots + K_d C\,(I - A)\,A^{i\text{-}2} Bu(1,k) \\
+ K_d C\,(I - A)\,A^{i\text{-}1} x(1,k) + K_d\left[y^*(i+1) - y^*(i)\right]
\end{aligned}
\tag{15}
$$

It can be observed that convergence $u(1,k) \rightarrow u^*(1)$ occurs first. After that the output convergence $y(2,k) \rightarrow y^*(2)$ is achieved. Then after one or few batches, $u(2,k) \rightarrow u^*(2)$ convergence is achieved followed by $y(3,k) \rightarrow y^*(3)$. Convergence of other inputs $u(i,k)\text{'s}$ and corresponding outputs $y(i+1,k)\text{'s}$ occurs in further batches. The batch to batch sequential convergence of samples is shown in Figure 1.

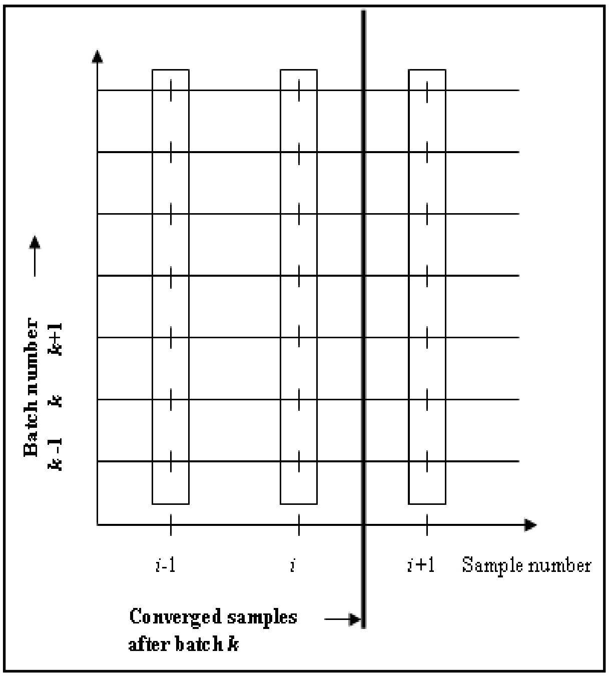

**Figure 1 Sequential Convergence in ILC**

*2) Convergence Condition for Control Input Sequence*

To obtain a stable and bounded sequence of control input $u(i,k)$ in (13), the Eigenvalues of $\left(I\text{ - }K_d CB\right)$ must lie inside the unit circle. Hence, the maximum absolute eigenvalue should be less than unity as follows:

$$
\max\left|\lambda\left(I\text{ - }K_d CB\right)\right| < 1 \tag{16}
$$

For monotonic convergence, the condition in (16) is expressed as norm [21]:

$$
\left\|I\text{ - }K_d CB\right\| < 1 \tag{17}
$$

The (17) gives the necessary and sufficient condition for convergence of D-ILC algorithm. It is pointed that since this condition does not depend on the system matrix $A$, it marks the ability of ILC algorithm to achieve convergence even when the model parameters are unknown.

*3) Rate of Convergence of Control Input Errors*

Using D-ILC algorithm, the component-wise control input errors between desired control input $u^*(i)$ and $u(i,k+1)$ are calculated as follows:

$$
\begin{aligned}
u^*(i) - u(i,k+1) &= u^*(i) - \begin{bmatrix} u(i,k) \\ +K_d\{e(i+1,k) \\ -e(i,k)\} \end{bmatrix} \\
&= u^*(i) - u(i,k) \\
&\quad - K_d C\left[\begin{Bmatrix} \left(Ax^*(i) + Bu^*(i)\right) \\ -\left(Ax(i,k) + Bu(i,k)\right) \end{Bmatrix}\right] \\
&\quad + K_d\left\{y^*(i) - y(i,k)\right\}
\end{aligned}
\tag{18}
$$

Let's denote $u^*(i) - u(i,k) = \Delta u(i,k)$ and use in (18) and after simplification we get:

$$
\begin{aligned}
\Delta u(i,k+1) &= \left(I - K_d CB\right)\left\{\Delta u(i,k)\right\} \\
&\quad + K_d C\,(I - A)\left\{x^*(i) - x(i,k)\right\}
\end{aligned}
\tag{19}
$$

Since initial conditions are preserved & initial error is zero, i.e. $x^*(1) = x(1,k)$, hence at 1st time index the error is:

$$
\Delta u(1,k+1) = \left(I - K_d CB\right)\left\{\Delta u(1,k)\right\} \tag{20}
$$

At $i^{th}$ time index, the error becomes:

$$
\begin{aligned}
\Delta u(i,k+1) &= \left(I\text{ - }K_d CB\right)\Delta u(i,k) \\
&\quad + K_d C\,(I\text{ - }A)\,B\Delta u(i\text{ - }1,k) \\
&\quad + \cdots + K_d CA^{i\text{-}1}\,(I\text{ - }A)\,B\Delta u(2,k) \\
&\quad + K_d CA^{i\text{-}2}\,(I\text{ - }A)\,B\Delta u(1,k)
\end{aligned}
\tag{21}
$$

By writing (20) and (21) in matrix form, the evolution of vectors of control input errors from batch to batch is given as follows:

$$
\Delta u(k+1) = T\ \Delta u(k) \tag{22}
$$

where, the operator matrix $T$ controls the evolution of control input errors from batch to batch as follows:

$$\begin{bmatrix} (I - K_d CB) & 0 & 0 & \cdots & 0 \\ K_d C(I - A)B & (I - K_d CB) & 0 & \cdots & 0 \\ K_d CA(I - A)B & K_d C(I - A)B & \ddots & 0 & \vdots \\ \vdots & \vdots & \ddots & \ddots & 0 \\ K_d CA^{M-2}(I - A)B & \cdots & \cdots & \cdots & (I - K_d CB) \end{bmatrix} \quad (23)$$

The solution of (22) is given as follows:

$$\Delta u(k) = T^{k-1} \Delta u(1) \quad (24)$$

*Lemma:*

The D-ILC algorithm produces a sequence of bounded control inputs which over the long term converge component-wise to the desired control input sequence at the rate equal to the magnitude of the Eigenvalue of the matrix relating the evolution of control input error provided initial conditions are same and desired output matches with the measured output at the beginning of each batch.

*Proof of Lemma:*

Consider the solution for evolution of control input errors in (24). Due to repeated eigenvalues, matrix $T$ cannot be diagonalised using eigen-decomposition or SVD because there are repeated eigen vectors which make the matrix of Eigen vectors singular. Therefore, the following assumptions have been considered:

1. The rate of convergence of each component $\Delta u(i,k)$ can be found if $(M \times M)$ matrix $T$ is decomposed into Jordan Normal form. For a non-singular matrix $Q$ such that $Q^{-1} \times Q = I$, Jordan Decomposition is $T = Q^{-1} D Q$.

2. The matrix $D$ has the eigenvalues of matrix $T$ as its diagonal elements along with a sub-diagonal containing all 1's.

3. To calculate the convergence rates of individual components of control input error vector $\Delta u(k)$ in (24) we have to decompose as follows [22]:

$$T^{k-1} = Q^{-1} D^{k-1} Q \quad (25)$$

4. The control input error in (22) can be written as follows:

$$\Delta u(k) = T^{k-1} \Delta u(1) = Q^{-1} D^{k-1} Q \Delta u(1) \quad (26)$$

5. The rate of convergence $\Gamma_{\Delta u(i,k)}$ is the ratio of $\infty$-norm at batch $k$ with respect to the $\infty$-norm at batch $k-1$:

$$\Gamma_{\Delta u(i,k)} = \frac{\left\|\Delta u(i,k)\right\|_\infty}{\left\|\Delta u(i,k-1)\right\|_\infty}$$

$$= \frac{\left[\begin{array}{l} \left|\lambda^{k-1}\right| + \left|(k-1)\lambda^{k-2}\right| \\ + \left|\dfrac{(k-1)(k-2)}{2!}\lambda^{k-3}\right| \\ + \cdots + \left|\dfrac{(k-1)\ldots(k-i+1)}{(i-1)!}\lambda^{k-i}\right| \end{array}\right]}{\left[\begin{array}{l} \left|\lambda^{k-2}\right| + \left|(k-2)\lambda^{k-3}\right| \\ + \left|\dfrac{(k-2)(k-3)}{2!}\lambda^{k-4}\right| \\ + \cdots + \left|\dfrac{(k-2)\ldots(k-1-i+1)}{(i-1)!}\lambda^{k-1-i}\right| \end{array}\right]} \quad (27)$$

Consequently, after simplification, (27) can be written as follows:

$$\Gamma_{\Delta u(i,k)} = |\lambda| \sum_{j=0}^{i-1} \left\{ \left| \binom{k-1}{j} \right| \left| \left(\frac{1}{\lambda}\right)^j \right| \right\} \bigg/ \left\{ \left| \binom{k-2}{j} \right| \left| \left(\frac{1}{\lambda}\right)^j \right| \right\} \quad (28)$$

where

$$\binom{k-1}{j} = \frac{(k-1)!}{(k-1-j))!\,j!} \quad (29)$$

In the limit $k \to \infty$, the ratio to the right of summation in (28) is unity, so that every component $\Delta u(i,k)$ has long term convergence rate $\approx |\lambda| = \left|(I - K_d CB)\right|$. □

## III. Case Study

A damped pendulum in Figure 2 is an interesting control problem which has been widely studied. Here we apply the D-type ILC algorithm for learning to track the desired angle & corresponding angular velocity by generating the desired control signal at each sample time. The set of desired control signal for a complete swing has been obtained from a fine-tuned PD controller. The angle $\theta$ is measured anti-clock-wise. The control input torque $u$ is applied in anti-clock-wise direction as well. The pendulum is at rest with initial position $\theta_0 = \pi / 4$ radians at the left side. The initial angular velocity, $\omega_0 = 0$ rad/s. The pendulum has been simulated using following parameters:

Length $L$ = 1m, mass $m$ = 0.5 Kg, acceleration due to gravity $g$ = 9.81 m/s2 and damping co-efficient $b$ = 0.25

N-s/m. Using state vector $x = [\theta, \quad \omega]^T$, the linearised discrete-time state space matrices for the pendulum, sampled at 0.05 seconds are as follows:

$$A_d = \begin{bmatrix} 0.9879 & 0.0492 \\ -0.4824 & 0.9633 \end{bmatrix}, \quad B_d = \begin{bmatrix} 0.0012 \\ 0.0492 \end{bmatrix}, \\ C_d = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \quad D_d = \begin{bmatrix} 0 \\ 0 \end{bmatrix} \tag{30}$$

The time period for the pendulum is 2 seconds, so there are 40 samples for each swing from left to right and back.

For ILC update, the error considered is the state error. The selected learning gain matrix $K_d = 0.5 \times [0,1]$ allows the forward difference error of the angular velocity only to update the control inputs. The tracking of the desired control input $u$, angle $\theta$ and angular velocity $\omega$ has been monitored for 2500 swings in Figure 3 and Figure 4.

The RMS values reached minima around 2000 swings:

Final RMS of error in angle = 1.2015e-015,

Final RMS of error in angular velocity = 2.2210e-015,

Final RMS of control input error = 1.6876e-014

These values show that limit of precision has been reached. The evolution of the control input errors at selected time indices is shown in Figure 5. The semi-log plot in Figure 6 give the convergence rate of control input errors at selected time indices. The rate of convergence varies in the earlier swings. The convergence occurs sequentially as the control input for earlier time indices converge before the later ones. The kinks in convergence rates for initial swings occur due to oscillations or zero-crossings of the control input errors. Finally, the D-ILC algorithm achieves its limit at large batch numbers. As shown in Figure 6, that just before the control input errors are near the minimum threshold, all the individual components $\Delta u(i,k)$ achieve the same rate (0.9754) equal to the eigenvalue of matrix $T$.

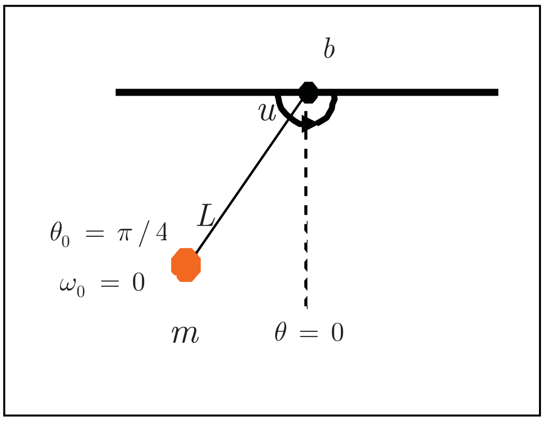

**Figure 2 Damped Pendulum**

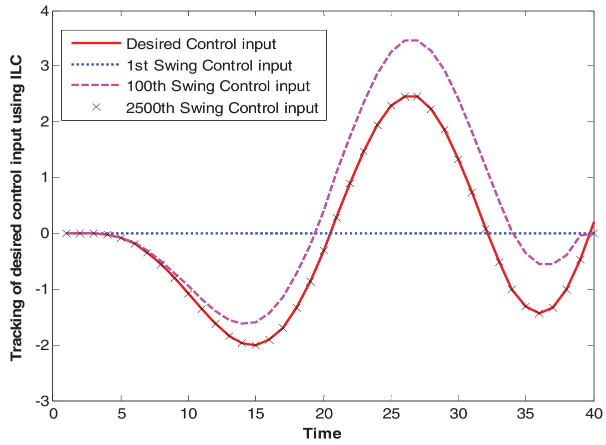

**Figure 3 Tracking control input**

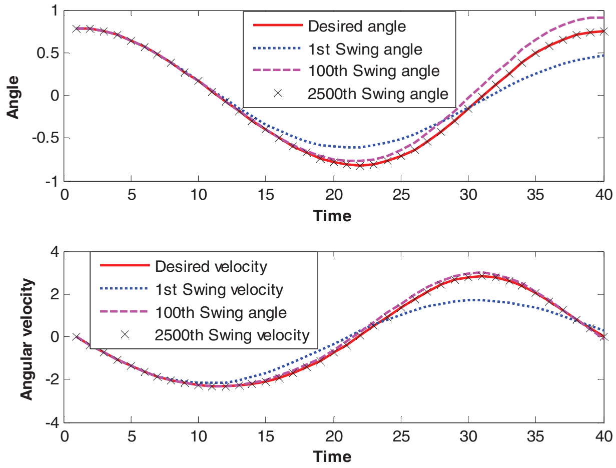

**Figure 4 Tracking angle and velocity**

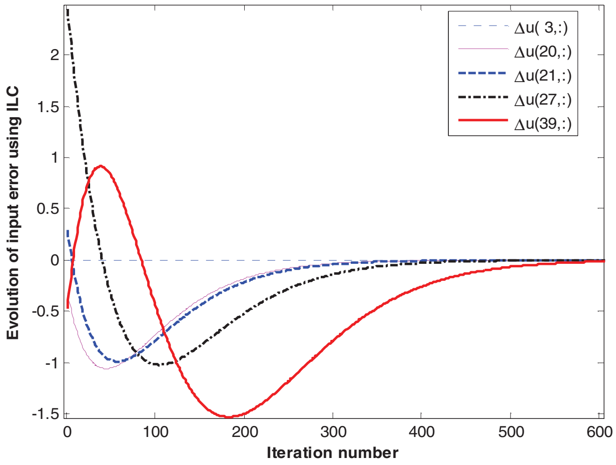

**Figure 5 Evolution of control input errors**

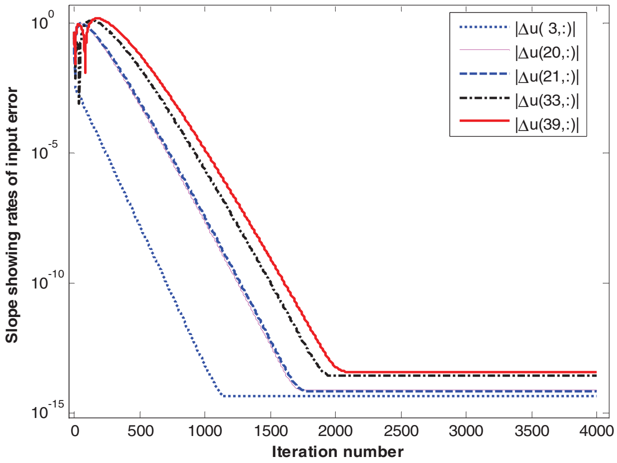

**Figure 6 Convergence rate of control input errors**

## IV. Conclusion

The rate of convergence of D-ILC algorithm has been investigated in terms of input errors at component level which evolve sequentially. In the long term, all input components acquire same convergence rate equal to the eigenvalue of the Toeplitz matrix which relates the input errors from batch to batch. This knowledge can be helpful in designing the Iterative Learning controllers and their performance comparison.

*Abstract*—**Stability analysis and control for linear periodic time-delay systems described by state space models are investigated in this paper. Semi-discretization method is used to develop a mapping of the system response in a finite-dimensional state space. The stability region and stability boundary can be found by comparing the maximum absolute value of the mapping's eigenvalues with 1. More importantly, an efficient stability criterion is presented for linear periodic neutral systems. Besides, minimization of the maximum absolute value of the mapping's eigenvalues leads to optimal control gains. Two numerical examples are given to illustrate the proposed method's effectiveness.**

***Keywords-periodic time-delay systems; periodic neutral systems; stability analysis; feedback control; semi-discretization.***

## I. Introduction

Generally speaking, linear periodic time-delay systems can be divided into three categories according to the system complexity: (i) systems with a single time-delay, (ii) systems with multiple time-delays and (iii) neutral systems. Linear periodic systems with a single or multiple time-delays are actually special cases of linear periodic neutral systems.

In recent years, the stability analysis of linear time-delay systems, especially neutral systems, has attracted considerable attention. Among different derivation methods for stability criteria, one main method is based on Lyapunov-Krasovskii functional (LKF) and linear matrix inequality (LMI) [1-5]. In [1] delay-dependent stability conditions were obtained for neutral systems with time-varying delays in terms of LMIs and descriptor model transformation. Reference [2] derived a stability criterion which was formulated in an LMI for uncertain neutral systems with norm-bounded or time-varying uncertainty. A discretized LKF approach was developed to analyze the stability of linear neutral systems with mixed neutral and discrete delays in [3]. Combining the parameterized model transformation method with a method taking the relationships between the terms in the Leibniz-Newton formula into account and using LMI, [4] put forward delay-dependent robust stability criteria and a stabilizing method for neutral systems. Reference [5] studied the stability of neutral type systems with uncertain time-varying delays and norm-bounded uncertainties by utilizing the input-output approach and LKF. Besides, some other methods have also been introduced, e.g. [6] presented necessary and sufficient conditions for delay-dependent stability by principle of the argument.

Meanwhile, control for linear time-delay systems has also been investigated intensively using LMI, LKF and sliding-mode control (SMC) [7-12]. Reference [7] proposed a sufficient condition for the solvability of the design of memoryless state feedback controllers in terms of LMI and gave an explicit expression for the desired controller. In [8], a criterion for the existence of dynamic output feedback controllers was derived based on the LMI and LKF, and a parameterized characterization of the controllers was also given. In [9], LMI optimization approach is used to design the robust output dynamic observer-based controls. Reference [10] raised a robust control design method with LMI and discretized parameter-dependent LKF. In [11], the design of SMC for a class of neutral delay systems with uncertainties in both the state matrices and the input matrix was studied. Reference [12] put forward a robust adaptive SMC design scheme for discrete-time state-delay systems with mismatched uncertainties and external disturbances.

Although there are a large number of references discussing linear systems with time-delay, one type of time-delay system, i.e. linear periodic time-delay systems, has not received much attention. Semi-discretization has been introduced to study this type of time-delay systems. This method proposes to discretize some spatial or temporal variables and treat the rest of them as continuous variables, and thus the exact solution of linear systems can be obtained to construct a very accurate mapping of the state vector over a mapping time step. Therefore semi-discretization is able to handle periodic time-delay systems. Semi-discretization was utilized for the stability analysis of second order linear periodic time-delay system with a single delay represented by ordinary differential equations (ODEs) in [13]. In [14] the stability analysis of higher order systems with both discrete and continuous time-delays was studied based on semi-discretization. Reference [15] reported an application of semi-discretization to the feedback controls and optimal gain design of linear periodic systems with a single time-delay.

This work was supported by the Scientific Research Foundation for the Returned Overseas Chinese Scholars, State Education Ministry (WF2100100001) and the Fundamental Research Funds for the Central Universities (WK2100100003).

Reference [16] extended this idea to the stability analysis of linear neutral systems represented by ODEs.

In this paper, we further extend this method to the investigation regarding stability analysis and control design of all types of linear periodic time-delay systems described by state space models.

The rest of this paper is organized as follows. In Section II, semi-discretization method is deployed to derive stability criteria for different types of linear periodic time-delay systems. Also, optimal feedback control of such systems is discussed. Section III presents two numerical examples to illustrate this method's effectiveness. The conclusions are presented in Section IV.

## II. Main Results

In this section, two topics are covered: Subsection A presents stability criteria for three types of linear periodic time-delay systems. Subsection B introduces one scheme for the optimal feedback control design.

### *A. Stability Criteria*

Linear periodic time-delay systems have a general state space form as shown by (1).

$$\dot{\mathbf{x}}(t) = \mathbf{A}(t)\mathbf{x}(t) + \sum_{j=1}^{m}[\mathbf{B}_j(t)\mathbf{x}(t-\tau_j) + \mathbf{C}_j(t)\dot{\mathbf{x}}(t-\tau_j)], \quad (1)$$

where $\mathbf{x} \in \mathbf{R}^N$, and the coefficient matrices $\mathbf{A}(t)$, $\mathbf{B}_j(t)$ and $\mathbf{C}_j(t)$ are all periodic matrices with period $T$. $m$ is the number of time-delays. Without loss of generality, it is assumed that $\tau_j$'s are already arranged such that $\tau_1 < \tau_2 < \cdots < \tau_m$.

With different constraints on $m$ and $\mathbf{C}(t)$'s , (1) is able to represent different types of linear periodic time-delay systems. The general forms of periodic time-delay systems with a single delay and periodic time-delay systems with multiple delays are given by (2) and (3).

$$\dot{\mathbf{x}}(t) = \mathbf{A}(t)\mathbf{x}(t) + \mathbf{B}(t)\mathbf{x}(t-\tau) \quad (2)$$

$$\dot{\mathbf{x}}(t) = \mathbf{A}(t)\mathbf{x}(t) + \sum_{j=1}^{m}\mathbf{B}_j(t)\mathbf{x}(t-\tau_j) \quad (3)$$

Because (2) and (3) are special cases of (1), stability criteria for linear periodic systems with a single or multiple time-delays are derivable from the criterion for linear periodic neutral systems. Hence Theorem 1 will be first introduced as a stability criterion for linear periodic neutral systems, and then the stability criteria for the other two types of systems are given in Corollaries 1 and 2, respectively.

*Theorem 1*: Suppose for one linear periodic time-delay system, the mapping of the state vector over one period is obtained using semi-discretization, and is shown as

$$\mathbf{y}_{p+1} = \mathbf{\Phi}\mathbf{y}_p, \quad (4)$$

where $p$ indicates the index of one period, and $\mathbf{y}_p$ is the state vector at the beginning of the $p$th period. $\mathbf{\Phi}$ is the product of transition matrices over the period, namely,

$$\mathbf{\Phi} = \left(\prod_{i=0}^{k-1}\mathbf{H}_i^T\right)^T, \quad (5)$$

where $\mathbf{H}_i$ is the transition matrix over a time interval $[t_i, t_{i+1}]$, and satisfies (6). Note that the period $T$ is equally partitioned into $k$ intervals.

$$\mathbf{y}_{i+1} = \mathbf{H}_i\mathbf{y}_i, \quad (6)$$

where $i$ indicates the index of one time interval, and $\mathbf{y}_i$ is the state vector at the beginning of the $i$th interval.

The transition matrices $\mathbf{H}_i$'s are given in (7).

$$\mathbf{H}_i = \begin{bmatrix} \mathbf{H}_{i,11} & \mathbf{H}_{i,12} \\ \mathbf{H}_{i,21} & \mathbf{H}_{i,22} \\ \mathbf{H}_{i,31} & \mathbf{H}_{i,32} \\ \mathbf{H}_{i,41} & \mathbf{H}_{i,42} \end{bmatrix}_{2(n_m+1)N\times 2(n_m+1)N} \quad (7)$$

where

$$\mathbf{H}_{i,11} = \begin{bmatrix}\mathbf{Q}_i & \mathbf{0}_{N\times(n_1-1)N} & \mathbf{P}_i\mathbf{B}_{1,i} & \cdots & \mathbf{0}_{N\times(n_m-n_{m-1}-1)N} & \mathbf{P}_i\mathbf{B}_{m,i}\end{bmatrix}_{N\times(n_m+1)N},$$
$$\mathbf{H}_{i,12} = \begin{bmatrix}\mathbf{0}_{N\times n_1 N} & \mathbf{P}_i\mathbf{C}_{1,i} & \cdots & \mathbf{0}_{N\times(n_m-n_{m-1}-1)N} & \mathbf{P}_i\mathbf{C}_{m,i}\end{bmatrix}_{N\times(n_m+1)N},$$
$$\mathbf{H}_{i,21} = \begin{bmatrix}\mathbf{I}_{n_m N\times n_m N} & \mathbf{0}_{n_m N\times N}\end{bmatrix}_{n_m N\times(n_m+1)N},$$
$$\mathbf{H}_{i,22} = \mathbf{0}_{n_m N\times(n_m+1)N},$$
$$\mathbf{H}_{i,31} = \begin{bmatrix}\mathbf{A}_i\mathbf{Q}_i & \mathbf{0}_{N\times(n_1-2)N} & \mathbf{B}_{1,i} & \mathbf{A}_i\mathbf{P}_i\mathbf{B}_{1,i} & \cdots & \mathbf{B}_{m,i} & \mathbf{A}_i\mathbf{P}_i\mathbf{B}_{m,i}\end{bmatrix}_{N\times(n_m+1)N},$$
$$\mathbf{H}_{i,32} = \begin{bmatrix}\mathbf{0}_{N\times(n_1-1)N} & \mathbf{C}_{1,i} & \mathbf{A}_i\mathbf{P}_i\mathbf{C}_{1,i} & \cdots & \mathbf{C}_{m,i} & \mathbf{A}_i\mathbf{P}_i\mathbf{C}_{m,i}\end{bmatrix}_{N\times(n_m+1)N},$$
$$\mathbf{H}_{i,41} = \mathbf{0}_{n_m N\times(n_m+1)N},$$
$$\mathbf{H}_{i,42} = \begin{bmatrix}\mathbf{0}_{n_m N\times N} & \mathbf{I}_{n_m N\times n_m N}\end{bmatrix}_{n_m N\times(n_m+1)N}.$$

In (7):

$$\begin{aligned}&\mathbf{A}_i = \mathbf{A}(t_i), \mathbf{B}_{j,i} = \mathbf{B}_j(t_i), \mathbf{C}_{j,i} = \mathbf{C}_j(t_i),\\ &\mathbf{Q}_i = e^{\mathbf{A}_i\Delta t}, \mathbf{P}_i = \int_{t_i}^{t_{i+1}} e^{\mathbf{A}_i(\Delta t-\hat{t})}d\hat{t},\\ &n_j = \tau_j/\Delta t, j = 1,2,...,m.\end{aligned} \quad (8)$$

Let $|\lambda|_{\max}$ denote the maximal absolute value of eigenvalues of $\mathbf{\Phi}$. Then the stability region is determined by

$$|\lambda|_{\max} < 1, \quad (9)$$

and the stability boundary is determined by

$$|\lambda|_{\max} = 1. \quad (10)$$

*Proof*: First let us discretize the period $T$ into an integer $k$ intervals of equal length $\Delta t$ such that $T = k\Delta t$.

Consider (1) in a time interval $t \in [t_i, t_{i+1}]$, where $t_i = i\Delta t, i = 0,1,2,...,k$. In each small time interval $[t_i, t_{i+1}]$, the delayed responses $\mathbf{x}(t-\tau_j)$ and time-dependent coefficient matrices are assumed to be constant. Thus we have the notations in (8). Besides we denote

$$\begin{aligned} &\mathbf{x}(t_i) = \mathbf{x}_i, \\ &\mathbf{x}(t_{i+1}) = \mathbf{x}_{i+1}, \\ &\mathbf{x}(t-\tau_j) = \mathbf{x}(i\Delta t - n_j \Delta t) = \mathbf{x}_{i-n_j}. \end{aligned} \tag{11}$$

Within one particular interval, (1) becomes:

$$\dot{\mathbf{x}}(t) - \mathbf{A}_i \mathbf{x}(t) - \sum_{j=1}^{m} [\mathbf{B}_{j,i} \mathbf{x}(t-\tau_j) + \mathbf{C}_{j,i} \dot{\mathbf{x}}(t-\tau_j)] = 0. \tag{12}$$

The general solution of (12) is given by

$$\mathbf{x}(t) = e^{\mathbf{A}_i (t-t_i)} \mathbf{x}_i + \int_{t_i}^{t} e^{\mathbf{A}_i (t-t_i-\hat{t})} \sum_{j=1}^{m} [\mathbf{B}_{j,i} \mathbf{x}(\hat{t}-\tau_j) + \mathbf{C}_{j,i} \dot{\mathbf{x}}(\hat{t}-\tau_j)] d\hat{t}, \tag{13}$$

where $t \in [t_i, t_{i+1}]$.

Let $t$ be $t_{i+1}$ in (13), then

$$\mathbf{x}_{i+1} = \mathbf{Q}_i \mathbf{x}_i + \mathbf{P}_i \sum_{j=1}^{m} (\mathbf{B}_{j,i} \mathbf{x}_{i-n_j} + \mathbf{C}_{j,i} \dot{\mathbf{x}}_{i-n_j}), \tag{14}$$

where the definition of $\mathbf{Q}_i$ and $\mathbf{P}_i$ is given in (8).

In order to construct a mapping over one time interval, one $2(n_m + 1) \times N$ dimensional state vector is defined as:

$$\mathbf{y}_i = \begin{bmatrix} \mathbf{x}_i^T & \mathbf{x}_{i-1}^T & \cdots & \mathbf{x}_{i-n_m}^T & \dot{\mathbf{x}}_i^T & \dot{\mathbf{x}}_{i-1}^T & \cdots & \dot{\mathbf{x}}_{i-n_m}^T \end{bmatrix}^T. \tag{15}$$

To find the transition matrix $\mathbf{H}_i$ is equivalent to find a mapping from $\mathbf{y}_i$ to $\mathbf{y}_{i+1}$. $\mathbf{y}_{i+1}$ has the form in (16).

$$\mathbf{y}_{i+1} = \begin{bmatrix} \mathbf{x}_{i+1}^T & \mathbf{x}_i^T & \cdots & \mathbf{x}_{i-n_m+1}^T & \dot{\mathbf{x}}_{i+1}^T & \dot{\mathbf{x}}_i^T & \cdots & \dot{\mathbf{x}}_{i-n_m+1}^T \end{bmatrix}^T. \tag{16}$$

All entries except $\mathbf{x}_{i+1}^T$ and $\dot{\mathbf{x}}_{i+1}^T$ in $\mathbf{y}_{i+1}$ also appear in $\mathbf{y}_i$, which indicates that corresponding entries in $\mathbf{H}_i$ are identity matrices with appropriate dimensions.

Moreover, (14) actually provides a representation of $\mathbf{x}_{i+1}$ using the entries in $\mathbf{y}_i$. Hence the last problem lies in the representation of $\dot{\mathbf{x}}_{i+1}$.

Let $t$ be $t_{i+1}$ in (12), and it becomes:

$$\dot{\mathbf{x}}_{i+1} = \mathbf{A}_i \mathbf{x}_{i+1} + \sum_{j=1}^{m} (\mathbf{B}_{j,i} \mathbf{x}_{i-n_j+1} + \mathbf{C}_{j,i} \dot{\mathbf{x}}_{i-n_j+1}). \tag{17}$$

Plug (14) into (17) and we get (18).

$$\begin{aligned} \dot{\mathbf{x}}_{i+1} = {} & \mathbf{A}_i \mathbf{Q}_i \mathbf{x}_i + \\ & \sum_{j=1}^{m} [\mathbf{A}_i \mathbf{P}_i \mathbf{B}_{j,i} \mathbf{x}_{i-n_j} + \mathbf{B}_{j,i} \mathbf{x}_{i-n_j+1} + \mathbf{A}_i \mathbf{P}_i \mathbf{C}_{j,i} \dot{\mathbf{x}}_{i-n_j} + \mathbf{C}_{j,i} \dot{\mathbf{x}}_{i-n_j+1}]. \end{aligned} \tag{18}$$

Combining the results above together, and the transition matrix over $[t_i, t_{i+1}]$ can then be expressed as (17).

The mapping of the state vector over one period $T = k\Delta t$ is therefore shown by (4), and $\mathbf{\Phi}$ is given by (5).

The stability of the system is determined by the eigenvalues of $\mathbf{\Phi}$, i.e.

$$|\mathbf{y}_{p+1}| \le |\lambda|_{\max} |\mathbf{y}_p|. \tag{19}$$

When $|\lambda|_{\max} < 1$, $\mathbf{\Phi}$ is a contraction, and the system is asymptotically stable. Then the stability region and stability boundary can be found using (9) and (10), respectively.

Moreover, (19) also indicates that the smaller $|\lambda|_{\max}$ is, the faster the system response converges to zero. Hence $|\lambda|_{\max}$ also provides an indicator of the control performance.

□

Furthermore, as particular cases of the previous result, the stability criteria for periodic time-delay systems with a single delay and multiple delays are presented in the sequel.

*Corollary 1*: For a linear periodic time-delay system with one single time-delay, the stability region and stability boundary are determined by (9) and (10), respectively. The mapping over one period and the corresponding mapping matrix $\mathbf{\Phi}$ are the same as in Theorem 1, and transition matrices $\mathbf{H}_i$'s can be instead calculated using (20).

$$\mathbf{H}_i = \begin{bmatrix} \mathbf{H}_{i,1} \\ \mathbf{H}_{i,2} \end{bmatrix}_{(n+1)N \times (n+1)N}, \tag{20}$$

where

$$\begin{aligned} &\mathbf{H}_{i,1} = \begin{bmatrix} \mathbf{Q}_i & \mathbf{0}_{N \times (n-1)N} & \mathbf{P}_i \mathbf{B}_i \end{bmatrix}, \\ &\mathbf{H}_{i,1} = \begin{bmatrix} \mathbf{I}_{nN \times nN} & 0_{nN \times N} \end{bmatrix}, \\ &n = \tau / \Delta t, \end{aligned}$$

and $\mathbf{Q}_i$, $\mathbf{P}_i$ and $\mathbf{B}_i$ are the same as in (8).

*Corollary 2*: For a linear periodic time-delay system with multiple time-delays, the stability region and stability boundary are determined by (9) and (10), respectively. The mapping over one period and the corresponding mapping matrix $\mathbf{\Phi}$ are the same as in Theorem 1, and transition matrices can be found with (21).

$$\mathbf{H}_i = \begin{bmatrix} \mathbf{H}_{i,1} \\ \mathbf{H}_{i,2} \end{bmatrix}, \tag{21}$$

where

$$\mathbf{H}_{i,1} = \begin{bmatrix} \mathbf{Q}_i & \mathbf{0}_{N\times(n_1 N - N)} & \mathbf{P}_i \mathbf{B}_{1,i} & \cdots & \mathbf{0}_{N\times(n_m N - n_{m-1} N)} & \mathbf{P}_i \mathbf{B}_{m,i} \end{bmatrix},$$
$$\mathbf{H}_{i,2} = \mathbf{I}_{(n_m+1)N\times(n_m+1)N},$$
$$n_j = \tau_j / \Delta t,\ j = 1, 2, ..., m,$$

and $\mathbf{Q}_i$, $\mathbf{P}_i$ and $\mathbf{B}_{j,i}$ are the same as in (8).

### *B. Optimal Feedback Control*

In this section, we consider the optimal feedback control design for linear periodic time-delay systems.

Equation (22) is a general linear periodic time-delay system with feedback control, which can be either delayed or not.

$$\dot{\mathbf{x}}(t) = \mathbf{A}(t)\mathbf{x}(t) + \sum_{j=1}^{m} [\mathbf{B}_j(t)\mathbf{x}(t-\tau_j) + \mathbf{C}_j(t)\dot{\mathbf{x}}(t-\tau_j)] + \mathbf{D}(t)\mathbf{u}(t), \tag{22}$$

where $\mathbf{x} \in \mathbf{R}^N$, $\mathbf{u} \in \mathbf{R}^M$. $\mathbf{A}(t)$, $\mathbf{B}_j(t)$, $\mathbf{C}_j(t) \in \mathbf{R}^{N\times N}$, and $\mathbf{D}(t) \in \mathbf{R}^{N\times M}$ are periodic matrices with period $T$.

According to whether delays exist in $\mathbf{u}(t)$ or not, $\mathbf{u}(t)$ have two different forms which are represented by (23).

$$\mathbf{u}(t) = -\mathbf{K}\mathbf{x}(t) \text{ or } \mathbf{u}(t) = -\mathbf{K}\mathbf{x}(t-\tau_u). \tag{23}$$

where $\mathbf{K} \in \mathbf{R}^{M\times N}$ is the gain matrix.

Obviously, (22) is able to be transformed into the form of (1). Therefore, the stability region and stability boundary can be obtained by using stability criteria presented in Subsection A. Furthermore, optimal control gains can also be found, and the search scheme is discussed as follows.

If the problem is restricted in a finite and compact region $\mathbf{\Omega}$ in the parametric space $\mathbf{K}$, we can find the regions of stability and optimal control gains in the region to minimize $|\lambda|_{\max}$. This leads to one optimization problem:

$$\min_{\mathbf{K}\in\mathbf{\Omega}}[\max|\lambda(\mathbf{\Phi})|] \text{ subject to } |\lambda|_{\max} < 1. \tag{24}$$

This optimization formulation offers an approach to design feedback controls for linear periodic time-delay systems, and the control performance criterion is chosen as the decay rate of the mapping $\mathbf{\Phi}$ over one period. For some further discussion, please refer to Sheng and Sun [15].

## III. Examples

In this section, two examples are presented to illustrate semi-discretization's validity. All computations are carried out by Matlab R2010b.

Example 1: Equation (25) describes a linear time-invariant neutral system.

$$\dot{\mathbf{x}}(t) = \mathbf{A}\mathbf{x}(t) + \mathbf{B}\mathbf{x}(t-\tau) + \mathbf{C}\dot{\mathbf{x}}(t-\tau), \tag{25}$$

where

$$\mathbf{A} = \begin{bmatrix} -2 & 0 \\ 0 & -0.9 \end{bmatrix},\ \mathbf{B} = \begin{bmatrix} -1 & 0 \\ -1 & -1 \end{bmatrix},\ \mathbf{C} = \begin{bmatrix} c & 0 \\ 0 & c \end{bmatrix},\ 0 \le c \le 1.$$

When $c = 0$, this system is simplified to be a linear time-delay system with a single time-delay, so Corollary 1 is applied to get the upper stability bound of $\tau$; when $c \neq 0$, this system is a linear neutral system, and Theorem 1 is used.

The upper stability bound is calculated with different criteria, which are given in [1, 2, 4 and 6]. The comparison with the criteria presented in this paper is listed in Table I.

Table I suggests that the upper bounds obtained by the methods in this paper are much less conservative and much more accurate than those of [1, 2 and 4], and meanwhile they are comparable with those of [6].

TABLE I. Comparison of Time-Delay's Upper Bound for Example 1

| Criteria \ c | 0 | 0.5 | 0.9 |
|---|---|---|---|
| [1] | 4.47 | 1.14 | 0.13 |
| [2] | 4.35 | 3.62 | 0.99 |
| [4] | 4.47 | 3.67 | 1.41 |
| [6] | 6.15-6.2 | 4.735-4.74 | 1.57-1.575 |
| Semi-Discretization | 6.17 | 4.67 | 1.52 |

Example 2: A linear periodic neutral system is given by (26).

$$\dot{\mathbf{x}}(t) = \mathbf{A}(t)\mathbf{x}(t) + \sum_{j=1}^{2} [\mathbf{B}_j\mathbf{x}(t-\tau_j) + \mathbf{C}_j\dot{\mathbf{x}}(t-\tau_j)], \tag{26}$$

where

$$\mathbf{A}(t) = \begin{bmatrix} -0.9 & -1 \\ 1+0.3\sin 2t & 0.9+0.4\cos 4t \end{bmatrix},$$
$$\mathbf{B}_1 = \begin{bmatrix} 0 & 0 \\ -k_1 & -k_2 \end{bmatrix},\ \mathbf{B}_2 = \begin{bmatrix} 1 & 0.4 \\ 0 & 1 \end{bmatrix},$$
$$\mathbf{C}_1 = \begin{bmatrix} 0 & -0.4 \\ -0.5 & 0 \end{bmatrix},\ \mathbf{C}_2 = \begin{bmatrix} -0.5 & 0 \\ 0 & -0.5 \end{bmatrix},$$
$$\tau_1 = \frac{\pi}{10},\ \tau_2 = \frac{\pi}{5}.$$

In this example, the coefficient matrix $\mathbf{A}(t)$ is periodic with period $\pi$, and the feedback controller is delayed with delay $\pi/10$.

Theorem 1 is utilized for searching the stability region on the $k_1 - k_2$ plane. Besides, the optimal pair of control gains is also found by solving the optimization problem stated by (24).

The stability region and the optimal control gain pair are shown by Fig. 1, where the labels of contours are the maximum absolute values of eigenvalues of the mapping matrices, i.e. $|\lambda|_{\max}$. The stability region is within the bold black line, and the optimal gain pair is $(k_1,\ k_2) = (0.3556,\ 2.8256)$, with $|\lambda|_{\max}$ = 0.3234, which is indicated by red "+". Besides, the blue circle and black triangle indicate $(0.8,\ 3)$ and $(1,\ 2)$, respectively.

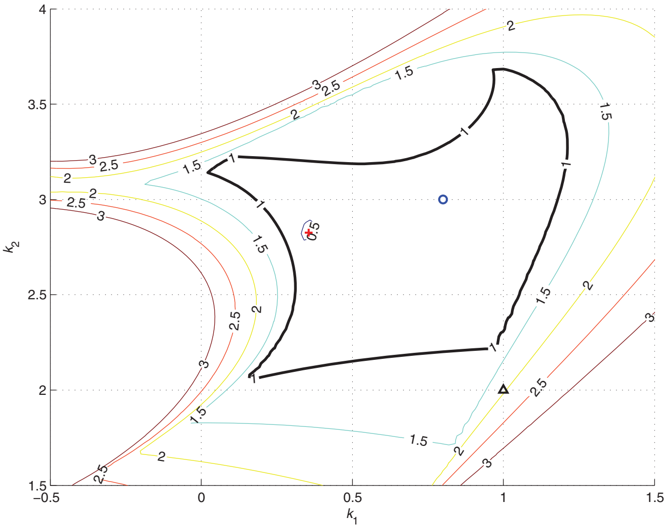

Figure 1. Stability region and the optimal pair of control gains.

Fig. 2 shows simulation results when different pairs of control gains are applied for (26), where the horizontal axis is simulation time, and the vertical axis is the norm of state, which is defined as $\|\mathbf{x}\| = \sqrt{x_1^2 + x_2^2}$. The initial conditions are set to be $\mathbf{x}_0 = [0 \quad 0.1]^T$. Note that $(0.3556,\ 2.8256)$ is the optimal controller, and therefore the corresponding system response converges to zero fastest. $(0.8,\ 3)$ is within the stability region, but the corresponding $|\lambda|_{\max}$ is 0.8403, which is larger than that when the optimal controller is applied, so the system response converges to zero asymptotically yet slowly. $(1,\ 2)$ is one pair causing the system to be unstable, with $|\lambda|_{\max} = 1.9439 > 1$, and hence the system response increases very quickly.

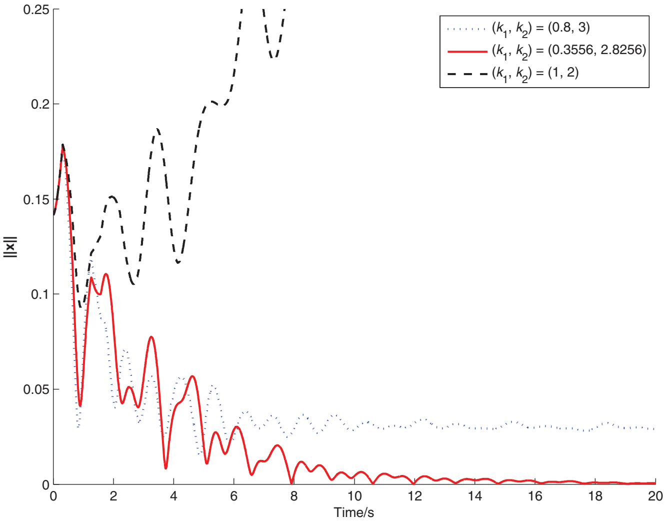

Figure 2. System responses with different control gains.

## IV. Conclusion

In this paper, stability analysis and control design of linear periodic time-delay systems have been investigated. Based on the semi-discretization method, stability criteria have been derived for different types of linear periodic time-delay systems, and optimal feedback control design scheme has also been presented. Two illustrative examples have been given to demonstrate the merits of the obtained results.

**Keywords:** Super-resolution, multi-wavelets, cycle-spinning.

## Abstract

In this paper a multi-wavelet and cycle-spinning based image resolution enhancement technique is presented. The proposed technique generates a high-resolution image for the input low-resolution image using the input image and an inverse multi-wavelet transform (all multi-wavelet high frequency subbands' coefficients are set to zero). The concept of the cycle spinning algorithm in conjunction with the multi-wavelet transform is then used to generate a high quality super-resolution image for the input image from the resulting high resolution image, as follows: A number of replicated images with different spatial shifts from the resulting high-resolution image is first generated; Each of the replicated images is de-correlated into its subbands using a multi-wavelet transform; The multi-wavelet high frequency subbands' coefficients of each of the de-correlated images are set to zero and then a primary super-resolution image for each of these images is produced using an inverse multi-wavelet transform; The resulting primary super-resolution images are then spatially shift compensated and the output super-resolution image is created by averaging the resulting shift compensated images. Experimental results were generated using four standard test images and compared to the state of art techniques. Results show that the proposed technique significantly outperforms the classical and non-classical super-resolution methods both subjectively and objectively.

## 1 Introduction

The Super-Resolution (SR) techniques aim at displaying or printing an image at a resolution higher than that the original image without severely affecting the visual quality of the image. Since natural images exhibit abrupt discontinuities at object boundaries, traditional image interpolation methods such as linear and higher-order polynomial interpolation algorithms (which implicitly assume the underlying image is locally smooth) may not be able to offer the required visual quality [1].

Wavelets have been applied to image resolution enhancement to address the over smoothing problem of the traditional super-resolution techniques and promising results have been reported in the literature [2, 4, 7, 8, 9, 10]. The common feature of the wavelet based techniques is the assumption that the image to be enhanced is the wavelet approximation band of the high-resolution image. These techniques generate the high frequency wavelet coefficients from the given low resolution image [9]. A wavelet-based interpolation method was proposed by Carey et al. in [1]. Their proposed method estimates the wavelet high frequency coefficients of the image by exploiting the regularity of edges across the scales. They reported promising results. However, this method may not be able to estimate wavelet high-frequency coefficients with small values. A wavelet based image resolution enhancement algorithm using an adapted cycle-spinning technique was reported in [8]. This algorithm uses the information in the low-resolution image wavelet subbands to estimate the local edge orientation of the image. This local edge orientation information is then used to determine the cycle spinning parameters to generate the enlarged image. Authors reported superior results compared to Kinebuchi and Muresan method. Temizel and Vlachos proposed another wavelet based image resolution enhancement using cycle-spinning [7], which gives superior results to the state of the art. Another wavelet based image resolution enhancement algorithm, which operates in a quad-tree wavelet decomposition framework and exploits wavelet coefficient correlation in a local neighbourhood sense, was presented in [9]. This method employed linear least-squares regression algorithm to estimate the wavelet high-frequency coefficients. This method gives superior results compared to the conventional methods for a wide range of test images. Another image resolution enhancement method in wavelet domain using inter-subband correlation was presented by Piao et al. [4]. They designed filters to estimate high frequency subbands from the lower bands. They reported superior results, up to 0.36dB, to the competing methods.

Wavelets filters generally have poor frequency characteristic. Hence, wavelet baseband of the images usually contain some of the image high-frequency information [4]. This property of the wavelets is usually used to improve the quality of the enlarged image especially around their edges. Applications of multi-wavelet transform [6] that use two or more wavelets in image decomposition generate four or more approximation bands from the input image. Similar to wavelets, multi-wavelet filters also have poor frequency characteristics. Therefore, their resulting approximation bands carry different high-frequency information of the image. This feature of multi-wavelets makes them a potential tool in enhancing image resolution. The application of multi-wavelets in enlarging images and also application of cycle spinning algorithm in multi-wavelet domain for enlarging images have

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

not been reported in the literature. Hence, in this paper, cycle-spinning algorithm is adapted into multi-wavelet domain and used for enlarging images. The rest of the paper is organized as follows: In Section 2, a brief review of the multi-wavelet transform is presented. The proposed image resolution enhancement technique is discussed in Section 3. Experimental results are presented in Section 4. Finally the paper is concluded at Section 5.

## 2 Multi-wavelet transform

Multi-wavelet transforms are very similar to scalar wavelet transforms with some vital differences. Classical wavelet theory is based on the following refinement equations:

$$\begin{aligned} \phi(t) &= \sum_{k=-\infty}^{k=\infty} h_k \phi(mt-k) \\ \psi(t) &= \sum_{k=-\infty}^{k=\infty} g_k \psi(mt-k) \end{aligned} \qquad (1)$$

where $\phi(t)$ is a scaling function, $\psi(t)$ is a wavelet function, $h_k$ and $g_k$ are scalar filters, $m$ represents the subband number and $k$ is the shifting parameter. In contrast to wavelet transforms, multi-wavelets have two or more scaling and wavelet functions. The set of scaling and wavelet functions of a multi-wavelet in vector notation can be defined as:

$$\begin{aligned} \Phi(t) &\equiv [\phi_1(t) \quad \phi_2(t) \quad \phi_3(t) \quad \ldots \quad \phi_r(t)]^T \\ \Psi(t) &\equiv [\psi_1(t) \quad \psi_2(t) \quad \psi_3(t) \quad \ldots \quad \psi_r(t)]^T \end{aligned} \qquad (2)$$

where $\Phi(t)$ and $\Psi(t)$ are the multi-scaling and multi-wavelet functions, respectively, with $r$ scaling- and wavelet-functions. In the case of scalar wavelets their multiplicity order $r$ is equal to 1, while multi-wavelets support $r \geq 2$. To date, most multi-wavelets have multiplicity order, $r = 2$. A multi-wavelet with two scaling and wavelet functions can be defined as [6]:

$$\begin{aligned} \Phi(t) &= \sqrt{2} \sum_{k=-\infty}^{k=\infty} H_k \Phi(m\,t-k) \\ \Psi(t) &= \sqrt{2} \sum_{k=-\infty}^{k=\infty} G_k \Psi(m\,t-k) \end{aligned} \qquad (3)$$

where $H_k$ and $G_k$ are $2 \times 2$, ( $r \times r$ ), matrix filters and $m$ is the subband number. Similar to wavelet transforms, multi-wavelets can be implemented using Mallat's filter bank theory [3]. A visual comparison of the resulting subbands for a 2D wavelet and respectively multi-wavelet, is shown in Figures 1(a) and 1(b). From Figure 1, the multi-wavelet transform generates four subbands instead of each subband created by the wavelet transform, and these four subbands carry different spectral content of the input image due to the properties of multi-wavelet filters.

The major advantage of multi-wavelets over scalar wavelets is their ability to possess symmetry, orthogonality and higher order of approximation simultaneously, which is not possible for scalar wavelets. Furthermore, the multi-channel structure of the multi-wavelet transform is a closer approximation to the human visual system than what wavelets offer. These features of multi-wavelets make them a potential tool in enhancing image resolution. Further information about the generation of multi-wavelets, their properties and their applications can be found in [5, 6].

## 3 Multi-wavelet based image resolution enhancement technique

Figure 2 shows a block diagram of the proposed multi-wavelet based image resolution enhancement technique. A low resolution image is input to the system. The input image coefficients are weighted to generate four multi-wavelet basebands. The weighting factor for each of the multi-wavelet basebands equals to the overall multi-wavelet filters gain for that subband. The Inverse Multi-Wavelet Transform (IMWT) block produces a High-Resolution (HR) image for the input image using the information in the resulting basebands (the coefficients in multi-wavelet high frequency subbands are set to zero.). The concept of the cycle spinning technique is then combined with the multi-wavelet transform to generate a super-resolution image for the input image from the resulting HR-image, as follows: The resulting HR-image is first spatially shifted with different 2D shift values, generating N Shifted High Resolution (SHR) images. Then the N 2D-shift vectors are determined using equation 4:

$$\begin{bmatrix} (-k,-k) & (-k,-k+1) & \cdots & (-k,k) \\ (-k+1,-k) & (-k+1,-k+1) & \cdots & (-k+1,k) \\ \cdots & \cdots & \cdots & \cdots \\ (k,-k) & (k,-k+1) & \cdots & (k,\ k) \end{bmatrix} \qquad (4)$$

Figure 2: Block diagram of the multi-wavelet based image enlargement algorithm.

where $k$ is the maximum number of pixel shifts in both horizontal and vertical directions. In this paper $k$ was set to 3, as system exhibits its best performance with this value. Number of shifted images, N, can be calculated using equation 5:

$$N = (2k + 1)^2 \qquad (5)$$

where $k$ is the maximum number of pixel shifts in both horizontal and vertical directions.

Each of the resulting N Shifted High Resolution (SHR) images is then processed as follows: I) a 2D Multi-Wavelet Transform (MWT) is applied on the SHR-image, de-correlating the SHR-image into its multi-wavelet subbands; II) the coefficients in the resulting multi-wavelet high frequency subbands are set to zero; III) a 2D Inverse Multi-Wavelet Transform (IMWT) is used to generate a Primary Spatially Shifted Super Resolution (PSSSR) image from the resulting coefficients; IV) the PSSSR-image is spatially inverse shifted, bringing back the image coefficients onto its original positions.

The output super-resolution image is created by averaging the resulting N-shift compensated PSSSR-images.

# 4 Experimental results

To generate experimental results, four standard test images called: Lena, Elaine, Baboon and Peppers are taken. Each of these four images, is first lowpass filtered using a 2D Blackman filter, and then down sampled by a factor of 2 in both horizontal and vertical directions, generating a replica low resolution image for each of them. The Blackman 2D FIR filter coefficients are tabulated in Table 1.

| | | |
|---|---|---|
| 0.0381 | 0.1051 | 0.0381 |
| 0.1051 | 0.4273 | 0.1051 |
| 0.0381 | 0.1051 | 0.0381 |

Table 1: The Blackman 2D FIR filter coefficients.

To evaluate the performance of the proposed method, the resulting low resolution Lena, Elaine, Baboon and Peppers test images are enlarged using the proposed method, Nearest-neighbourhood, Bilinear, Bicubic, Sinc, Cycle Spinning (CS) [8], Directional Cycle Spinning (DSC) [9], and Yinji [4] methods. In this research, ghm multi-wavelet was used to generate the experimental results. The Peak Signal to Noise Ratio (PSNR) measurements for the enlarged images were calculated and tabulated in Table 2.

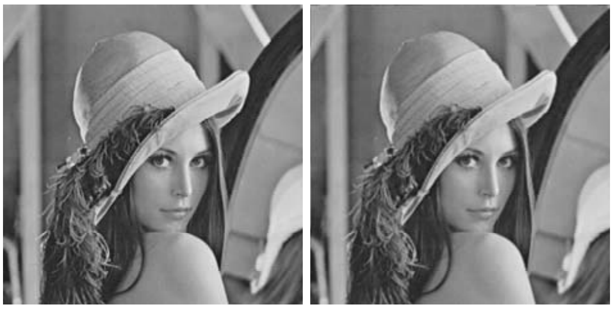
| | Lena | Elaine | Pepper | Baboon |
|---|---|---|---|---|
| Nearest | 29.15 | 30.15 | 29.20 | 25.30 |
| Bilinear | 29.90 | 30.45 | 29.69 | 26.28 |
| Bicubic | 30.25 | 30.59 | 29.90 | 26.91 |
| Sinc | 34.49 | 32.89 | 33.26 | 31.55 |
| Yinji | 33.75 | 32.50 | 32.79 | 30.17 |
| CS | 34.31 | 32.92 | 33.22 | 31.16 |
| DCS | 34.77 | 33.19 | 33.54 | 32.16 |
| Proposed | 34.96 | 33.35 | 33.63 | 32.55 |

Table 2: The PSNR comparison of different methods.

From table 2, it can be seen that the proposed method outperforms the competing methods when enlarging the images that contain significant high frequency information. The proposed technique produces almost the same objective quality when enlarging images containing less high frequency components.

To give a visual perception of the resulting enlarged images, original Lena test image and its enlarged image using the proposed technique are shown in Figure 3. From Figure 3, it can be seen that the enlarged image is almost the same as the original image and it is hard to differentiate between the original and the enlarged image.

To facilitate the assessment of different enlargement techniques, the enlarged image using the proposed method, Nearest neighbourhood, Bilinear, Bicubic, Sinc, Cycle Spinning (CS), Directional Cycle Spinning (DSC), and Yinji methods are subtracted from the ground truth image and magnified by a factor of 10 (shown in Figure 4). From these figures it is obvious that the proposed technique exhibits the lowest residuals compared to the other techniques.



(a) (b)

Figure 3: a) Original Lena test image; b) enlarged Lena test image using the proposed technique.

## 4 Conclusions

In this paper, a new image resolution enhancement technique was proposed. The proposed technique adopts the cycle-spinning scheme into multi-wavelet domain, increasing the quality of the enlarged images. Experiments on natural test images showed the proposed technique outperforms the state of the art techniques especially when the enlarged images contain high frequency information.

# Configurations of Binary Distillation column for optimal control

**Abdelmadjid KHELASSI, Riad BENDIB, Abdelhai BENHALLA**
University M'Hamed Bougara of Boumerdes,
Faculty of Hydrocarbons and Chemistry, Laboratory of Applied Automatic
E-mail :madjidk@hotmail.com

*Abstract-* **Choice of the control structure is a major concern and considerable research activity has been devoted to finding the best control configuration. In this work eight distillation control structures have been investigated by simulation based on models that are deduced using a software package for distillation column. These programs use transformations between the structures. The Dynamic Relative Magnitude Criterion, DRMC has been used to evaluate the interactions and disturbances propagation between the two interacting controlled loops of distillation column. Comparison between the results given by DRMC and those given by the Relative Gain Array, RGA has been also given in this work.**

***Keywords: Configuration;, Distillation; Interaction; DRMC; RGA; Optimal control.***

## I. INTRODUCTION

Recently there has been considerable interest in developing process control strategies for multivariable control system, that is, problems where several process variables are to be controlled and several variables can be manipulated [1]. Although a variety of advanced control techniques are available, only a few industrial applications have been reported. The conventional industrial approach to multivariable control problems is to use a "multiloop control system" consisting of *m* conventional PI or PID controllers where *m* is the number of controlled variables [2].

A big part of monovariable control problems can be solved by the classic PID-type compensator and fuzzy controllers. A number of investigators have developed measures of interaction that allow a control system designer to determine the proper input-output pairing for a set of single-input/single-output (SISO) controllers. There are many cases , however, where the measures of interaction show the absence of an adequate control configuration.

The goal of this paper is to give insight into the different structures of controlling binary distillation column and give the best scheme that allows us to minimise the energy consumed by this column

The configurations considered here are the Energy balance "LV-configuration" [3], the material balance " DV-configuration" [3], the ratio configuration such as (L/D,V/B) (L/D, V/F), (D/ (L+D), V), (L/D, V), (D/ (L+D), V/B), and LB [4], [5], [6].

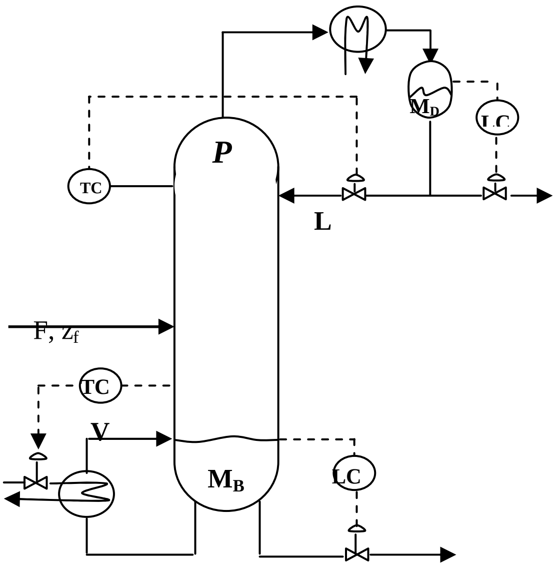

**Fig (1)** LV configuration

## II. DISTILLATION CONTROL STRUCTURES

### *A. Energy balance structure (L V)*

The energy balance structure can be considered to be the standard control configuration for dual composition control of distillation. In this control structure, the reflux flow rate *L* and the boil-up manipulator *V* are used to control the outputs concentrations or temperatures.

A typical distillation column with LV configuration is shown in Fig (1).

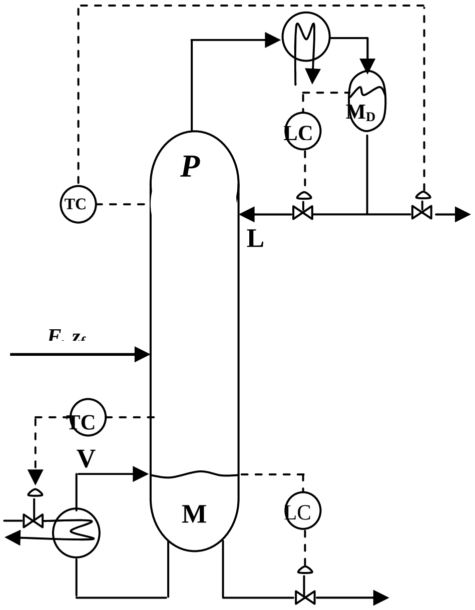

**Fig (2)** DV configuration

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

### *B. Material balance structures (D,V) and (L,B)*

Two other frequently used control structures are the material balance structures (D, V) and (L, B)**.** In the (D, V) structure, D and V are used as primary manipulators whereas L and B usually are used as inventory control manipulators. The implementation of this control scheme is shown in Fig (2).

### *C. The ratios scheme* $\left({}^{L}\!/_{D}, {}^{V}\!/_{B}\right)$

Ratio control configurations have been used in industry for at least forty years [7]. Condenser level is adjusted with both L and D such that their ratio is constant and reboiler level with both V and B such that their ratio is constant. The simplest justification for using ratios as inputs follows from steady state considerations: to keep the compositions constant, the ratio $L/V$ inside the column (slope of the operating line on the McCabe- Thiel diagram [8],[9]) should be constant.

### *D. The ratios scheme* $(L/D, V/F)$

The $(L/D, V/F)$ is an example of a control structure where a primary manipulator include a measurable disturbance. The inclusion of $F$ in the manipulator $V/F$ means that there is such a built-in feed forward from measured disturbances in *F* that V is changed in the same proportion as *F*. This results in a better rejection of disturbances in *F* than is the case in other structures.

### *E. Ryskamp's control scheme*

This control structure is suggested by Ryskamp (10), where the primary outputs are Controlled by $D/(L+D)$ and $V$. This scheme holds the reflux ratio constant if the top composition controller is constant. An increase of heat input from the bottom composition controller does not make top product as impure as would occur with reflux constant (conventional control) nor as over-pure as would occur with distillation flow constant (material balance control).Thus, this property of the scheme is sometimes said to result in "implicit decoupling", in contrast to "explicit decoupling" accomplished by external decoupling elements.

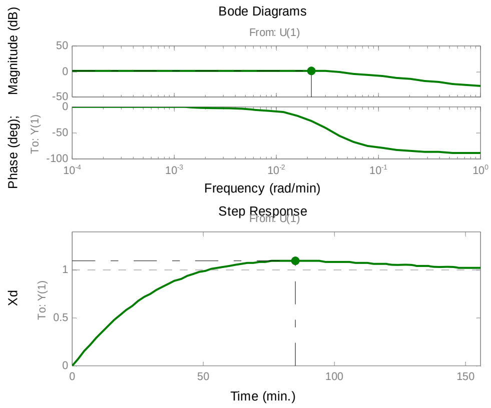

**Fig (3-a)** The closed loop bode diagram and step response 1st loop (LV scheme)

### *F. (L/D, V) structure*

This control structure is equivalent to Ryskamp's structure, because $\Delta\left(D/(L+D)\right) = -(\overline{D}/(\overline{L}+\overline{D}))^2\Delta(L/D)$ [7]; the only difference is a different scaling of gains associated with the top primary manipulator.

### *G. (D/(L+D),V/B) structure*

This control scheme is an extension of Ryskamp's structure, is suggested and studied by Takamatsu, Hashimoto, and Hashimoto (11).

## III. ANALYSIS OF INTERACTIONS IN THE LISTED STRUCTURES USING DRMC

### *A. Conventional control structure (LV) Configuration*

To specify parameters for the PI controllers root locus method has been used. In our case the design objective is to get a closed loop response where the percent overshot is small or equal to 07% . The closed loop step responses and bode diagrams for both loops are shown in Fig(3),

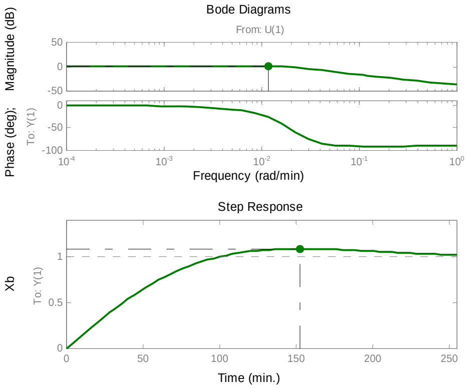

**Fig (3-b)** The closed loop bode diagram and step response 2nd loop (LV scheme)

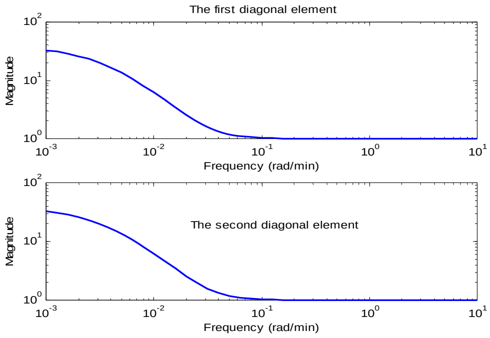
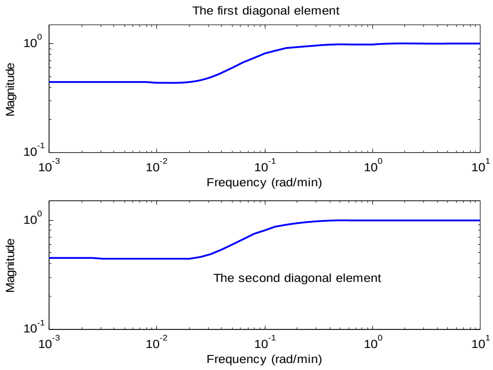
As it is shown in Fig (4) the magnitude of the diagonal elements for the range where the system works (i.e. the resonant frequency) are far from unity $\delta_{11}$ *and* $\delta_{22} \approx 7$ which means that strong interactions exist between the loops, the fact that let the (LV) configuration to be not recommended for two point control ( i.e. where all loops are in automatic). The off-diagonal elements $\delta_{12} = 0.8$ *and* $\delta_{21} \approx 1$ in the resonant frequencies which indicate that there exist large disturbances between the two loops and propagate approximately by the same magnitude.



**Fig(4)** The DRMC diagonal elements

*B. Material balance (D,V) structure*

The DRMC values, the diagonal elements

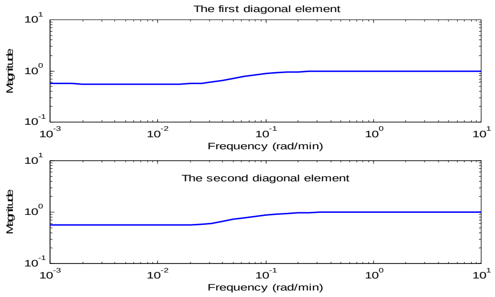


Fig(5) The DRMC elements of DV configuration

The distillation column under this configuration is slightly interactive as it is indicated by the DRMC diagonal elements shown in Fig (5) ( $\delta_{11}$ and $\delta_{22} = 0.45$ are close to unity). For the off-diagonal elements we notice that $\delta_{21} = 0.1, \delta_{12} = 0.09$ i.e. $\delta_{21} > \delta_{12}$ which means that there exist disturbances that propagate from the top loop to the bottom loop. In general this configuration is a good choice in the sense of interactions but in reality there are problems that affect the operation of the column under this control scheme [7],[12], the major problem that may rise with this configuration is the effect of level control, such that with fast condenser level control, the increase in boil-up goes up the column, then returned back as a reflux through the action of the condenser level controller (since D is constant), and we have an increase in the internal flows only.

*C. Material balance (L,B) structure*

The DRMC elements, the diagonal elements



Fig(6) The DRMC diagonal elements
LB configuration

The distillation column under this configuration is almost non-interactive as it is indicated by the DRMC diagonal elements shown in Fig (6) ( $\delta_{11}$ and $\delta_{22} = 0.6$ are close to unity). For the off-diagonal elements $\delta_{21} \approx \delta_{12} = 0.1$ which means that there are disturbances that propagate between the loops by the same magnitude. As the first material balance configuration there is a problem of level control, another practical problem is that this configuration is extremely sensitive to disturbances in feed flow rate [7].

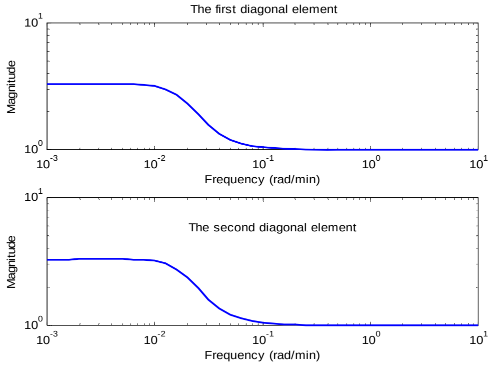
The DRMC values, the diagonal elements



Fig(7) The DRMC diagonal elements (L//D V/B) configuration

The distillation column under this configuration is interactive as it is indicated by the diagonal elements of the DRMC shown in Fig (7) ( $\delta_{11}$ and $\delta_{22} = 3.2$ ), but compared with the energy balance configuration the degree of interactions is smaller (this also can be deduced using the RGA). The examination of the off-diagonal elements show that $\left(\delta_{21} = 0.6\right)$ is greater than $\left(\delta_{12} = 0.35\right)$ which indicates that there is disturbance propagation from the top loop to the bottom loop. The main disadvantages of this configuration is the need for measurements of all flows L, D, B and V which makes it more failure sensitive and more difficult to implement.

### *E. The two ratios scheme* $\left(L/_{D}, V/_{F}\right)$

The (L/D,V/F) model is deduced from the LV steady state model.

**The DRMC values, The diagonal elements**

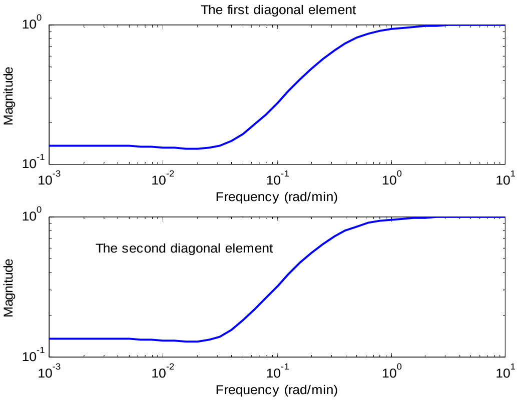


Fig (8) The DRMC diagonal elements(L//D V/F) configuration

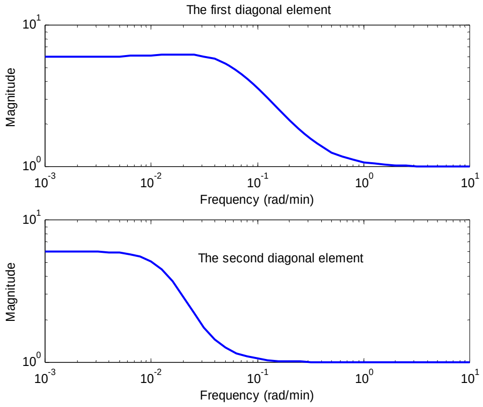
The examination of DRMC values (at the resonant frequencies) shows that ($\delta_{11}$ and $\delta_{22} \approx 0.15$) which indicates that more interaction compared with the previous two ratios configuration is expected, for the off-diagonal elements $(\delta_{21} = 0.2)$ is greater than $\left(\delta_{12} \approx 1.6\text{x}10^{-2}\right)$ which indicates that there exists a disturbance propagation from the top loop to the bottom loop, in general we can say that this configuration behaves between the (DV) and (L/D,V/B) , but in this configuration we avoid the disturbances created by the flow rate ( because F is included in the primary manipulator). The major drawback for this control scheme is the need of measurements for all flows which makes it more difficult to implement.

### *F. Ryskamp's scheme* $\left(D/(L+D), V\right)$

The DRMC values, the diagonal elements



**Fig(9)** The DRMC diagonal elements Ryskamp's configuration

The diagonal elements at the resonant frequencies shown in Fig (9) are far from unity $\delta_{11}$ and $\delta_{22} = 5.5$, but there values are small compared with those of LV control scheme, which indicates that the degree of interactions exist in this configuration is small compared with conventional control, this is according to decoupling (implicit) effect which results from the property that the scheme holds the reflux ratio constant if the top composition controller is constant. The DRMC off-diagonal elements that indicate that there is a large disturbance propagation from the bottom loop to the top loop (since$(\delta_{12} = 0.6) > (\delta_{21} = 0.1)$).

### *G. The (L/D,V) control scheme*

The properties of $(L/D,V)$ structure are similar to those of the $(L/D,V/F)$ structure, particularly in our case where the feed rate is $F = 1$. The $(L/D,V)$ model is deduced from the LV steady state model.

### *H. The (D/(L+D),V/B) control structure*

The DRMC values, the diagonal elements

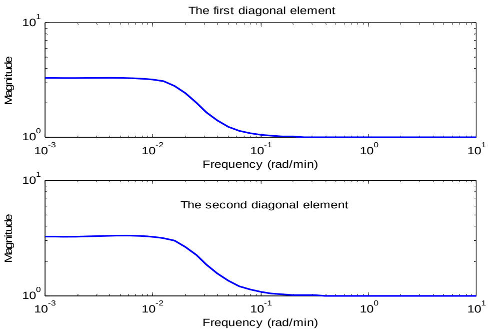


**Fig (10)** The DRMC diagonal elements (D/(L+D),V/B) configuration

Fig (10) presents DRMC diagonal elements for this structure, the examination of the diagonal elements shows that there exist interactions between the two loops, but with a magnitude smaller than those of Ryskamp's scheme $\left(\delta_{11}, \delta_{22} = 3.2\right)$ (this is what Shinskey (1984) and Hashimoto have shown [7]), and disturbances propagate from the top loop to the bottom loop as it is given by the off-diagonal elements $\left(\delta_{21} = 0.5\right) > \left(\delta_{12} = 0.3\right)$

## IV. ANALYSIS OF INTERACTIONS USING RGA

TABLE I
COMPARISON BETWEEN THE RGA VALUES AND DRMC VALUES FOR THE STUDIED STRUCTURES

| **Structure** | $\lambda_{11}$ | $\delta_{11}$ |
|---|---|---|
| **LV** | **36.06** | **7** |
| **DV** | **0.446** | **0.45** |
| **LB** | **0.56** | **0.6** |
| **(L/D V/B)** | **3.28** | **3.2** |
| **(L/D V/F)** | **5.98** | **0.15** |
| **Ryskamp's** | **5.98** | **5.5** |
| **(L/D, V)** | **5.98** | **0.15** |
| **(D/(L+D) V/B)** | **3.28** | **3.2** |

As it is shown in Table I, there are deviations between the values given by the RGA and those given by the DRMC, since the first method gives information about the steady state behavior of the system, whereas the DRMC deals with the dynamic behavior of the system.

## CONCLUSION

In order to overcome the problem of interactions several distillation control schemes are suggested by many contributors. DRMC is used to assess interactions in eight well known control configurations for binary distillation columns. The mathematical model for each configuration is deduced by using transformations between control schemes taking the (LV) configuration as a base model. It has been shown from the analysis that the conventional control structure (LV) suffers from severe interactions the diagonal elements are far from unity and the off diagonal elements show that there exist large disturbances that propagate between the loops approximately by the same magnitude. The material balance control (DV) is non-interactive the diagonal elements are close to unity, the off diagonal elements show that there exist disturbances that propagate from the top loop to the bottom loop since $\delta_{12} > \delta_{21}$, the same remark with the second material balance (LB) the diagonal elements are close to unity which indicates that for this configuration low interaction is expected, the off diagonal elements show that there exist disturbances that propagate between the loops by the same magnitude.

The ratio schemes are introduced to reduce the degree of interactions exist in the conventional control scheme (LV) and that is what it has been shown using DRMC for the remaining control schemes. For the two ratios control scheme $\left(L/D, V/B\right), \left(L/D, V/F\right)$ and $\left(L/D, V\right)$ are non-interactive with respect to (LV) control (as it is indicated by the DRMC diagonal elements for the three cases). Ryskamp's configuration is an interactive one but with smaller degree than that of (LV) control scheme, the larger degree of interaction in Ryskamp's has been reduced using its extension control scheme i.e. $(D/(L+D), V/B)$.

Iran. Email: Shiveex@Gmail.Com

**ABSTRACT:**
Game theoretic reasoning pervades economic theory and is used widely in other social and behavioral sciences. It is widely used in decision of economic behavior and other game conditions with risk characters. A model is an abstraction we use to understand our observations and experiences. This paper proposes an imperfect information multi-player system using risk dominance strategy for its decision module. In this article, the Influence of the strategy in different conditions is discussed. A model is unlikely to help us understand a phenomenon if its assumptions are wildly at odds with our observations. The cases that risk dominance worked and the process of the module to exclude risk is illustrated. In the end, basing on the results of experiments, the performance of the strategy is discussed.

**KEYWORDS:** Game theory, Imperfect game, Decision tree.

## 1. INTRODUCTION

Risk dominance and payoff dominance are two related refinements of the Nash Equilibrium (NE) solution concept in game theory, defined by John Harsanyi and Reinhard Selten[2]. Nash equilibrium is considered payoff dominant if it is Pareto superior to all other Nash equilibrium in the game. When faced with a choice among equilibrium, all players would agree on the payoff dominant equilibrium since it offers at least as much payoff as each player's best alternative. Conversely, Nash equilibrium is considered risk dominant if it has the largest basin of attraction [3], meaning the more uncertainty players have about the actions of the other player(s), the more likely they will choose the risk dominant strategy [4].

A game with imperfect information means the players face risks not only come from the uncertain strategies of other players but also from the uncertain game conditions [5]. Thus, risk dominance strategy is imported as the decision module of an imperfect information game called Military Chess.

The main contribution of the system that is presented is the realization of a decision module basing on risk dominance strategy which is used for the selection of optimal step in the Military game. The performance of the strategy is also discussed in the following experiments.

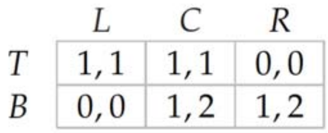
This paper is organized as follows. Section 2 briefly introduces the related theories and works about the risk dominance strategy in game theory. Section 3 gives a primary introduction of Military Chess game. And then, in Section 4, a specific description is presented about the risk dominance strategy and the realization details of the decision module in our game system. Section 5 analyzes the performance of the new system that is tested locally and on the Internet. And finally, section 6 contains our conclusion.

## 2. ITERATED ELIMINATION OF WEAKLY DOMINATED ACTIONS

A strictly dominated action is clearly unattractive to a rational player. Now consider an action a is weakly dominated in the sense that there is another action that yields at least as high a payoff as does $a_i$ whatever the other players choose and yields a higher payoff than does $a_i$ for some choice of the other players. In the game in Figure 1, for example, the action T of player 1 weakly (though not strictly) dominates B.

A weakly dominated action that is not strictly dominated, unlike a strictly dominated one, is not an unambiguously poor choice: by Lemma 356.1 such an action is a best response to some belief. For example, in the game in Figure 1, if player 1 is sure that player 2 will choose R then B is an optimal choice for her. However, the rationale for choosing a weakly dominated action is very weak: there is no advantage to a player’s choosing a weakly dominated action, whatever her belief. For example, if player 1 in the game in Figure 1 has the slightest suspicion that player 2 might choose L then T is better than B, and even if player 2 chooses R, T is no worse than B.

If we argue that it is unreasonable for a player to choose a weakly dominated action then we can argue also that each player should work under the assumption that her opponents will not choose weakly dominated actions, and they will assume that she does not do so, and so on. Thus, as in the case of strictly dominated actions, we can argue that weakly dominated actions should be removed iteratively from the game. That is, first we should mark actions of player 1 that are weakly dominated; then, without removing these actions of player 1, mark actions of player 2 that are weakly dominated, and proceed similarly with the other players. Then we should remove all the marked actions, and again mark weakly dominated actions for every player. Once again, having marked weakly dominated actions for every player, we should remove all the actions and go through the process again. We should repeat the process until no more actions can be eliminated for any player. This procedure, however, is less compelling than the iterative removal of strictly dominated actions since the set of actions that survive may depend on whether we remove all the weakly dominated actions at each round, or only some of them, as the two-player game in Figure 1 shows. The sequence in which we first eliminate L (weakly dominated by C) and then T (weakly dominated by B) leads to an outcome in which player 1 chooses B and the payoff profile is (1, 2). On the other hand, the sequence in which we first eliminate R (weakly dominated by C) and then B (weakly dominated by T) leads to an outcome in which player 1 chooses T and the payoff profile is (1, 1).



|  | *L* | *C* | *R* |
|---|---|---|---|
| *T* | 1,1 | 1,1 | 0,0 |
| *B* | 0,0 | 1,2 | 1,2 |

**Figure 1.** A two-player game in which the set of actions that survive iterated elimination of weakly dominated actions depends on the order in which actions are eliminated.

In the games studied in this chapter, the players are representatives from an evolving population of organisms (humans, animals, plants, bacteria, ... ). Each player's payoffs measure the increments in the player's biological fitness, or reproductive success (e.g. expected number of healthy offspring), associated with the possible outcomes, rather than indicating the player's subjective feelings about the outcomes.

Each player's actions are modes of behavior that the player is programmed to follow.

The players do not make conscious choices. Rather, each player's mode of behavior comes from one of two sources: with high probability it is inherited from the player's parent (or parents), and with low (but positive) probability it is assigned to the player as the result of a mutation. For most of the models in this article, inheritance is conceived very simply: each player has a single parent, and, unless it is a mutant, simply takes the same action as does its parent. This model of inheritance captures the essential features of both genetic inheritance and social inheritance: players either follow the programs encoded in their genes, which come from their parents, or learn how to behave by imitating their parents. The distinction between genetic and social evolution may be significant if we wish to change society, but is insignificant for most of the models considered in this article.

Members of a single large population of organisms are repeatedly randomly matched in pairs. The set of possible modes of behavior of each member of any pair is the same, and the consequence of an interaction for an organism depends only on the actions of the organism and its opponent, not on its name. As an example, think of a population of identical animals, pairs of which periodically are engaged in conflicts (over prey, for example). The actions available to each animal may correspond to various degrees of aggression, and the outcome for each animal depends only on its degree of aggression and that of its opponent. Each organism produces offspring (reproduction is asexual), to each of whom, with high probability, it passes on its mode of behavior; with low probability, each offspring is a mutant that adopts some other mode of behavior.

Harsanyi and Selten's risk dominance is based on what they refer to as a tracing procedure [2], the details of which are beyond the scope of this paper. As an alternative, Selten proposes a measure of risk dominance that is easy to calculate for our games [6], and is indicative of the outcome of the tracing procedure. Let $u_1(X, X)$ be the payoff of player1 with strategy pair *(X, X)*, Selten's [6] weighted average log measure of risk dominance of the equilibrium *(A, A)* over *(B, B)* is given by:

$$R = \log\left[\frac{u_1(A,A)-u_1(B,A)}{u_1(B,B)-u_1(A,B)}\right] \tag{1}$$

If *R* is positive, Harsanyi and Selten's tracing procedure selects *(A, A)* as risk dominance. If *R* is zero, the mixed strategy Nash equilibrium is risk dominant. If *R* is negative, *(B, B)* is risk dominant. Notice that any affine transformation of the payoffs in the game would not change either the sign or the magnitude of *R*.

This criterion can explain the experimental result of Paul Straub. In Game 1, *R* of player 1 can be calculated by (1) that equal to Log (2.5), so *(A, A)* is both payoff and risk dominance. In Game2, *R* of player 1 changes to Log (0.67) which is a negative value, so the strategy *B* has risk dominance. That is why the players picked strategy *B* in the final three rounds of the session utilizing Game 2.

There are two main factors that affect the risk characteristics of the games [7]. One is the trust level between the players as showing in table 2. Generally speaking, the coordinate game will keep a comparative higher trust level which weakens the influence of risk dominance. However, in uncoordinated games and zero sum games, there is almost no trust between players. In another side, the imperfect information game situation will greatly enhance the uncertainty of the game, thus the effect of risk dominance strategy should be carefully considered in decision process.

The notion of Nash equilibrium requires only that each player's strategy be optimal in the whole game, given the other players' strategies; after histories that do not occur if the players follow their strategies, the actions specified by a player's Nash equilibrium strategy may not be optimal. In some cases we can think of the actions prescribed by a strategy for histories that will not occur if the players follow their strategies as "threats"; the notion of Nash equilibrium does not require that it be optimal for a player to carry out these threats if called upon to do so. In the previous chapter we studied the notion of subgame perfect equilibrium, which does impose such a requirement: a strategy profile is a subgame perfect equilibrium if every player's strategy is optimal not only in the whole game, but after every history (including histories that do not occur if the players adhere to their strategies).

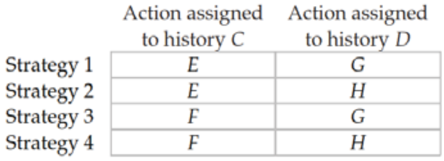
**Table 1.** Payoff and risk dominance in two games condition

| Game1 | Player2 | | | | |
|---|---|---|---|---|---|
| Player 1 | | A | | B | |
| | A | | 8 | | 3 |
| | | 8 | | 4 | |
| | B | | 4 | | 6 |
| | | 3 | | 6 | |
| Game2 | Player 2 | | | | |
| Player 1 | | A | | B | |
| | A | | 8 | | 4 |
| | | 8 | | 0 | |
| | B | | 0 | | 6 |
| | | 4 | | 6 | |

**Table 2.** Games with low trust level, risk dominance will be very important in decision process

| Game | Player2 | | | | |
|---|---|---|---|---|---|
| Player1 | | A(20%) | | B(80%) | |
| | A | | 8 | | 4 |
| | | 8 | | 0 | |
| | B | | 0 | | 6 |
| | | 4 | | 6 | |

**Table 3.** The four strategies of player 2 in the game in Figure 1.



| | Action assigned to history *C* | Action assigned to history *D* |
|---|---|---|
| Strategy 1 | *E* | *G* |
| Strategy 2 | *E* | *H* |
| Strategy 3 | *F* | *G* |
| Strategy 4 | *F* | *H* |

## 3. MILITARY CHESS GAME SYSTEM WITH MONTE-CARLO SAMPLING

In this section, the imperfect information game system basing on a game called Military Chess is presented.

### 3.1. Introduction for Proposed Game

The Military Chess, which is also called Kriegspiel, has been a very popular game for many years. The rules of the Military Chess are quite complex. Simply speaking, the basic process of the game is to move pieces, attack opponent's pieces and finally occupy the position of enemy's flag. Maybe it sounds quite like Chess but there are at least three main differences between them as following.

Opposite and two opponents sits aside, like Bridge. Second, the pieces which have a certain military rank can only destroy those with lower ranks. Last but most important, player cannot see the ranks of other player's pieces, even though it belongs to his associate. As the result, players have to guess the ranks of other pieces. This is the most difficult and complex point of the development of Military Chess game system. A Military Chess game system is developed which is called mygames [11].

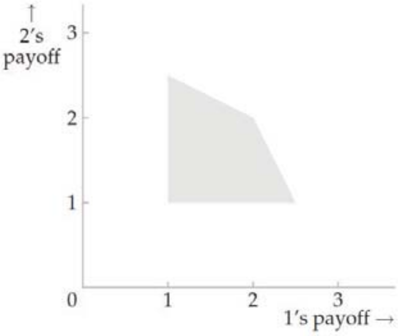


**Figure 2.** The approximate set of Nash equilibrium discounted average payoffs for the infinitely repeated Prisoner's Dilemma with one-shot payoffs to 1.

As in the case of a finite horizon game, if a strategy profile is a subgame perfect equilibrium then certainly it satisfies the one-deviation property, since no player must be able to increase her payoff by any change in her strategy. What we need to show is the converse: if a strategy profile is not a subgame perfect equilibrium then there is some subgame in which the first-mover can increase her payoff by changing only her initial action.

### 3.2. Monte-Carlo Sampling

In imperfect information game, none of the players in the game have the whole knowledge about the current game state. In order to solve such problem in practice, one has to either resort to special cases, or fall back heuristics which is created by Monte-Carlo sampling [5].

Monte-Carlo sampling is an algorithm that deals with imperfect information games. When evaluating the choices of one player, the Monte-Carlo method randomly guesses the unseen pieces of the other players. The game is then searched using min-max game tree as if these pieces are known to each player. As demonstrated in figure 2, the square represents the max node and the circle represents the min node. Only the root node is the random (the diamond) and all the other nodes are board states with perfect information.

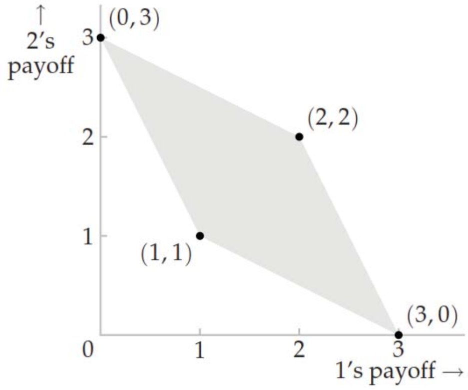

**Figure 3.** Game tree of imperfect information using Monte-Carlo sampling

### 3.3. Realization with Monte-Carlo Sampling

The set of Nash equilibria consists of the action profile (Hare,...,Hare) in which all hunters catch hares, and any action profile in which exactly k hunters pursue the stag and the remaining hunters catch hares.

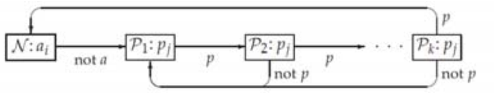

**Figure 4.** A subgame perfect equilibrium strategy for player i in a two-player infinitely repeated game. The outcome p is that in which each player's action is one that holds the other player down to her minmax payoff.

In the process of game, when it is the agent's turn to move, the current state that agent faces is an imperfect information state. Monte-Carlo sampling process transforms the imperfect information state to perfect information state. Next, basing on the sampled perfect information, move generator module generates moves list and build the game tree. And then, tree search algorithm is used searching the optimal move from the game tree. When a move has been chosen, the system check the end condition, which could be set for a limit of running time or a limit times for system's iteration. This process will iterate many times which is set by users. Each iteration generates a candidate move. When the end condition is fulfilled, system will collect all the candidate moves in before iterations and decision module will take an analysis about them and finally choose the optimal move.

## 4. DECISION MODULE IN THE SYSTEM WITH RISK DOMINANCE STRATEGY

The task of decision module is to select one optimal move from tens of candidates. The criterion is the expect payoff of the moves. However, in the case of imperfect information, the uncertainty of the game condition leads the payoff for one move is uncertain. Decision module builds a suppositional game condition to deal with the problem. Just like the table 5 illustrates, player 1 denotes the player for whom the system make decision, and player 2 is set to denotes different Monte-Carlo sample results from the uncertain game circumstance which greatly influences the payoff of the player1's strategies.

For concisely express, set the numbers of candidate move and different conditions are both three. *E(X)* means the expect payoff of move $X$, $P_a$ means the appear probability of condition *a* and $V_{Ab}$ means the payoff when condition *b* appears and player1 adopts move *A*. Let *M* means the cluster of all conditions and the system calculates the *E(X)* as following:

$$E(X)=\sum_{i\in M} V_{Xi}P(i) \qquad (2)$$

And the finial optimal result will be decided by $\max\{E(A),E(B),E(C)\}$ .

The system calculates the *E* value with equation (2) of each move, and then chooses the largest to be the optimal strategy. The process of decision can deal with most of the conditions well except some special cases which is also the reason the risk dominance strategy be adopted.

There are some cases that terrible departure lost appears just like table 6 shows. When condition b happens, candidate move *B* will leads a terrible lost.

The low appearance probability of condition *b* will smooth the lost of *B* when calculates *E (B)*. Just like no one want to take the risk of low probability to eat candy in a bowl which is full of hundreds of candy and only one of them is poison, the task of risk dominance strategy in this case is to exclude *B*-like candidate moves from the final result.

The decision module creates the game condition like table 7 shows. Value *(A, a)* means the average payoff of other conditions and *(B, b)* means the payoff in the dangerous condition. Using equation (1) to calculate the value *R* is Log (5) which is a positive value and it can be concluded that the strategy *A* is risk dominance. That is the process that risk strategy *B* is excluded.

# Robust $H_\infty$ Control of Singular Systems over Networks with Data Packet Dropouts

Yongbo Lai, Guoping Lu
Department of Electrical Engineering
Jiangsu College of Information Technology
Wuxi, China
E-mail: yongbo100@sina.com, Lgp@jsit.edu.cn

*Abstract*—**The problems of stochastic stability and $H_\infty$ control for a class of discrete time singular networked control systems (SNCSs) with data packet dropouts and nonlinear perturbation are investigated in this paper. By modeling the sensor-to-controller and controller-to-actuator with random data packet dropouts as Markov chains, the closed-loop system can be expressed as a jump discrete singular system with four modes. A sufficient condition for the existence of a controller is established in terms of linear matrix inequalities (LMIs), the controller gain can be solvable via the cone complementary linearization method, and the designed controller guarantees the systems to be regular, causal and stochastically stable and satisfies $H_\infty$ performance. In addition, a numerical example is given to illustrate the effectiveness of the proposed approach.**

***Keywords-singular systems; networked control systems; data dropout; $H_\infty$ control ; Markov chain***

## I. INTRODUCTION

Networked control systems (NCSs) have been widely used in various industrial areas, with the rapid development of computer, network and communication technology. The primary advantages of NCSs are simplified system structure, lower cost of system integration, ease of diagnosis, remote distributed control, and increasing system agility. In an NCS, several important issues need to be treated, which include the network induced delay and data packet loss, more recently, the analysis and synthesis problem of networked systems with data dropout and network induced time delays have attracted many research interests [1-7]. Due to bandwidth limited communica -tion channels, packed loss and time delays are the most important and special two issues of NCSs. Generally speaking, there were three main approaches for modeling packed loss and time delays in the NCSs. The first one is to model the data loss and induced delays as a binary switches sequence which obeys the Bernoulli process with certain probability, the NCSs in both continuous time case and discrete time case with packet loss and delays were studied in [5,6]. The second approach is to model the process as discrete time Markov jumping systems, in which transmission times are varying within a time interval or driven by a stochastic process with Markov chain, a class of methods for stabilization analysis for an NCS were proposed [3,4]. The third model is to view data packet loss as a special time delay system, which deals with the stability and controllability [2]. However, it can only be used to treat the systems with sense-to-controller packet loss or controller-to-actuator packet loss cases.

In [15], the stabilization problem for a class of NCSs in the discrete time domain is studied by modeling the sensor-to controller packet loss and controller-to-actuator packet loss as Markov chains. It is worth noting that the mentioned literature results are still very limited for they are all concerned with a nonsingular controlled plant. In real projects, a certain linear NCS model provides just an approximate singular of the real facts. Recently a few results have been reported for the singular NCSs [7, 16].

In actual physical networked transmission field, there coexist data packed loss and nonlinear perturbation, however, the aforementioned articles do not consider the two problems simultaneously. The $H_\infty$ control problem for discrete time singular markov jump systems with data loss and nonlinear perturbation is also an important problem, and it is not simple extension to stability for the systems over networks. Motivated by recent research on singular perturbed systems and networked control systems [8-14, 18], this paper considers the problems of stochastic stability and $H_\infty$ control for a class of discrete time singular networked control systems with data packet dropouts and nonlinear perturbation. Firstly, we consider the case that modeling the sensor-to-controller and controller-to-actuator with random data packet dropouts as Markov chains, and the nonlinear perturbation satisfying Lipschitz condition, the closed-loop system can be expressed as a jump discrete singular system with four modes in Section II; Next, the state feedback controller design and solvable problem are proposed in section III and section IV; Finally, an example is given to illustrate the effectiveness of the proposed approach in section V.

*Notations:* Throughout this paper, for real symmetric matrices $X$ and $Y$, the notation $X \geq Y$ (respectively, $X > Y$) means that the matrix $X - Y$ is semi-positive definite(respectively, positive definite); $\mathbb{R}^n$ and $\mathbb{R}^{n\times m}$ denote the *n*-dimensional Euclidean space and the set of all *n*×*m* real matrices, respectively; $I$ is the identity matrix with appropriate dimension; the superscript $T$ represents the transpose of a matrix; $\|X\|$ refers to Euclidean norm of the vector $X$ ; $\mathbb{Z}$ denotes the set of non-negative integer numbers;

This work was supported by the National Natural Science Foundation of China under Grant No.61174066, also by the Jiangsu Overseas Research & Training Program for University Prominent Young & Middle aged Teachers & Presidents.

$\mathcal{E}\{\bullet\}$ denotes the mathematical expectation, and $*$ denotes the matrix entries implied by symmetry of a matrix.

## II. Problem Statements and Preliminaries

In this paper, considering a typical NCS model with data packet dropouts exist in the communication links from sensor to controller and controller to actuator as shown in Fig. 1.

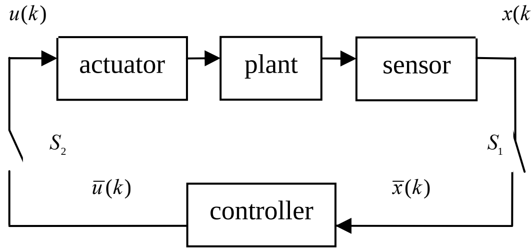

Fig.1 Framework of networked control system

The physical process to be controlled is the following singular discrete-time nonlinear model:

$$\begin{cases} Ex(k+1) = Ax(k) + Bu(k) + B_\omega \omega(k) + f(x,u,k) \\ z(k) = Cx(k) + Du(k) + D_\omega \omega(k) \end{cases} \tag{1}$$

Where $x(k) \in \mathbb{R}^n$ is the system state, the matrix $E \in \mathbb{R}^{n\times n}$ may be singular, we shall assume that $rank(E) = r \le n$, $u(k) \in \mathbb{R}^p$ is the control input, $\omega(k) \in \mathbb{R}^q$ is the disturbance input which belongs to $L_2[0,\infty)$, and $z(k) \in \mathbb{R}^m$ is the system controlled output; $f(\bullet) \in \mathbb{R}^n$ is nonlinear uncertain perturbation, with $f(0,0,k) = 0$ satisfies Lipschitz condition; $A, B, B_\omega, C, D, D_\omega$ are known real constant matrices with appropriate dimensions.

Assume the system state can be measured and the data are transmitted in a single packet at each time step, the data loss information is important for controller design, it is desirable that the state feedback controller is

$$\bar{u}(k) = K\bar{x}(k) \tag{2}$$

which $K$ is the controller gain to be determined.

In Fig.1, $S_1, S_2$ are networked switches, and $\alpha, \beta$ $[\alpha, \beta \in (0,1)]$ are the states, respectively, when $\alpha = \beta = 0$, there is no data packet loss, then $\bar{x}(k) = x(k)$, $\bar{u}(k) = u(k)$; when $\alpha = \beta = 1$ there exist data packet loss, then

$\bar{x}(k) = \bar{x}(k-1)$, $u(k) = u(k-1)$.

Then $\bar{x}(k)$ and $u(k)$ can be written as:

$$\begin{cases} \bar{x}(k) = (1-\alpha)x(k) + \alpha\bar{x}(k-1) \\ u(k) = (1-\beta)\bar{u}(k) + \beta u(k-1) \end{cases} \tag{3}$$

By introducing new state vectors $\xi(k) = [x^{\mathrm{T}}(k), \bar{x}^{\mathrm{T}}(k-1), u^{\mathrm{T}}(k-1)]^{\mathrm{T}}$, then the closed-loop system resulting from equations (1), (2) and (3) can be expressed as ($i \in (1,2,3,4)$)

$$\begin{cases} \bar{E}\xi(k+1) = A_i\xi(k) + \bar{B}_\omega\omega(k) + \bar{f}(k) \\ z(k) = C_i\xi(k) + D_\omega\omega(k) \end{cases} \tag{4}$$

Where

1) $\alpha = \beta = 0$, $A_1 = \begin{pmatrix} A+BK & 0 & 0 \\ I & 0 & 0 \\ K & 0 & 0 \end{pmatrix}, C_1 = [C+DK, 0, 0]$

2) $\alpha = 0, \beta = 1$, $A_2 = \begin{pmatrix} A & 0 & B \\ I & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, C_2 = [C, 0, D]$

3) $\alpha = 1, \beta = 0$, $A_3 = \begin{pmatrix} A & BK & 0 \\ 0 & I & 0 \\ 0 & K & 0 \end{pmatrix}, C_3 = [C, DK, 0]$

4) $\alpha = 1, \beta = 1$, $A_4 = \begin{pmatrix} A & 0 & B \\ 0 & I & 0 \\ 0 & 0 & I \end{pmatrix}, C_4 = [C, 0, D]$

$$\bar{B}_\omega = [B_\omega^T \quad 0 \quad 0]^T, \ \bar{E} = \begin{bmatrix} E & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \quad \bar{f}(k) = [f^T(\bullet) \quad 0 \quad 0]^T$$

It is noted from above analysis, the closed-loop system (4) is component by four sub-systems, so it can be constructed as Markov jump systems

$$\begin{cases} \bar{E}\xi(k+1) = A_{\theta(k)}\xi(k) + \bar{B}_\omega\omega(k) + \bar{f}(k) \\ z(k) = C_{\theta(k)}\xi(k) + D_\omega\omega(k) \end{cases} \tag{5}$$

where $\{\theta(k), k \in \mathbb{Z}\}$ is discrete Markov chains that takes values in $l = \{1,2,3,4\}$. Its transition probability matrix is $\Pi = \{\lambda_{ij}\}$, which is defined $\lambda_{ij} = P(\theta(k+1) = j \mid \theta(k) = i)$ with $\lambda_{ij} \ge 0$ and $\sum_{j=1}^{4} \lambda_{ij} = 1$ for all $i \in l$.

Assume the nonlinear $\bar{f}(k)$ of system (4) satisfies

$$\bar{f}^{\mathrm{T}}(k)\bar{f}(k) \le \xi^{\mathrm{T}}(k)H\xi(k) \tag{6}$$

Hear $H$ is known real constant matrix.

***Remark 2.1*** When $E = I, f = 0$, system(5) reduces to

$$\begin{cases} \xi(k+1) = A_{\theta(k)}\xi(k) + \bar{B}_\omega\omega(k) \\ z(k) = C_{\theta(k)}\xi(k) + D_\omega\omega(k) \end{cases} \tag{7}$$

is a special case of this paper, which discussed in [18].

The following definitions will be used in the sequel.

**Definition 2.1** [12] The discrete singular system (5) under without disturbance ($\omega(k) \equiv 0$) is said to be stochastically stable if for any $x_0 \in \mathbb{R}^n$, there exist $\delta(x_0, \theta_0) > 0$ and a scalar $\rho$, such that

$$\lim_{N\to\infty} \mathcal{E}\left\{ \sum_{k=0}^{N} \|x\|^2 \middle| x_0, \theta_0 \right\} \le \rho\delta(x_0, \theta_0) \tag{8}$$

**Definition 2.2** [10] For all $i \in l$, the discrete singular system (5) is said to be

i . regular if $\det(z\bar{E} - A_i)$ is not identically zero.

ii. causal if $\deg(\det(z\bar{E} - A_i)) = rank(\bar{E})$.

iii. stochastically admissible if it is regular, causal and stochastically stable.

**Definition 2.3** [11] System (5) with $u(k) \equiv 0$ is said to be robustly mean square quadratic stability, if there exists a scalar $\gamma > 0$ such that $\|z(k)\|_2 \leq \gamma \|\omega(k)\|_2$ , for any nonzero disturbance $\omega(k) \in L_2[0, \infty)$ , where

$$\|z(k)\|_2 = \sum_{k=0}^{\infty} \mathcal{E}\left\{z^T(k)z(k)\right\}, \|\omega(k)\|_2 = \sum_{k=0}^{\infty} \mathcal{E}\left\{\omega^T(k)\omega(k)\right\}$$

The objective of this paper is to establish a sufficient condition such that the closed-loop system (5) is stochastically stable and to design a state-feedback controller in the form of (2), to satisfy $H_\infty$ performance.

## III. Stability Analysis

In this section, we analyze the stochastic stability and $H_\infty$ performance of system (5). Before presenting the main results, we introduce the following lemma.

**Lemma 3.1** [10] The system (5) with $\omega(k) \equiv 0$ is stochastically admissible if and only if there exists $P_i > 0$ such that the following matrix inequalities holds:

$$\begin{cases} \bar{E}^T P_i \bar{E} \geq 0 \\ A_i^T \bar{P}_i A_i - \bar{E}^T P_i \bar{E} < 0 \end{cases} \tag{9}$$

where $\bar{P}_i = \sum_{j=1}^{N} \lambda_{ij} P_i$

Now, we propose the results of this section as follows.

**Theorem 3.1** Given scalar $\gamma > 0$ for each $i \in l$ , if and only if there exist matrices $P_i = P_i^T$ and $\varepsilon > 0$ such that the following matrix inequalities (10) and (11) hold

$$\bar{E}^T P_i \bar{E} \geq 0 \tag{10}$$

$$\begin{bmatrix} A_i^{\mathrm{T}} \bar{P}_i A_i - \bar{E}^{\mathrm{T}} P_i \bar{E} & A_i^{\mathrm{T}} \bar{P}_i \bar{B}_\omega & C_i^{\mathrm{T}} & H^{\mathrm{T}} \\ * & \bar{B}_\omega^{\mathrm{T}} \bar{P}_i \bar{B}_\omega - \gamma^2 I & D^T & 0 \\ * & * & -\gamma I & 0 \\ * & * & * & -\varepsilon^{-1} I \end{bmatrix} < 0 \tag{11}$$

then the SNCs (5) is stochastically admissible and robust asymptotically stable , moreover satisfies $H_\infty$ performance $\gamma$ norm.

Where $\bar{P}_i = \sum_{j=1}^{4} \lambda_{ij} P_i$

***Proof:*** stochastically admissible and asymptotically stable analysis.

construct the following lyapunov function

$$V(\xi(k), \theta(k)) = \xi^T(k) \bar{E}^T P_{\theta(k)} \bar{E} \xi(k) \tag{12}$$

when $\omega(k) \equiv 0$ , for simplicity $\theta(k) = i$ , calculating the difference of $\Delta V(k, \theta(k))$ along the trajectory of system (5) and taking the mathematical expectation, we have

$$\mathcal{E} \Delta V(\xi(k), \theta(k)) = \mathcal{E}[V(\xi(k+1), \theta(k+1))] - V(\xi(k), \theta(k))$$

$$= \mathcal{E}\left\{\xi^T(k+1) \bar{E}^T P_{i+1} \bar{E} \xi(k+1)\right\} - \xi^T(k) \bar{E}^T P_i \bar{E} \xi(k)$$

$$= \begin{bmatrix} \xi(k) \\ \bar{f}(k) \end{bmatrix}^{\mathrm{T}} \begin{bmatrix} A_i^{\mathrm{T}} \bar{P}_i A_i - \bar{E}^{\mathrm{T}} P_i \bar{E} & H^{\mathrm{T}} \\ H & -\varepsilon^{-1} I \end{bmatrix} \begin{bmatrix} \xi(k) \\ \bar{f}(k) \end{bmatrix}$$

$$\leq -\lambda_{\min} \left\{ -\begin{bmatrix} (A_i^{\mathrm{T}} \bar{P}_i A_i - \bar{E}^{\mathrm{T}} P_i \bar{E}) & H^{\mathrm{T}} \\ H & -\varepsilon^{-1} I \end{bmatrix} \right\} \bar{\xi}^{\mathrm{T}}(k) \bar{\xi}(k)$$

$$\leq -\rho x^{\mathrm{T}}(k) x(k) \tag{13}$$

where $\lambda_{\min}(\bullet)$ denotes the minimum eigenvalue of matrix $(\bullet)$ , $\bar{\xi}(k) = \left[ \xi^{\mathrm{T}}(k) \quad \bar{f}(k)^{\mathrm{T}} \right]^{\mathrm{T}}$ and $0 < \rho < \min\left\{\lambda_{\min}(\bullet)\right\}$ .

Inequality (13) implies that

$$\mathcal{E}[V((k+1), \theta(k+1))] - \mathcal{E}[V(0, \theta(0))] \leq -\rho \sum_{k=0}^{N} \mathcal{E}[x^{\mathrm{T}}(k) x(k)] \tag{14}$$

So $\sum_{k=0}^{N} \mathcal{E}[x^{\mathrm{T}}(k) x(k)] \leq \dfrac{1}{\rho} \mathcal{E}[V(\xi(0), \theta(0))]$ ,

let $N \to \infty$ then

$$\sum_{k=0}^{\infty} \mathcal{E}[x^{\mathrm{T}}(k) x(k)] \leq \frac{1}{\rho} \mathcal{E}[V(\xi(0), \theta(0))] < \infty \tag{15}$$

applying definition 2.1 and lemma 3.1, we can obtain the system is stochastically admissible and asymptotically stable.

Then we prove system (5) with zero initial condition, the output $z(k)$ satisfies $H_\infty$ performance.

Definition $J = \sum_{k=0}^{N} \mathcal{E}\left\{\gamma^{-1} z^T(k) z(k) - \gamma \omega^T(k) \omega(k)\right\}$ (16)

Through computation, we have

$$J \leq \mathcal{E} \sum_{k=0}^{N} \left\{\Delta V(k, \theta(k)) + \gamma^{-1} z^T(k) z(k) - \gamma \omega^T(k) \omega(k)\right\}$$

$$= \mathcal{E} \sum_{k=0}^{N} \left\{ \begin{bmatrix} \xi(k) \\ \bar{f}(k) \\ \omega(k) \end{bmatrix}^{\mathrm{T}} \begin{bmatrix} \tilde{A} & A_i^{\mathrm{T}} \bar{P}_i \bar{B}_\omega & C_i^{\mathrm{T}} \\ * & \bar{B}_\omega^{\mathrm{T}} \bar{P}_i \bar{B}_\omega - \gamma^2 I & D^T \\ * & * & -\gamma I \end{bmatrix} \begin{bmatrix} \xi(k) \\ \bar{f}(k) \\ \omega(k) \end{bmatrix} \right\} \tag{17}$$

where $\tilde{A} = A_i^{\mathrm{T}} \bar{P}_i A_i - \bar{E}^{\mathrm{T}} P_i \bar{E} + \varepsilon H^{\mathrm{T}} H$

According to the theorem 3.1, applying Schur complements formula

$\lim\limits_{N \to \infty} \mathcal{E} \sum_{k=0}^{N} \left\{Inequality(17)\right\} < 0$ ,

then $\sum_{k=0}^{\infty} \mathcal{E}\left\{z^T(k) z(k)\right\} < \gamma \sum_{k=0}^{\infty} \mathcal{E}\left\{\omega^T(k) \omega(k)\right\}$ ,

so the system has $H_\infty$ performance $\gamma$ norm.

This completes the proof.

***Remark 3.1*** For systems (7), considered the random data packet dropout as Bernoulli process ( $\alpha = \beta = 1$ or $\alpha = \beta = 0$ ) for state feedback controller designing in [18]. Without disturbance ( $\omega(k) \equiv 0$ ) for systems (7), a question of robust mean square stability of networked control systems with packed dropout was investigated in [15], in the theorem 3.1, we consider the system with external and nonlinear disturbance simultaneously, and establish a sufficient stochastic stability condition for state feedback controller designing, which is more generality in actual networked data transmission and application.

## IV. State Feedback $H_\infty$ Controller Design

In theorem 3.1, not given out the controller gain $K$ solve method, in this section, we will present a design method for the state feedback controller (2) in terms of LMIs.

**Theorem 4.1** Given scalars $\gamma > 0$, $\varepsilon > 0$ for each $i \in l$, if there exist matrices $X_i > 0$, $P_i > 0$ and $K$, such that the inequalities (18) and (19) are feasible, then the SNCs (5) is stochastically admissible and asymptotically stable, satisfies $H_\infty$ performance norm $\gamma$.

$$\bar{E}^T X_i \bar{E} \geq 0 \tag{18}$$

$$\begin{bmatrix} \Omega_1 & \Omega_2 & \Omega_3 & \Omega_4 & \Omega_5 \\ * & -\sum_{j\in l} \lambda_{ij} P_i & 0 & C_{0i} + DKE_i & 0 \\ * & * & -\gamma I & D_\omega^T & 0 \\ * & * & * & -\gamma I & 0 \\ * & * & * & * & -\varepsilon H^{-1} \end{bmatrix} < 0 \tag{19}$$

where

$$\Omega_2 = \begin{bmatrix} \sqrt{\lambda_{i1}}(A_{0i} + M_i K N_i) \\ \sqrt{\lambda_{i2}}(A_{0i} + M_i K N_i) \\ \sqrt{\lambda_{i3}}(A_{0i} + M_i K N_i) \\ \sqrt{\lambda_{i4}}(A_{0i} + M_i K N_i) \end{bmatrix} \quad \Omega_3 = \begin{bmatrix} \sqrt{\lambda_{i1}}\bar{B}_\omega \\ \sqrt{\lambda_{i2}}\bar{B}_\omega \\ \sqrt{\lambda_{i3}}\bar{B}_\omega \\ \sqrt{\lambda_{i4}}\bar{B}_\omega \end{bmatrix}$$

$$\Omega_1 = -diag\left[X_i, X_i, X_i, X_i\right] \quad \Omega_4 = \begin{bmatrix} 0 & 0 & 0 & 0 \end{bmatrix}^{\mathrm{T}}$$

$$\Omega_5 = \begin{bmatrix} X_i & 0 & 0 & 0 \end{bmatrix}^{\mathrm{T}}$$

***Proof:*** First, in theorem 3.1, we rewrite $A_i$ and $C_i$ as

$$A_i = A_{0i} + M_i K N_i, \quad C_i = C_{0i} + DKE_i$$

where

$$A_{01} = \begin{bmatrix} A & 0 & 0 \\ I & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}, C_{01} = \begin{bmatrix} C & 0 & 0 \end{bmatrix}$$

$$A_{02} = \begin{bmatrix} A & 0 & B \\ I & 0 & 0 \\ 0 & 0 & I \end{bmatrix}, C_{02} = \begin{bmatrix} C & 0 & D \end{bmatrix}$$

$$A_{03} = \begin{bmatrix} A & 0 & 0 \\ 0 & I & 0 \\ 0 & 0 & 0 \end{bmatrix}, C_{03} = \begin{bmatrix} C & 0 & 0 \end{bmatrix}$$

$$A_{04} = \begin{bmatrix} A & 0 & B \\ 0 & I & 0 \\ 0 & 0 & I \end{bmatrix}, C_{04} = \begin{bmatrix} C & 0 & D \end{bmatrix}$$

$$M_1 = M_2 = \begin{bmatrix} B^T & 0 & I \end{bmatrix}^T, M_3 = M_4 = \begin{bmatrix} 0 & 0 & 0 \end{bmatrix}^T$$

$$N_1 = \begin{bmatrix} I & 0 & 0 \end{bmatrix}, N_2 = \begin{bmatrix} 0 & I & 0 \end{bmatrix} \quad N_3 = N_4 = \begin{bmatrix} 0 & 0 & 0 \end{bmatrix}$$

$$E_1 = \begin{bmatrix} I & 0 & 0 \end{bmatrix}, E_3 = \begin{bmatrix} 0 & I & 0 \end{bmatrix} \quad E_2 = E_4 = \begin{bmatrix} 0 & 0 & 0 \end{bmatrix}$$

Then applying Schur complements formula, inequality (11) can be rewritten as an equivalent form (20)

$$\begin{bmatrix} \bar{\Omega}_1 & \bar{\Omega}_2 & \bar{\Omega}_3 & \bar{\Omega}_4 & \bar{\Omega}_5 \\ * & -\sum_{j\in l} \lambda_{ij} P_i & 0 & C_{0i} + DKE_i & 0 \\ * & * & -\gamma I & D_\omega^T & 0 \\ * & * & * & -\gamma I & 0 \\ * & * & * & * & -\varepsilon H^{-1} \end{bmatrix} < 0 \tag{20}$$

where

$$\bar{\Omega}_1 = -diag\left[P_i^{-1}, P_i^{-1}, P_i^{-1}, P_i^{-1}\right], \ \bar{\Omega}_2 = \Omega_2, \bar{\Omega}_3 = \Omega_3, \bar{\Omega}_4 = \Omega_4$$

$$\bar{\Omega}_5 = \begin{bmatrix} P_i^{-1} & 0 & 0 & 0 \end{bmatrix}^{\mathrm{T}}$$

Let $P_i^{-1} = X_i$ in inequality (20), it yields (19).

This completes the proof.

***Remark 4.1*** It should be noted that inequality (20) are non-convex due to $P_i^{-1}$, which can be solved via the cone complementary linearization method [17], the controller gain solve method converted into the following nonlinear optimization problem involving LMI conditions.

$$\min_{\gamma, P_i, X_i} tr(\sum_{i=1}^{4} P_i X_i)$$

$$\text{s}ubject\,to \quad i)(18) and (19), \ ii)\begin{bmatrix} P_i & I \\ I & X_i \end{bmatrix} > 0 \tag{21}$$

The $\gamma$ sub-optimal $H_\infty$ controller gain $K$ can be found using the following algorithm:

***Algorithm 4.1***

*Step 1* Find an initial feasible set $(P^0, X^0, K^0)$ satisfying (21), let $k = 0$.

*Step 2* Solve the following LMI problem

$$\begin{cases} \min_{\gamma, P_i, X_i} tr(\sum_{i=1}^{4} P_i^k X_i + P_i X_i^k) \\ \text{s}ubject\,to \quad i)(18) and (19), ii)\begin{bmatrix} P_i & I \\ I & X_i \end{bmatrix} > 0 \end{cases}$$

*Step 3* let $P_i^{k+1} = P_i, X_i^{k+1} = X_i, K^{k+1} = K^k$

*Step 4* If $k > N$, where $N$ is the maximum numbers of iterations allowed, give up and stop.

*Step 5* If $(P, X, K)$ satisfy (21), then stop, if not, let $k = k + 1$ go to step2.

## V. Illustrative Example

In this section, we present a numerical example to illustrate the theoretical results developed earlier. Consider the system (1) with the following matrices borrowed from [18] example 3, we have the parameters

$$E = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix}, A = \begin{bmatrix} 1 & 1 \\ -1 & -0.5 \end{bmatrix}, \ B = \begin{bmatrix} 6 \\ 2 \end{bmatrix}, B_\omega = \begin{bmatrix} -0.03 & 0.01 \\ 0 & 0.01 \end{bmatrix}$$

$$C = \begin{bmatrix} -0.1 & -0.05 \end{bmatrix}, D_\omega = \begin{bmatrix} 0.01 & 0.01 \end{bmatrix}, \ D = 0.5, H = \begin{bmatrix} 1 \\ 1 \end{bmatrix}$$

Applying augmentation matrix method, it can be obtained parameters of system (5)

$$A_{01}=\begin{bmatrix}1 & 1 & 0 & 0 & 0 & 0\\ -1 & -0.5 & 0 & 0 & 0 & 0\\ 1 & 0 & 0 & 0 & 0 & 0\\ 0 & 1 & 0 & 0 & 0 & 0\\ 0 & 0 & 0 & 0 & 0 & 0\\ 0 & 0 & 0 & 0 & 0 & 0\end{bmatrix}$$

$$A_{02}=\begin{bmatrix}1 & 1 & 0 & 0 & 6 & 0\\ -1 & -0.5 & 0 & 0 & 2 & 0\\ 1 & 0 & 0 & 0 & 0 & 0\\ 0 & 1 & 0 & 0 & 0 & 0\\ 0 & 0 & 0 & 0 & 1 & 0\\ 0 & 0 & 0 & 0 & 0 & 1\end{bmatrix}$$

$$A_{03}=\begin{bmatrix}1 & 1 & 0 & 0 & 0 & 0\\ -1 & -0.5 & 0 & 0 & 0 & 0\\ 0 & 0 & 1 & 0 & 0 & 0\\ 0 & 0 & 0 & 1 & 0 & 0\\ 0 & 0 & 0 & 0 & 0 & 0\\ 0 & 0 & 0 & 0 & 0 & 0\end{bmatrix}$$

$$A_{04}=\begin{bmatrix}1 & 1 & 0 & 0 & 6 & 0\\ -1 & -0.5 & 0 & 0 & 2 & 0\\ 0 & 0 & 1 & 0 & 0 & 0\\ 0 & 0 & 0 & 1 & 0 & 0\\ 0 & 0 & 0 & 0 & 1 & 0\\ 0 & 0 & 0 & 0 & 0 & 1\end{bmatrix}$$

$$C_{01}=C_{03}=\begin{bmatrix}-0.1 & -0.05 & 0 & 0 & 0 & 0\end{bmatrix}$$

$$C_{02}=C_{04}=\begin{bmatrix}-0.1 & -0.05 & 0 & 0 & 0.5 & 0\end{bmatrix}$$

$$M_1=M_2=\begin{bmatrix}6 & 2 & 0 & 0 & 0 & 0\end{bmatrix}$$

$$M_3=M_4=\begin{bmatrix}0 & 0 & 0 & 0 & 0 & 0\end{bmatrix} \quad N_1=\begin{bmatrix}1 & 0 & 0 & 0 & 0 & 0\end{bmatrix}$$

$$N_2=\begin{bmatrix}0 & 0 & 1 & 0 & 0 & 0\end{bmatrix} \quad N_3=N_4=\begin{bmatrix}0 & 0 & 0 & 0 & 0 & 0\end{bmatrix}$$

$$E_1=\begin{bmatrix}1 & 0 & 0 & 0 & 0 & 0\end{bmatrix}$$

$$E_3=\begin{bmatrix}0 & 0 & 1 & 0 & 0 & 0\end{bmatrix}, E_2=E_4=\begin{bmatrix}0 & 0 & 0 & 0 & 0 & 0\end{bmatrix}$$

The transition probability matrix is given as

$$\Pi=\begin{bmatrix}0.3 & 0.5 & 0.1 & 0.1\\ 0.2 & 0.3 & 0.5 & 0.0\\ 0.1 & 0.7 & 0.0 & 0.2\\ 0.6 & 0.1 & 0.2 & 0.1\end{bmatrix}$$

applying algorithm 4.1 to this example, it can be obtained $\gamma_{\min}=0.175$, the controller gain matrix

$$K=\begin{bmatrix}0.2490 & -0.4263\\ -0.2328 & 0.4256\end{bmatrix}$$

In the initial condition $x(0)=[1 \quad -1]^{\mathrm{T}}$ and $\theta(0)=1$, the external disturbance $\omega(k)$ is assumed to be,

$$\omega(k)=\begin{cases}0.2, & 10\le k\le 15\\ -0.2, & 15\le k\le 25\\ 0, & else\end{cases}$$

the system state response and control output trajectory are given in Fig.2 and Fig.3, respectively.

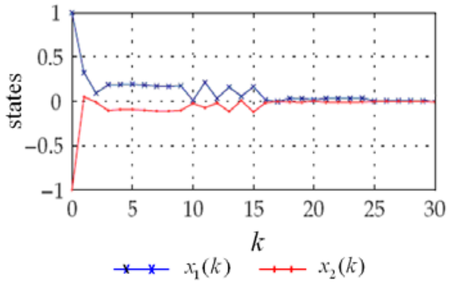

Fig.2 The state response of system

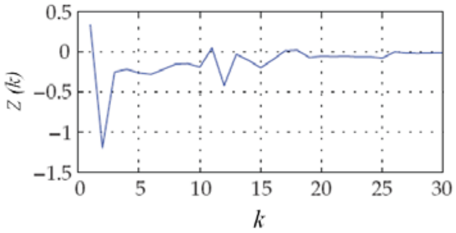

Fig.3 The control output of system

from the simulation, it shows the asymptotical stability of the closed-loop system.

For system (1), when $E=I, f=0$, in [14] only considered the networked control systems are modeled as a Markov jump linear system with two operation modes, compared with references [15, 16, 18], our result has more generality in practical application.

## CONCLUSION

In this paper, the problem of robust $H_\infty$ control of discrete time singular systems over networks has been investigated, both the data packed dropout and nonlinear disturbance are considered, the system communication link failure is modeled as markovian jump singular systems with four models, based on the Lyapunov function method and LMI technique, an approach has been developed to design a state feedback $H_\infty$ controller, such that the closed-loop system is stochastically stable and preserves a guaranteed $H_\infty$ performance. An example is shown that the approach presented in this paper is effective.

# dSpace Based Direct-driven Permanent Magnet Synchronous Wind Power System Modeling and Simulation

**Yan-xia Shen , Fan Li， Dinghui Wu, Ting-long Pan， Xiang-xia Liu**

**Institute of Electrical Automation**
**Jiangnan University**
**Wuxi,China**
**shenyx@jiangnan.edu.cn**

*Abstract*— **When wind speed is below the rated value, the efficiency of captured wind energy must be maximized and the mechanical oscillation be guaranteed to be small. To deal with these problems, This essay describes the advantages of the direct-driven permanent magnet synchronous wind power system, and then introduces the two-frequency-loop model based on frequency separation principle, The LPV model and LPV control method are suggested for the high-frequency part of the system. The output of the high-frequency part is used to compensate the mechanical torque. The mathematical model is built with MATLAB, and the online test is carried out by dSpace. The simulation results show that the controller reduces mechanical oscillation effectively, and enhances the system reliability.**

***Keywords-LPV; direct-driven; permanent magnet synchronous wind turbine; Wind Power Conversion System; dSpace***

## I. INTRODUCTION

Wind power is one of clean renewable resources. After 20 years development, the system performance of wind power generation is gradually improved, and its cost is greatly reduced. Wind power has become an important strategy for national economic development [1, 2].

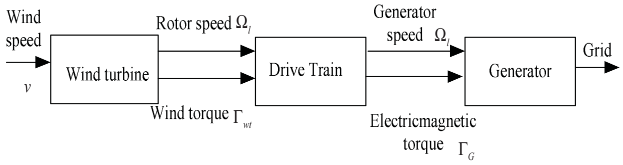
The wind power system mostly adopts DFIG at present, with a gearbox between generator and wind turbine. The gearbox not only consumes a part of energy, but also has big noises, high failure rate and high maintenance costs. Permanent magnet synchronous generator is a newer type motor without brush and commutator, so it has big power factor. Without gearbox, namely that the wind turbine and generator is connected directly, it can promote the efficiency, improve the reliability of the system and decrease failure rate and maintenance costs.

In the wind power system, the control objective under rated wind speed is to maximize the efficiency of captured wind energy, but the traditional control methods usually cause high mechanical oscillation. Since the wind energy conversion system (WECS) is a typical strong nonlinear system, many control means need to transform nonlinear model to linear model, such as PI or PID control [3], and with some advanced control ways, like LQ and LQG control [4], however, the robustness of all these control methods is low, this becomes an applying restrictions for these control methods. The randomness of wind often results in low resolution linear model, reference [5] proposed LPV (Linear Parameter Varying) control which can solve above problems efficiently.

Firstly, this paper introduces two frequency loop model of the system [6, 7], and then in the low-frequency part, PI control is employed. After build LPV model for the high-frequency part, the LPV control method is adopted to promote the accuracy of the model, also, maximize the efficiency of captured wind energy and restrain oscillation. This paper built simulation model based on MATLAB, then loaded into dSPACE to make on-line experiment, the experiment result s show LPV control can improve the performance of the system, and it proved the feasibility and superiority of the control method.

## II. WIND ENERGY CONVERSION SYSTEM MODEL

It is reasonable to ignore the dynamic process of generator electromagnetic response in this paper, since the electromagnetic time constant is much smaller than the mechanical time constant. The structure of variable speed constant frequency wind power energy conversion system is shown in Fig. 1.



Wind speed
$v$
Wind turbine
Rotor speed $\Omega_l$
Wind torque $\Gamma_{wt}$
Drive Train
Generator speed $\Omega_l$
Electricmagnetic torque $\Gamma_G$
Generator
Grid

Figure. 1 Structure of Variable Speed Constant Frequency WECS

In Fig. 1, the wind turbine and generator are connected directly, drive train represents the shaft, and there is no gearbox between them. For this reason, they have the same speed $\Omega$.

### A. Wind Speed Model

Wind speed $v(t)$ which is a non-statistical random process is decomposed into two components in [8, 9], that is

$$v(t)=\overline{v}(t)+\Delta v(t) \tag{1}$$

978-1-4673-1560-9/12/$31.00 ©2012 IEEE

Where $\bar{v}(t)$ is the low-frequency component, which describes long-time scale and low-frequency changes, it is usual to assume $\bar{v}(t)$ as a Weibull distribution; and $\Delta v(t)$ is high-frequency component, it is made up of Gaussian white noise $e(t)$ as a disturbance signal composed of a first-order filter.

$$\Delta \dot{v}(t) = -\frac{1}{T_w}\Delta v(t) + \frac{1}{T_w}e(t) \tag{2}$$

Where $T_w$ is the time constant of the filter, and $T_w = L_t / \bar{v}$. $L_t$ is the length of wind speed turbulence.

### B. Wind Turbine Model

According to the Bates theory, the mechanical power captured by turbine is:

$$P_{wt} = 0.5\pi\rho R^2 C_p(\lambda) v^3 \tag{3}$$

Where $\rho$ is air density, $R$ is the radius of wind turbine, $v$ is wind speed, $\lambda$ is tip speed ratio, and $\lambda = R \cdot \Omega_l / v$, $\Omega_l$ is the angular velocity of wind turbine rotor, $C_p(\lambda)$ is the power factor of wind turbine, which is defined as:

$$C_p(\lambda, \beta) = 0.22(\frac{116}{\lambda} - 0.4\beta - 5)e^{\frac{-12.5}{\lambda}}$$

Where $\beta$ is the pitch angle of variable-pitch control. For the fixed-pitch control $\beta = 0$.

The torque of wind turbine is:

$$\Gamma_{wt} = \frac{P_{wt}}{\Omega_l} = 0.5\pi\rho R^3 v^2 C_\Gamma(\lambda) \tag{4}$$

Where $C_\Gamma(\lambda)$ is torque coefficient which is defined as $C_\Gamma(\lambda) = C_p(\lambda)/\lambda$.

### C. Drive Train Model

Neglecting the transients, the rigid drive train is expressed as:

$$J_l \dot{\Omega}_l = \Gamma_{wt} - \frac{i}{\eta}\Gamma_G \tag{5}$$

Where $J_l$ is the total inertia of drive train, $i$ is the gear box ratio, for the direct-driven case, its value is 1, $\eta$ is the efficiency of the transmission shaft, $\Gamma_G$ is the electromagnetic torque of the generator. As mentioned above, the formula (4) and (5) constitute the basic low-frequency model of the wind power conversion system.

### D. Model of PMSG

Assuming that,

- Ignore the influence of the core magnetic saturation, excluding the eddy current and hysteresis loss.
- The conductivity of permanent magnetic materials is zero.
- There is no damper winding in rotor.
- The three-phase of stator is symmetrical and the induced EMF (electromotive force) is sinusoidal.

The electromagnetic torque of permanent magnet generator in d,q coordinate system is:

$$\Gamma_G = p(\Phi_d i_q - \Phi_q i_d) = p[\Phi_m i_q + (L_d - L_q) i_d i_q] \tag{6}$$

It is assumed that the load of the generator $R_l$ is independent and symmetric three-segment, and the states and input of the system are defined as:

$$x = [x_1(t) \quad x_2(t)]^T \equiv [i_d(t) \quad i_q(t)]^T$$

$$u \equiv R_l$$

The state model of the generator can be expressed:

$$\begin{cases} \dot{x} = \begin{bmatrix} \frac{1}{L_d + L_s}(-Rx_1 + p(L_q - L_s)x_2\Omega_l) \\ -\frac{1}{L_q + L_s}(-Rx_2 - p(L_d + L_s)x_1\Omega_h + p\Phi_m\Omega_h) \end{bmatrix} + \\ \begin{bmatrix} -\frac{1}{L_d + L_s} & 0 \\ 0 & -\frac{1}{L_q + L_s} \end{bmatrix} \\ y \equiv \Gamma_G = p\Phi_m x_2 \end{cases} \tag{7}$$

Where $R$ is the stator resistance, $L_d$ and $L_q$ are the inductance of the stator in d, q coordinate system, $i_d$ and $i_q$ are the stator current, $L_s$ is the equivalent inductance of grid and converter, $\Phi_m$ is the flux, and is a constant for the permanent material, p is the pole pairs of the generator.

## III. LPV Controller Design

The LPV theory was firstly proposed by Professor Shamma, its dynamic characteristics depend on the adjustable parameters which are measured in real time [5]. Since these parameters can reflect the nonlinearity of the system, LPV system can be applied to describe nonlinear system. The gain scheduling controller is then designed using linear method to make controller gain change with the parameters.

The LPV model of the system can be expressed in [6, 7],

$$\begin{aligned} \dot{x}(t) &= Ax(t) + Bu(t) + Le(t) \\ y(t) &= Cx(t) \end{aligned} \tag{8}$$

The formula (8) shows that external interference $e(t)$ exists in the LPV model. In order to effectively suppress wind disturbance and improve the system dynamic performance, the controller is designed based on the LPV dynamic model, making the $H_\infty$ norm of the closed-loop transfer function $T_{ez}(s)$ from the disturbance input $e(t)$ to the control output $y(s)$ less than a given performance index, that is,

$$\left\| \boldsymbol{T}_{ez\infty}(s) \right\|_\infty < \gamma_\infty$$

Then the designed state feedback controller is:

$$u(t) = K(\rho(t)) \cdot x(t)$$

The closed-loop system is obtained as:

$$\begin{aligned} \dot{x}(t) &= (A(r(t)) + B(r(t))K(r(t)))x(t) + Le(t) \\ y(t) &= C(\rho(t))x(t) \end{aligned} \tag{9}$$

The affined parameters of this LPV model depend on $\rho(t)$, and the controller matrix is solved according to theorem 1.

Theorem 1[10]:

For the LPV model described by formula(8) and a given positive constant, if there are continuously differentiable symmetric positive definite matrix $X(\rho(t))$, symmetric positive definite matrix $Y$, matrix $V$ and $R(\rho(t))$ satisfying formula(10) for all the parameters, then the parameters of closed-loop (9) are quadratic stability and meet the given $H_\infty$ performance.

$$\begin{bmatrix} -(V+V^T) & * & * & * & * & * \\ M & -X(\rho(t))+Y & * & * & * & * \\ 0 & 0 & -Y & * & * & * \\ L^T(\rho(t)) & 0 & 0 & -\gamma_\infty I & * & * \\ 0 & C(\rho(t))V & 0 & 0 & -\gamma_\infty I & * \\ V^T & 0 & 0 & 0 & 0 & -X(\rho(t)) \end{bmatrix} < 0 \tag{10}$$

where $M = V^T A^T(\rho(t)) + R^T(\rho(t))B^T(\rho(t)) + X(\rho(t))$. If the inequality (10) has feasible solution, then the state feedback controller gain matrix which dependent on the parameters is

$$K(\rho(t)) = R(\rho(t))V^{-1}$$

According to the formula (5),

$$J_T \dot{\overline{\Delta\Omega_l}} = \overline{\Delta\Gamma_{wt}} - \frac{1}{\eta}\frac{\overline{\Gamma_G}}{\overline{\Gamma_{wt}}}\overline{\Delta\Gamma_G} \tag{11}$$

Where $J_T = J_l \overline{\Omega_l}/\overline{\Gamma_{wt}}$, $\dot{\overline{\Delta\Omega_l}} = \frac{\Delta\dot{\Omega}_l}{\overline{\Omega_l}}$, $\dot{\Omega}_l = \dot{\Omega}_l - \dot{\overline{\Omega_l}}$, $\overline{\Omega_l}$ is the stable value of the $\Omega_l$, also for the $\overline{\Omega_l}$, $\overline{\Delta\Omega_l}$ and $\overline{\Delta\Gamma_{wt}}$.

According to the high-frequency pulsation wind speed modeling method in [9] and formula (2), there is

$$\dot{\overline{\Delta v}} = \frac{1}{T_w}\left(e - \overline{\Delta v}\right) \tag{12}$$

From formula (4) and low-frequency sub-model,

$$\dot{\overline{\Delta\Gamma_{wt}}} = \gamma \cdot \dot{\overline{\Delta\Omega_l}} + (2-\gamma)\dot{\overline{\Delta v}} \tag{13}$$

Where $\gamma$ depends on the low-frequency operating point of the system, its value is $\gamma = \frac{\overline{\lambda} C_p'(\overline{\lambda})}{C_p(\overline{\lambda})} - 1$, and $C_p'(\overline{\lambda}) = \frac{dC_p(\overline{\lambda})}{d\lambda}$.

Put the formula (11) and (12) into (13), there is

$$\begin{aligned} \dot{\overline{\Delta\Gamma_{wt}}}(t) &= \left(\frac{\gamma}{J_T} - \frac{1}{T_w}\right)\overline{\Delta\Gamma_{wt}}(t) + \frac{\gamma}{T_w}\overline{\Delta\Omega_l}(t) \\ &- \frac{\gamma}{J_T\eta}\frac{\overline{\Gamma_G}}{\overline{\Gamma_{wt}}}\overline{\Delta\Gamma_G}(t) + \frac{2-\gamma}{T_w}e(t) \end{aligned} \tag{14}$$

Formula (11) and (14) constitute the high-frequency sub-model of the conversion system, for this model and according to the theory above, $u(t) = \overline{\Delta\Gamma_G}$ is chose as the control input, $x(t) = \left[\overline{\Delta\Omega_l} \quad \overline{\Delta\Gamma_{wt}}\right]^T$ is the state vector, $y(t) = \overline{\Delta\lambda}(t) = C(\rho(t))x(t)$ is defined to be the output vector, and the matrixes obtained by formula (14) are

$$A = \begin{bmatrix} 0 & 1/J_T \\ \gamma/T_w & \gamma/J_T - 1/T_w \end{bmatrix},\ B = \begin{bmatrix} \frac{-1}{J_T}\frac{\overline{\Gamma_G}}{\overline{\Gamma_{wt}}} \\ \frac{-\gamma}{J_T}\frac{\overline{\Gamma_G}}{\overline{\Gamma_{wt}}} \end{bmatrix},\ L = \begin{bmatrix} 0 & (2-\gamma)/T_w \end{bmatrix}^T,$$

$$C = \begin{bmatrix} \frac{2}{2-\gamma} & -\frac{1}{2-\gamma} \end{bmatrix}$$

Use the LMI toolbox to describe the matrix of the theorem 1 to obtain the controller K.

## IV. Online Simulation And Results Analysis

According to Fig. 1 and the analysis above, the general structure diagram of the direct-driven permanent magnet synchronous wind power system based on LPV is shown in Fig. 2, and the online experiment is done by dSPACE. dSPACE system is a development and testing platform based on MATLAB/Simulink in real-time environment, it can be connected with MATLAB/Simulink seamlessly, and can realize real-time control and modify for the control system, so it is much easier and overcomes some inconvenience of on-line simulation.

Figure. 2 Gain Scheduling Control Structure Based on LPV

In MATLAB simulation environment, find the solution of matrix in theorem 1 with LMI and Simulink toolbox, and build the general simulation diagram of the system, then download the simulation to the dSPACE to do the real-time simulation experiment. The parameters of the experiment are shown in Table 1.

TABLE I. EXPERIMENT PARAMETERS

| Name | Value | Name | Value |
|---|---|---|---|
| R | 2.5 m | ρ | 1.25kg/m$^3$ |
| $T_w$ | 21.4286s | η | 0.95 |
| $J_T$ | 0.563kg*m2 | $C_{pmax}$ | 0.476 |
| $T_{Gmax}$ | 40Nm | $\lambda_{out}$ | 7 |

The experiment results of power factor of the wind turbine $C_p$ and tip speed ratio $\lambda$ (lam) are shown in Fig. 3 and Fig. 4.

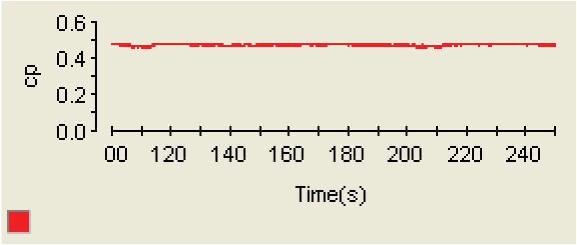

Figure. 3 Power Factor

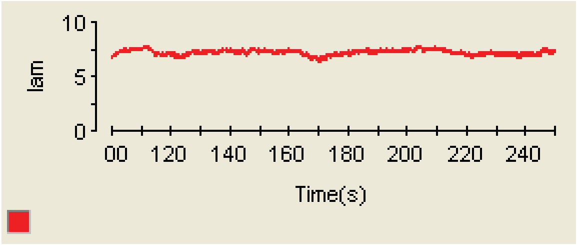

Figure. 4 Tip Ratio

From Fig. 3, it is easy to see that the value of $C_p$ is stable and very closed to the maximum value 0.476; and the Fig. 4 shows that the accuracy of tip speed ratio tracking the best value is high, and the robustness of the system is good, so the controller can capture the wind energy as much as possible, and the oscillation is small, solve the contradictions between the wind energy capturing and big oscillation. The experiment results show the effectiveness and advantages of this control method.

## V. CONCLUSIONS

The situation discussed in this paper is below the rated wind speed of the direct-driven permanent magnetic synchronous wind power system, we need to capture the maximum wind energy and to ensure the smaller mechanical vibration, while increasing the model precision, firstly we build the basic model of the system, then for the high-frequency part, according to the LPV theory to linear the part and design the LPV controller, with PI control of the low-frequency part, the torque can be controlled well. The simulation results based on the dSPACE show that the control method of this paper can fulfill the control objective and efficiently improve the performance, while the real-time experiments are still on research. The research of this paper has broad application prospects in direct-driven permanent magnetic synchronous wind power system.

***Abstract-*** **Mobile agents ( MA ) are autonomous software entities that are able to migrate across heterogeneous network execution environments. Mobility and autonomy compensate the deficiencies of distributed technology pretty well. But the security issues with mobile agents have not been solved and are becoming obstacles for the application of mobile agents. Homomorphic encryption is a technique in which the encrypted mobile codes can be executed directly on different platforms without decryption. This paper presents a protection scheme of mobile agent (AMHCFES) in network management application, which combining protect method of homomorphic encryption and composite function technology. The correctness and security proof of AMHCFES protection scheme are given in this paper, and malicious hosts can be avoided effectively using this scheme**

***Keywords- mobile agent; homomorphic encryption; composite functio; active protection***

## I. Introduction

The original idea of moving cryptography comes from calculating encrypted mobile agents directly, but as the homomorphic encryption scheme which supporting the idea of moving cryptography can't be found, so moving cryptography can't be used in practice.[1-5] This paper gives a practical scheme to realize the ideas of moving cryptography. This is a compound method, organized by composite function and homomorphic encryption scheme. Both codes and data can be encrypted using this method, and the encrypted program can be executed directly without decryption. This method is an extension of moving cryptography put forward by Sander and Tschudin, which preserve many advantages and get rid of many drawbacks of original cryptography[6-9].

## II. Theory Related

The scheme put forward in this paper is based on theory of three address code, homomorphic encryption scheme (HES) and composite function(FnC).

### *2.1 Three Address Code*

Most original programs will be translated into executing objective codes using compiler. There are several phases before creating objective codes. Explicit middle forms will be created after grammatical analysis and semantic analysis, three address codes is one of the middle forms[10]. Three address codes are description of a series of strings, e.g. x:=y op z here, x, y, z are names of constants or variables, op is a random operator. Usually, three addresses will be included in three address codes, two for operands, one for result. So, original expression may changed into following expressions:

$t1 := y * z$

$t2 := x + t1$

t1 and t2 are temporary variables created by compiler.

### *2.2 Addition-multiplication homomorphic(AMH)*

Addition –multiplication homomorphic is a subset of secret homomorphic. It is defined by Sander and Tschudin as following forms: Suppose R and S make a ring, then there is a encryption function $E : R \rightarrow S$ .

(a) Addition homomorphic means there is a valid algorithm PLUS to calculate E(x+y) according to E(x) and E(y), but don't need to know the concrete size of x and y.

(b) Multiplication homomorphic means there is a valid algorithm MULT to calculate E(xy) according to E(x) and E(y), but don't need to know the concrete size of x and y.

Addition homomorphic and multiplication homomorphic keep back addition and multiplication separately[11-15], both secrecy homomorphic and addition-multiplication homomorphic may guarantee the security of arithmetic operation on encrypted data, and needn't to decrypt the data.

### *2.3 Composite Function*

Composite function is defined as follows: it is consisted of output of h(x) and input of g(x), and shown as $f(x) = g . h$ or $f(x) = g(h(x))$ in math, h(x) is the hidden original function. The agent host which owns function must choose a conversion matrix g(x) to create a composite function f(x). Compare f(x) with encrypted function h(x), f(x) is a different function. So, security and integrity of data get guarantee[16-18]. Because the result of composite function f(x) is encrypted, malicious host don't know the result of function. The owner of function(that is the owner of mobile agent) gets the encrypted result through function g(x). Figure 1 is as follows.

This work is supported by natural science foundation of China (61170185), natural science foundation of Liaoning province (20101082) ,and scientific research project of Liaoning education department(L2011030)

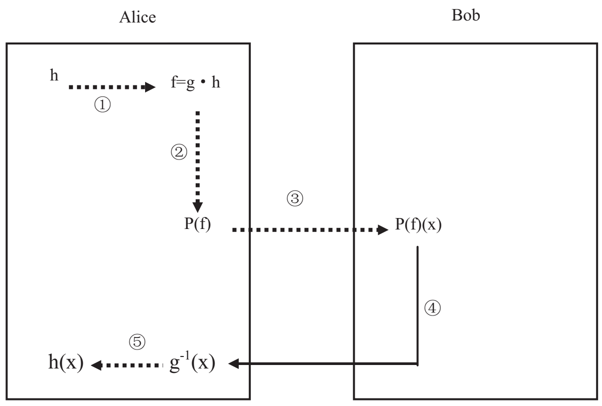

Fig.1 Composite Function

Alice is the owner of agent and have function h(x), she wants to calculate the input x of Bob, but she won't want expose herself function, so she choose a function g(x), and create a function f(x), then send it to Bob. Bob calculates result through f(x) function using his input x, and send result to Alice. Bob can't calculate function h(x), because what he can see is just f(x). Only Alice can get the real result of h(x), through adding f(x) into inverse function, that is h(x) = $g^{-1}$(f(x)).

## III. Addition Multiplication Homomorphic and Composite Function Encryption Scheme(AMHCFES)

First, data and state information of three address codes will be encrypted in this scheme, then three address codes operating code will be encrypted through composite function. Concrete operation steps are as follows:

Three address codes operands will be encrypted using addition-multiplication homomorphic encryption scheme.

Take away the operands dependance problem aroused by addition-multiplication homomorphic encryption scheme(take away encrypted data by addition-multiplication homomorphic)

Three address codes operating code statements will be encrypted using composite function technology.

Solve the operating code dependance problem aroused by composite function technology.
